The sense of touch is one of the most important senses in human development, particularly with regard to attachment to others. It has long been viewed as an essential part of childhood development (Baysinger, Plubell, & Harlow, 1973; Feldman, 2007; Haradon, Bascom, Dragomir, & Scripcaru, 1994) and also helps us feel socially attached to others (Field et al., 1997; Kelter, 2009). Touch is an essential part of everyday activities ranging from touching our food to eat to sharing human affection with another individual. Recent studies indicate that slow affectionate touch, rather than faster neutral touch, can serve as a buffer against physical pain. In addition, the same slow affectionate touch can reduce feelings of social exclusion and increase social bonding.

Skin is the largest organ in our body and has a variety of nerve endings that allow us to feel sensations such as pressure, pain, cold, and heat. The skin on our bodies also serves as a protector to important vital organs.

Touch and pain are aspects of the somatosensory system, which provides our brain with information about our own body (**interoception**) and properties of the immediate external world (**exteroception**) (Craig, 2002). We have somatosensory receptors located all over the body, from the surface of our skin to the depth of our joints. The information they send to the central nervous system is generally divided into four modalities: **cutaneous senses** (senses of the skin), **proprioception** (body position), **kinesthesis** (body movement), and **nociception** (pain, discomfort).

Cutaneous Senses (senses of the skin)

Cutaneous senses respond to tactile, thermal, and pruritic (itchy) stimuli, and events that cause tissue damage (hence pain). Cutaneous mechanoreceptors are located in the skin. They provide the senses of touch, pressure, vibration, proprioception, and others. They are all innervated by Aβ fibers (**Aβ fibers from the skin are mostly dedicated to touch)**, except the mechanoreceiving free nerve endings, which are innervated by Aδ fibers **(Aδ fibers serve to receive and transmit information primarily relating to acute pain; sharp, immediate, and relatively short-lasting)**.

The can be categorized by morphology, by the type of sensation they perceive, and by the rate of adaptation. Furthermore, each has a different receptive field:

- Ruffini's end organs detect tension deep in the skin.
- Meissner's corpuscles detect changes in texture (vibrations around 50 Hz) and adapt rapidly.
- Pacinian corpuscles detect rapid vibrations (about 200–300 Hz).
- Merkel's discs detect sustained touch and pressure.
- Mechanoreceiving free nerve endings detect touch, pressure, and stretching.
- Hair follicle receptors are located in hair follicles and sense the position changes of hair strands.

Ruffini Ending

The Ruffini ending (Ruffini corpuscle or bulbous corpuscle) is a class of slowly adapting mechanoreceptors thought to exist only in the glabrous dermis and subcutaneous tissue of humans. It is named after Angelo Ruffini (an Italian histologist and embryologist).

This spindle-shaped receptor is sensitive to skin stretch, and contributes to the kinesthetic sense of and control of finger position and movement. It is believed to be useful for monitoring the slippage of objects along the surface of the skin, allowing the modulation of grip on an object.

Ruffini endings are located in the deep layers of the skin. They register mechanical information within joints, more specifically angle change, with a specificity of up to two degrees, as well as continuous pressure states. They also act as thermoreceptors that respond for a long time, such as holding hands with someone during a walk. In a case of a deep burn to the body, there will be no pain as these receptors will be burned off.

Meissner's Corpuscles

Meissner's corpuscles (or tactile corpuscles) are responsible for sensitivity to light touch. In particular, they have the highest sensitivity (lowest threshold) when sensing vibrations lower than 50 hertz. They are rapidly adaptive receptors.

Pacinian Corpuscles

Pacinian corpuscles (or lamellar corpuscles) are responsible for sensitivity to vibration and pressure. The vibrational role may be used to detect surface texture, e.g., rough versus smooth.

Merkel Nerve

Merkel nerve endings are mechanoreceptors found in the skin and mucosa of vertebrates that provide touch information to the brain. The information they provide are those regarding pressure and texture. Each ending consists of a Merkel cell in close apposition with an enlarged nerve terminal.

This is sometimes referred to as a Merkel cell–neurite complex, or a Merkel disk receptor. A single afferent nerve fiber branches to innervate up to 90 such endings. They are classified as slowly adapting type I mechanoreceptors.

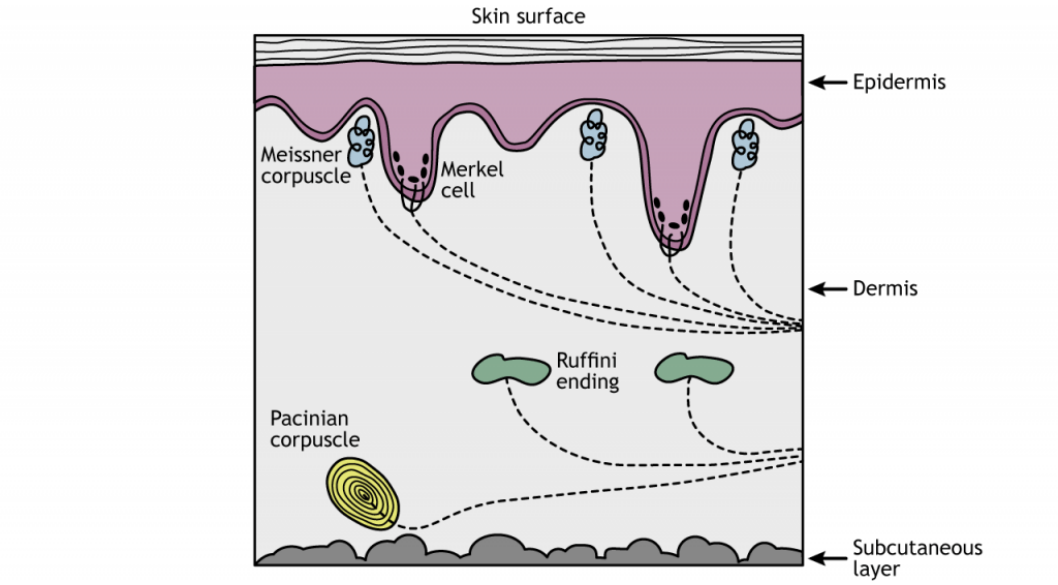

Figure 2.5.20.1: *The different mechanoreceptor types are located in different regions of the skin and are responsible for perception of different characteristics of a touch stimulus. Pacinian corpuscles and Ruffini endings are located deep in the dermis. Meissner corpuscles are located in the dermis near the epidermis, and Merkel cells are located in the epidermis, near the surface of the skin. Proprioception (body position)

Proprioception refers to the sense of knowing how one's body is positioned in three-dimensional space. Proprioception is the sense of the relative position of neighboring parts of the body and the strength of effort being employed in movement. It is distinguished from exteroception (perception of the outside world) and interoception (perception of pain, hunger, and the movement of internal organs). The initiation of proprioception is the activation of a proprioreceptor in the periphery. The proprioceptive sense is believed to be composed of information from sensory neurons located in the inner ear (motion and orientation) and in the stretch receptors located in the muscles and the joint-supporting ligaments (stance). Conscious proprioception is communicated by the posterior (dorsal) column–medial lemniscus pathway to the cerebrum. Unconscious proprioception is communicated primarily via the dorsal and ventral spinocerebellar tracts to the cerebellum.

An unconscious reaction is seen in the human proprioceptive reflex, or Law of Righting, a reflex that corrects the orientation of

the body when it is taken out of its normal upright position. In the event that the body tilts in any direction, the person will tilt their head back to level the eyes against the horizon. Infants are often seen doing this as soon as they gain control of their neck muscles. This control comes from the cerebellum, the part of the brain that affects balance.

Muscle spindles are sensory receptors within the belly of a muscle that primarily detect changes in the length of a muscle. They convey length information to the central nervous system via sensory neurons. This information can be processed by the brain to determine the position of body parts. The responses of muscle spindles to changes in length also play an important role in regulating the contraction of muscles.

The Golgi organ (also called Golgi tendon organ, tendon organ, neurotendinous organ or neurotendinous spindle) is a proprioceptive sensory receptor that provides the sensory component of the Golgi tendon reflex. The Golgi organ should not be confused with the Golgi apparatus—an organelle in the eukaryotic cell —or the Golgi stain, which is a histologic stain for neuron cell bodies. The Golgi tendon reflex is a normal component of the reflex arc of the peripheral nervous system. In a Golgi tendon reflex, skeletal muscle contraction causes the agonist muscle to simultaneously lengthen and relax. This reflex is also called the inverse myotatic reflex, because it is the inverse of the stretch reflex. Although muscle tension is increasing during the contraction, alpha motor neurons in the spinal cord that supply the muscle are inhibited and antagonistic muscles are activated.

Kinesthesis (body movement)

Kinesthesis or Kinesthesia is a term that is often used interchangeably with proprioception. Some users differentiate the kinesthetic sense from proprioception by excluding the sense of equilibrium or balance from kinesthesia. An inner ear infection, for example, might degrade the sense of balance. This would degrade the proprioceptive sense, but not the kinesthetic sense. The infected person would be able to walk, but only by using their sense of sight to maintain balance; the person may have difficulty walking when their eyes are closed.

Proprioception and kinesthesia are seen as interrelated and there is considerable disagreement regarding the definition of these terms. Some of this difficulty stems from Sherrington's original description of joint position sense (or the ability to determine where a particular body part exactly is in space) and kinesthesia (or the sensation that the body part has moved) under a more general heading of proprioception. Clinical aspects of proprioception are measured in tests that measure a subject's ability to detect an externally imposed passive movement, or the ability to reposition a joint to a predetermined position. Often it is assumed that the ability of one of these aspects will be related to another, unfortunately experimental evidence suggests there is no strong relation between these two aspects. This suggests that while these components may well be related in a cognitive manner, they seem to be separate physiologically.

Much of the forgoing work is dependent on the notion that proprioception is essentially a feedback mechanism: that is the body moves (or is moved) and then the information about this is returned to the brain whereby subsequent adjustments could be made. More recent work into the mechanism of ankle sprains suggest that the role of reflexes may be more limited due to their long latencies (even at the spinal cord level) as ankle sprain events occur in perhaps 100 milliseconds or less. As a result, a model has been proposed to include a 'feedforward' component of proprioception where the subject will also have central information about the body's position prior to attaining it.

Kinesthesia is a key component in **muscle memory** and **hand-eye coordination** and training can improve this sense. The ability to swing a golf club, or to catch a ball, requires a finely-tuned sense of the position of the joints. This sense needs to become automatic through training to enable a person to concentrate on other aspects of performance, such as maintaining motivation or seeing where other people are.

Nociception (pain, discomfort)

Nociception deals with a series of events and processes required for an organism to receive a painful stimulus, convert it to a molecular signal, and recognize and characterize the signal in order to trigger an appropriate defense response. This serves as an important function because our brains can often turn off or reduce the feelings of pain depending on the situation we may be experiencing or involved in. An example involves athletes who often do not feel pain until after they have completed the game or event they are participating in (Bantick, Wise, Ploghaus, Clare, Smith, & Tracey, 2002). In essence their brain is involved in a complicated process that requires them to utilize multiple systems to stay focused on the activity. The endorphins that are released when we are engaged or excited by a situation or event around us act as natural pain killers (Sternberg, Bailin, Grant, & Gracely, 1998).

The Primary Somatosensory Cortex

The primary somatosensory cortex is divided into four regions, each with its own input and function: areas 1, 2, 3a, and 3b. Most touch information from mechanoreceptors inputs to region 3b, whereas most proprioceptive information from the muscles inputs to region 3a. These regions then send and receive information from areas 1 and 2. As processing of somatosensory information continues, the stimuli required to activate neurons becomes more complex. For example, area 1 is involved in sensing texture, and area 2 is involved in sensing size and shape of an object. The posterior parietal cortex, an important output region of the somatosensory cortex, lies caudal to the postcentral gyrus; areas 5 and 7 are downstream structures that continue to process touch (see Figure 2.5.20.2).

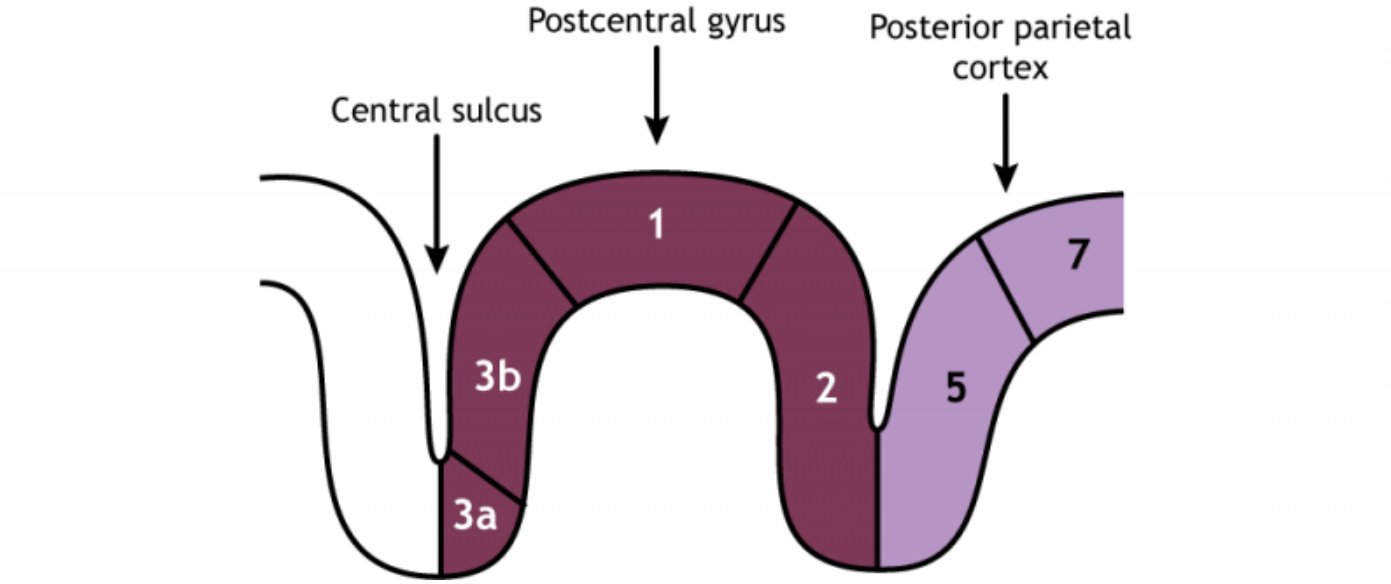

Figure 2.5.20.2: *The somatosensory cortex, located in the postcentral gyrus, just posterior to the central sulcus, is divided into 4 areas: 3a, 3b, 1, and 2. The posterior parietal cortex, an output region of the somatosensory cortex, lies just posterior to the postcentral gyrus and is divided into areas 5 and 7. 'Postcentral Gyrus' by Casey Henley is licensed under a Creative Commons Attribution Non-Commercial Share-Alike (CC BY-NC-SA) 4.0 International License.*

Testing of the senses begins with examining the regions known as dermatomes that connect to the cortical region where somatosensation is perceived in the postcentral gyrus. To test the sensory fields, a simple stimulus of the light touch of the soft end of a cotton-tipped applicator is applied at various locations on the skin. The spinal nerves, which contain sensory fibers with dendritic endings in the skin, connect with the skin in a topographically organized manner, illustrated as dermatomes (Figure 2.5.20.3 - it is not necessary to memorize the terms in this figure). For example, the fibers of the eighth cervical nerve innervate the medial surface of the forearm and extend out to the fingers. In addition to testing perception at different positions on the skin, it is necessary to test sensory perception within the dermatome from distal to proximal locations in the appendages, or lateral to medial locations in the trunk. In testing the eighth cervical nerve, the patient would be asked if the touch of the cotton to the fingers or the medial forearm was perceptible, and whether there were any differences in the sensations.

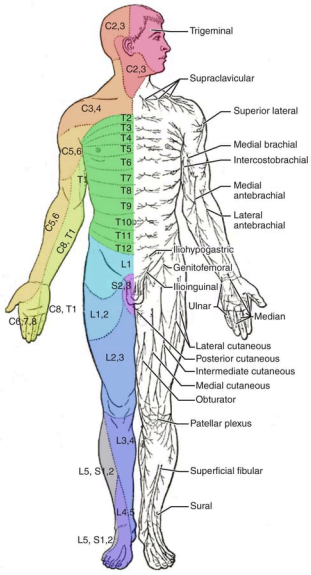

Figure 2.5.20.3 – ***Dermatomes:*** *The surface of the skin can be divided into topographic regions that relate to the location of sensory endings in the skin based on the spinal nerve that contains those fibers. (credit: modification of work by Mikael Häggström)*

2.6.1: Classification of Muscle Types and Functions

Learning Objectives

- Identify the three types of muscle tissue
- Compare and contrast the functions of each muscle tissue type
- Explain how muscle tissue can enable motion

Muscle Tissue: Key Properties and Classifications

Muscle tissue is generally characterized by properties that allow movement. A critical property is that muscles are ***excitable*** and are able to respond to a variety of stimuli. They are ***contractile***, meaning they can shorten and generate a pulling force. When attached between two movable objects, in other words, bones, contractions of the muscles cause the bones to move.

Some muscle movement is ***voluntary***, which means it is under conscious control. For example, a person decides to open a book and read a chapter on Psychology. Other movements are ***involuntary***, meaning they are *not* typically under conscious control, such as the contraction of your pupil in bright light or the rhythmic contraction of your heart muscles.

Muscle tissue used for voluntary and involuntary movement can be classified into three main types according to structure and function: **Skeletal, Cardiac, and Smooth**. Table 1 below illustrates the distinctions between these three muscle types.

Comparison of Structural and Functional Properties of Muscle Types

Table 1: Muscle Types - Structure, Function, and Location

Tissue	Histology	Function	Location
Skeletal	Long cylindrical fiber, striated, many peripherally located nuclei	Voluntary movement, produces heat, protects organs	Attached to bones and around entrance points to body (e.g., mouth, anus)
Cardiac	Short, branched, striated, single central nucleus	Contracts to pump blood	Heart
Smooth	Short, spindle-shaped, no evident striation, single nucleus in each fiber	Involuntary movement, moves food, involuntary control of respiration, moves secretions, regulates flow of blood in arteries by contraction	Walls of major organs and passageways

Skeletal muscle is attached to bones and its contraction makes possible locomotion (i.e. walking), facial expressions, maintaining posture, and other voluntary movements of the body. Skeletal muscles also generate heat as a byproduct of their contraction and thus participate in thermal regulation. Shivering is an involuntary contraction of skeletal muscles in response to perceived lower than normal body temperature.

Skeletal muscles act not only to produce movement but also to stop movement, such as resisting gravity to maintain posture. Small, constant adjustments of the skeletal muscles are needed to hold a body upright or balanced in any position. Muscles also prevent excess movement of the bones and joints, maintaining skeletal stability and preventing skeletal structure damage or deformation. Joints can become misaligned or dislocated entirely by pulling on the associated bones; muscles work to keep joints stable.

Skeletal muscles are also located throughout the body at the openings of internal tracts to control the movement of various substances. These muscles allow functions, such as swallowing, urination, and defecation, to be under voluntary control. Skeletal muscles also protect internal organs (particularly abdominal and pelvic organs) by acting as an external barrier or shield to external trauma and by supporting the weight of the organs.

Skeletal muscle tissue is arranged in bundles surrounded by connective tissue. Under the light microscope, muscle cells appear striated (striped) with many nuclei squeezed along the membranes. The **striation** is due to the regular alternation of the contractile proteins actin and myosin, along with the structural proteins that couple the contractile proteins to connective tissues. The cells are multinucleated as a result of the fusion of many precursor cells to form each long muscle fiber.

Cardiac muscle forms the contractile walls of the heart. The cells of cardiac muscle, known as cardiomyocytes, also appear striated under the microscope. Unlike skeletal muscle fibers, cardiomyocytes are single cells typically with a single centrally located nucleus. A principal characteristic of cardiomyocytes is that they contract on their own intrinsic rhythms without any external stimulation. Cardiomyocytes attach to one another with specialized cell junctions called intercalated discs. Intercalated discs have both anchoring junctions and gap junctions. Attached cells form long, branching cardiac muscle fibers that are, essentially, a mechanical and electrochemical syncytium allowing the cells to synchronize their actions. The cardiac muscle pumps blood through the body and is under involuntary control. The attachment junctions hold adjacent cells together across the dynamic pressure changes of the cardiac cycle.

Smooth muscle tissue contraction is responsible for involuntary movements in the internal organs. It forms the contractile component of the digestive, urinary, and reproductive systems as well as the airways and arteries. Each cell is spindle shaped with a single nucleus and no visible striations (Figure 4.18).

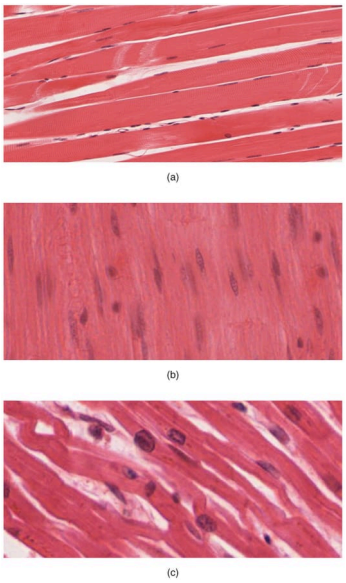

Figure 2.6.1.1: **Muscle Tissue** (a) Skeletal muscle cells have prominent striation and nuclei on their periphery. (b) Smooth muscle cells have a single nucleus and no visible striations. (c) Cardiac muscle cells appear striated and have a single nucleus. (Micrographs provided by the Regents of University of Michigan Medical School © 2012)

Slow and Fast Twitch Skeletal Muscles

Skeletal muscle fibers can be further subdivided into slow and fast-twitch subtypes depending on their metabolism and corresponding action. Most muscles are made up of combinations of these fibers, although the relative number varies substantially.

Slow Twitch

Slow-twitch fibers are designed for endurance activities that require long-term, repeated contractions, like maintaining posture or running a long distance. These activities require the delivery of large amounts of oxygen to the muscle, which can rapidly become rate-limiting if the respiratory and circulatory systems cannot keep up.

Due to their large oxygen requirements, slow-twitch fibers are associated with large numbers of blood vessels, mitochondria, and high concentrations of myoglobin, an oxygen-binding protein found in the blood that gives muscles their reddish color. One muscle with many slow-twitch fibers is the soleus muscle in the leg (~80% slow-twitch), which plays a key role in standing.

Fast Twitch

Fast-twitch fibers are good for rapid movements like jumping or sprinting that require fast muscle contractions of short duration. As fast-twitch fibers generally do not require oxygenation, they contain fewer blood vessels and mitochondria than slow-twitch fibers and less myoglobin, resulting in a paler color. Muscles controlling eye movements contain high numbers of fast-twitch fibers (~85% fast-twitch).

2.6.2: Synaptic Control of Movement- Neuromuscular Junction and Motor Units

Learning Objectives

- Describe the structural and functional aspects of motor neurons and the neuromuscular junction
- Explain the key steps of electrical excitation of muscle fibers
- Apply knowledge of motor units and motor unit recruitment to functional changes in muscle strength

Motor Neurons

Although the neuroanatomy of the motor system will be covered in a later section, it is important to realize that a large portion of the Central and Peripheral Nervous Systems contain collections of neurons that influence motor action in some way. Many of these neurons in the CNS belong to so-called, "motor circuits" and are classified as ***motor*** neurons as opposed to sensory or interneurons. Motor neurons located in cortical and subcortical regions of the forebrain, such as motor and premotor cortex and the basal ganglia are referred to as **Upper Motor Neurons**, while those located in the medulla and spinal cord are the **Lower Motor Neurons**. The function of the Upper Motor Neurons will be addressed in later sections. The Lower Motor Neurons of the spinal cord play a direct role in both triggering voluntary movement and maintaining muscle tone. These are the **Alpha** and **Gamma** motor neurons, respectively.

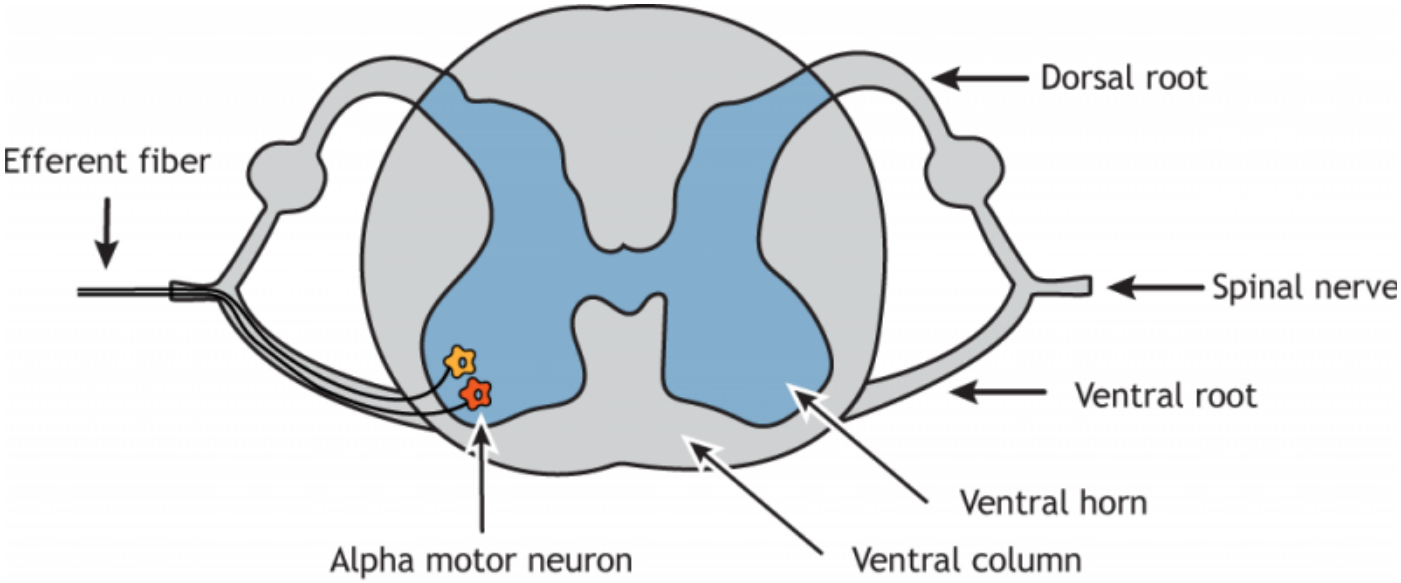

Figure 2.6.2.1: Alpha motor neurons are located in the ventral (anterior) horn of spinal cord. Their axons, which are efferent fibers, travel to the muscles via spinal nerves. 'Alpha Motor Neurons' by Casey Henley. License: CC BY-NC-SA 4.0 International License.

The cell bodies of the Alpha motor neurons are located in the central nervous system in the ventral (i.e. anterior) horn of the spinal cord. Their axons leave the spinal cord via the ventral roots and travel primarily to skeletal muscle via efferent (outgoing) spinal nerves to cause muscle contraction. Gamma motor neurons function to keep muscle fibers prepared for action by stimulating them in a way to maintain "tautness" or muscle tone. This resting muscle tonus allows the muscle to respond much more effectively to the alpha motor neuron stimulation, thus alpha and gamma neurons work together to maintain a muscle's sensitivity for movement. Just imagine how difficult it would be to shoot a rubber band across a room if it wasn't stretched or taut (Gamma motor neuron influence) prior to letting it go (Alpha motor neuron influence).

The Neuromuscular Junction

A unique specialization of the skeletal muscle is the site where a motor neuron's axon terminal meets the muscle fiber—called the **neuromuscular junction (NMJ)**. This is where the muscle fiber first responds to signaling by the motor neuron. Every skeletal muscle fiber in every skeletal muscle is innervated by a motor neuron at the NMJ. Excitation signals from the neuron are the only way to functionally activate the fiber to contract. It is important to note that one motor neuron can activate multiple muscle fibers due to axonal branching (see the Motor Units section below for more details on this topic).

Excitability of Muscle: Excitation-Contraction Coupling

All living cells have membrane potentials, or electrical gradients across their membranes. For example, in neurons which are not being stimulated the membrane potential is approximately -70 mV inside of the cell relative to the outside. This is referred to as a neuron's resting potential.

Although living cells have a cellular membrane, only some, such as neurons and muscle cells are excitable. In other words, they can shift quickly from a resting state to an excited one. Thus, neurons and muscle cells can use their membrane potentials to generate electrical signals. They do this by controlling the movement of charged particles, called ions, across their membranes to create electrical currents. This is achieved by opening and closing specialized proteins in the membrane called ion channels. Although the currents generated by ions moving through these channel proteins are very small, they form the basis of both neural signaling and muscle contraction.

Both neurons and skeletal muscle cells are electrically excitable, meaning that they are able to generate action potentials. An action potential is a special type of electrical signal that can travel along a cell membrane as a wave. This allows a signal to be transmitted quickly and faithfully over long distances.

Although the term **excitation-contraction coupling** confuses or scares some students, it comes down to this: for a skeletal muscle fiber to contract, its membrane must first be "excited"—in other words, it must be stimulated to fire an action potential. The muscle fiber action potential, which sweeps along the muscle fiber as a wave, is "coupled" to the actual contraction through the release of calcium ions (Ca^{++}) from the muscle cells. Once released, the Ca^{++} interacts with the shielding proteins, forcing them to move aside so that the actin-binding sites are available for attachment by myosin heads. The myosin then pulls the actin filaments toward the center, shortening the muscle fiber.

In skeletal muscle, this sequence begins with signals from the somatic motor division of the nervous system. In other words, the "excitation" step in skeletal muscles is always triggered by signaling from the nervous system.

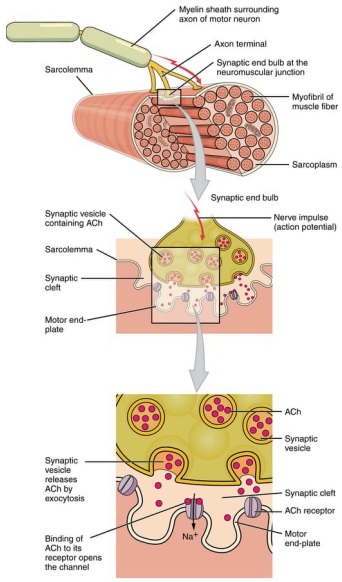

Figure 2.6.2.2: Motor End-Plate and Innervation at the NMJ, the axon terminal releases the neurotransmitter, Acetylcholine (ACh). The motor end-plate is the location of the ACh-receptors in the muscle fiber sarcolemma. When ACh molecules are released, they diffuse across a minute space called the synaptic cleft and bind to the receptors.

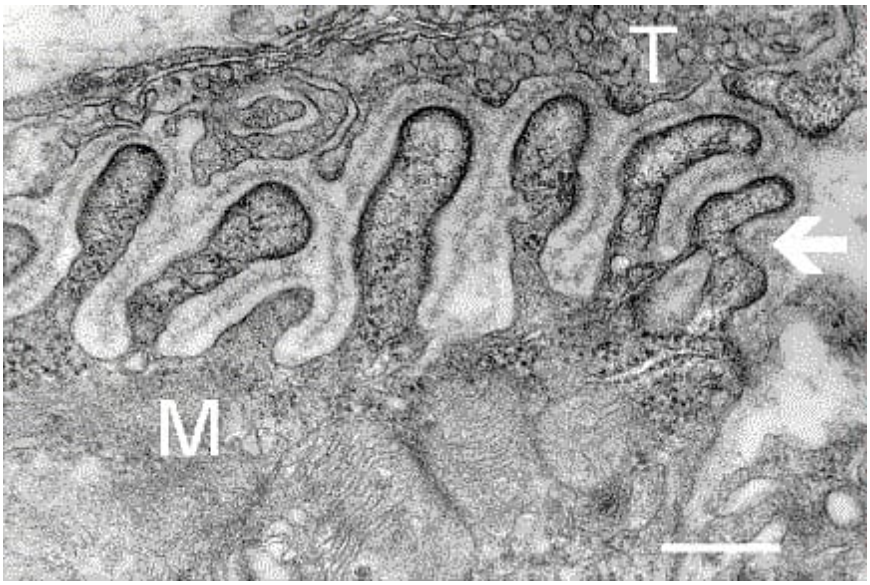

Figure 2.6.2.3: Electron micrograph showing a cross-section through the neuromuscular junction. T is the axon terminal, M is the muscle fiber. The arrow shows junctional folds with basal lamina. Postsynaptic densities are visible on the tips between the folds. The scale is 0.3 µm. (Wikimedia Commons) License: *Public Domain: No Known Copyright*

Although a small number of motor neurons activating the skeletal muscles of the face, head, and neck are located in the brainstem, most motor neurons originate in the spinal cord, directing skeletal muscle fibers to contract throughout the rest of the body. These neurons have long processes, called axons, which are specialized to transmit action potentials long distances— in this case, all the way from the spinal cord to the muscle itself (which may be up to three feet away). The axons of multiple neurons bundle together to form nerves, like wires bundled together in a cable.

Signaling begins when a neuronal **action potential** travels along the axon of a motor neuron, and then along the individual branches to terminate at the NMJ. At the NMJ, the axon terminal releases a chemical messenger, or **neurotransmitter**, called **acetylcholine (ACh)**. The ACh molecules diffuse across a minute space called the **synaptic cleft** and bind to ACh receptors located within the **motor end-plate** of the sarcolemma on the other side of the synapse. Once ACh binds, a channel in the ACh receptor opens and positively charged ions can pass through into the muscle fiber, causing it to **depolarize**, meaning that the membrane potential of the muscle fiber becomes less negative (closer to zero).

As the membrane depolarizes, another set of ion channels called **voltage-gated sodium channels** are triggered to open. Sodium ions enter the muscle fiber, and an action potential rapidly spreads (or "fires") along the entire membrane to initiate excitation-contraction coupling.

Things happen very quickly in the world of excitable membranes (just think about how quickly you can snap your fingers as soon as you decide to do it). Immediately following depolarization of the membrane, it repolarizes, re-establishing the negative membrane potential. Meanwhile, the ACh in the synaptic cleft is degraded by the enzyme acetylcholinesterase (AChE) so that the ACh cannot rebind to a receptor and reopen its channel, which would cause unwanted extended muscle excitation and contraction.

Propagation of an action potential along the sarcolemma is the excitation portion of excitation-contraction coupling.This excitation actually triggers the release of Calcium ions (Ca^{++}) from their storage in the cell's sacroplasmic reticulum (SR). For the action potential to reach the membrane of the SR, there are periodic invaginations in the sarcolemma, called **T-tubules** ("T" stands for "transverse"). The diameter of a muscle fiber can be up to 100 μm, so these T-tubules ensure that the membrane can get close to the SR in the sarcoplasm. The arrangement of a T-tubule with the membranes of SR on either side is called a **triad**. The triad surrounds the cylindrical structure called a **myofibril**, which contains actin and myosin.

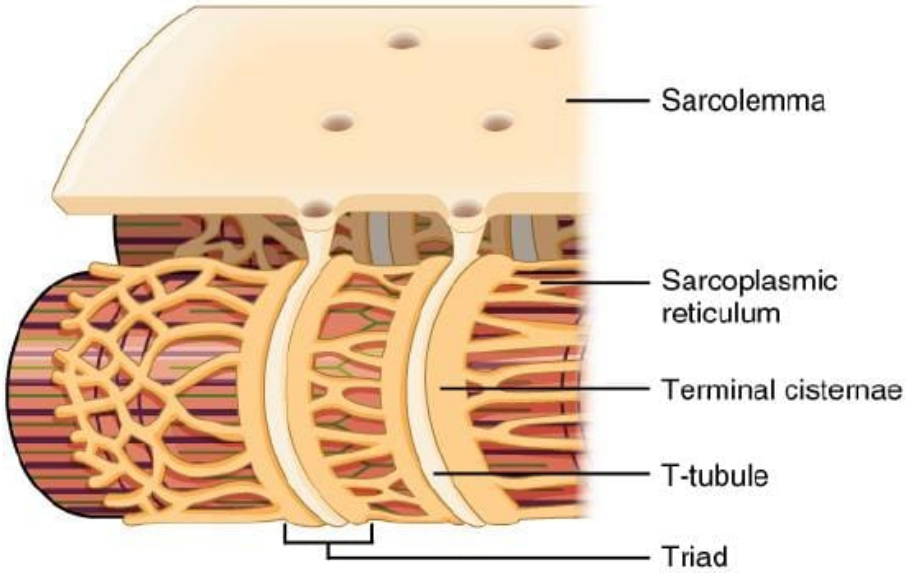

Figure 2.6.2.4: The T-tubule: Narrow T-tubules permit the conduction of electrical impulses. The SR functions to regulate intracellular levels of calcium. Two terminal cisternae (where enlarged SR connects to the T-tubule) and one T-tubule comprise a triad—a “threesome” of membranes, with those of SR on two sides and the T-tubule sandwiched between them.

The T-tubules carry the action potential into the interior of the cell, which triggers the opening of calcium channels in the membrane of the adjacent SR, causing Ca^{++} to diffuse out of the SR and into the sarcoplasm. It is the arrival of Ca^{++} in the sarcoplasm that initiates contraction of the muscle fiber by its contractile units, or sarcomeres.

Motor Units

As described in the Neuromuscular Junction section above, every skeletal muscle fiber is innervated by an axon terminal of a motor neuron in order to contract. Each muscle fiber is innervated by only one motor neuron, but each motor neuron innervates a group of muscle fibers due to the axon's ability to branch. Recall that the NMJ is the point of connection between each axon terminal and it's corresponding muscle fiber. A motor neuron and the group of muscle fibers in a muscle that it innervates is called a **motor unit**. The size of a motor unit is variable depending on the nature of the muscle.

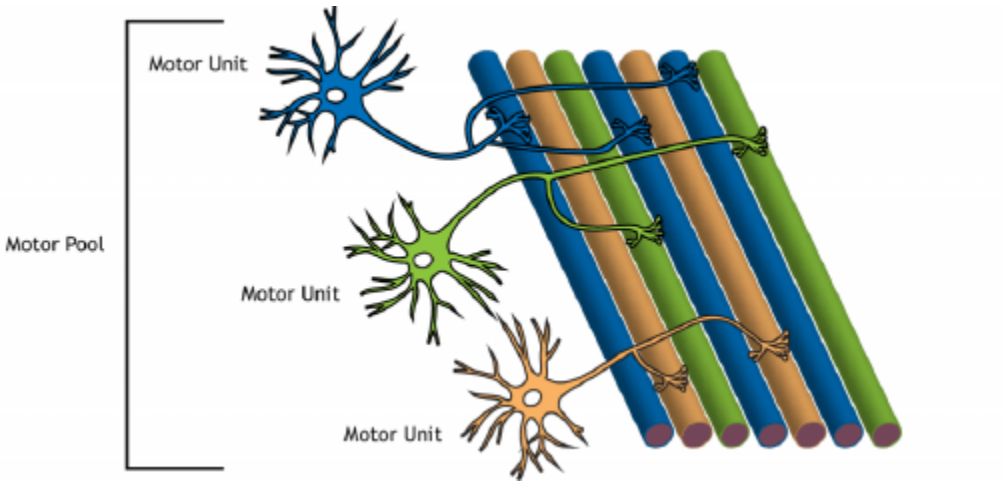

Figure 2.6.2.5: Motor neurons can innervate more than one muscle fiber within a muscle. The motor neuron and the fibers it innervates are a motor unit. Three motor units are shown in the image: one blue, one green, one orange. Those three motor units innervate all the muscles fibers in the muscle and are the motor pool for that muscle. ‘Motor Unit and Pool‘by Casey Henley. License: CC BY-NC-SA 4.0 International License.

A small motor unit is an arrangement where a single motor neuron supplies a small number of muscle fibers in a muscle. Small motor units permit very fine motor control of the muscle. The best example in humans is the small motor units of the extraocular

eye muscles that move the eyeballs. There are thousands of muscle fibers in each muscle, but every six or so fibers are supplied by a single motor neuron, as the axons branch to form synaptic connections at their individual NMJs. This allows for exquisite control of eye movements so that both eyes can quickly focus on the same object. Small motor units are also involved in the many fine movements of the fingers and thumb of the hand for grasping, texting, etc.

A large motor unit is an arrangement where a single motor neuron supplies a large number of muscle fibers in a muscle. Large motor units are concerned with simple, or “gross,” movements, such as powerfully extending the knee joint. The best example is the large motor units of the thigh muscles or back muscles, where a single motor neuron will supply thousands of muscle fibers in a muscle, as its axon splits into thousands of branches.

There is a wide range of motor units within many skeletal muscles, which gives the nervous system a wide range of control over the muscle. The small motor units in the muscle will have smaller, lower-threshold motor neurons that are more excitable, firing first to their skeletal muscle fibers, which also tend to be the smallest. Activation of these smaller motor units results in a relatively small degree of contractile strength (tension) generated in the muscle. As more strength is needed, larger motor units, with bigger, higher-threshold motor neurons, are enlisted to activate larger muscle fibers. This increasing activation of motor units produces an increase in muscle contraction known as **recruitment**.

As more motor units are recruited, muscle contraction grows progressively stronger. In some muscles, the largest motor units may generate a contractile force of 50 times more than the smallest motor units in the muscle. This allows a feather to be picked up using the biceps brachii arm muscle with minimal force, and a heavy weight to be lifted by the same muscle by recruiting the largest motor units.

When necessary, the maximal number of motor units in a muscle can be recruited simultaneously, producing the maximum force of contraction for that muscle, but this cannot last for very long because of the energy requirements to sustain the contraction. To prevent complete muscle fatigue, motor units are generally not all simultaneously active, but instead some motor units rest while others are active, which allows for longer muscle contractions. The nervous system uses recruitment as a mechanism to efficiently utilize a skeletal muscle.

2.6.3: Spinal Reflexes

Learning Objectives

- Distinguish between the types of spinal reflexes

Spinal reflexes include the stretch reflex, the Golgi tendon reflex, the crossed extensor reflex, and the withdrawal reflex.

Stretch Reflex

The stretch reflex (myotatic reflex) is a muscle contraction in response to stretching within the muscle. This reflex has the shortest latency of all spinal reflexes. It is a monosynaptic reflex that provides automatic regulation of skeletal muscle length.

When a muscle lengthens, the muscle spindle is stretched and its nerve activity increases. This increases alpha motor neuron activity, causing the muscle fibers to contract and thus resist the stretching. A secondary set of neurons also causes the opposing muscle to relax. The reflex functions to maintain the muscle at a constant length.

Golgi Tendon Reflex

The Golgi tendon reflex is a normal component of the reflex arc of the peripheral nervous system. The tendon reflex operates as a feedback mechanism to control muscle tension by causing muscle relaxation before muscle force becomes so great that tendons might be torn.

Although the tendon reflex is less sensitive than the stretch reflex, it can override the stretch reflex when tension is great, making you drop a very heavy weight, for example. Like the stretch reflex, the tendon reflex is ipsilateral.

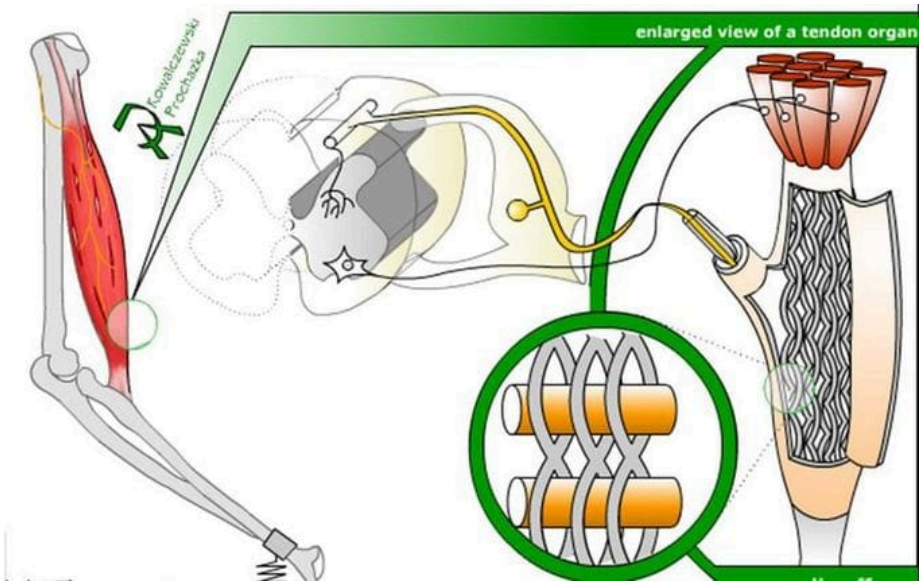
The sensory receptors for this reflex are called Golgi tendon receptors, and lie within a tendon near its junction with a muscle. In contrast to muscle spindles, which are sensitive to changes in muscle length, tendon organs detect and respond to changes in muscle tension that are caused by a passive stretch or muscular contraction.

Crossed Extensor Reflex

Jendrassik maneuver: The Jendrassik maneuver is a medical maneuver wherein the patient flexes both sets of fingers into a hook-like form and interlocks those sets of fingers together (note the hands of the patient in the chair). This maneuver is used often when testing the patellar reflex, as it forces the patient to concentrate on the interlocking of the fingers and prevents conscious inhibition or influence of the reflex.

The crossed extensor reflex is a withdrawal reflex. The reflex occurs when the flexors in the withdrawing limb contract and the extensors relax, while in the other limb, the opposite occurs. An example of this is when a person steps on a nail, the leg that is stepping on the nail pulls away, while the other leg takes the weight of the whole body.

The crossed extensor reflex is contralateral, meaning the reflex occurs on the opposite side of the body from the stimulus. To produce this reflex, branches of the afferent nerve fibers cross from the stimulated side of the body to the contralateral side of the spinal cord. There, they synapse with interneurons, which in turn, excite or inhibit alpha motor neurons to the muscles of the contralateral limb.



Withdrawal Reflex

The withdrawal reflex (nociceptive or flexor withdrawal reflex) is a spinal reflex intended to protect the body from damaging stimuli. It is polysynaptic, and causes the stimulation of sensory, association, and motor neurons.

When a person touches a hot object and withdraws his hand from it without thinking about it, the heat stimulates temperature and danger receptors in the skin, triggering a sensory impulse that travels to the central nervous system. The sensory neuron then synapses with interneurons that connect to motor neurons. Some of these send motor impulses to the flexors to allow withdrawal.

Some motor neurons send inhibitory impulses to the extensors so flexion is not inhibited—this is referred to as reciprocal innervation. Although this is a reflex, there are two interesting aspects to it:

1. The body can be trained to override that reflex.
2. An unconscious body (or even drunk or drugged bodies) will not exhibit the reflex.

Golgi tendon organ: The Golgi tendon organ, responsible for the Golgi tendon reflex, is diagrammed with its typical position in a muscle (left), neuronal connections in spinal cord (middle), and expanded schematic (right). The tendon organ is a stretch receptor that signals the amount of force on the muscle and protects the muscle from excessively heavy loads by causing the muscle to relax and drop the load.

Key Points

- The stretch reflex is a monosynaptic reflex that regulates muscle length through neuronal stimulation at the muscle spindle.

The alpha motor neurons resist stretching by causing contraction, and the gamma motor neurons control the sensitivity of the reflex.
- The stretch and Golgi tendon reflexes work in tandem to control muscle length and tension. Both are examples of ipsilateral reflexes, meaning the reflex occurs on the same side of the body as the stimulus.
- The crossed extensor reflex is a contralateral reflex that allows the body to compensate on one side for a stimulus on the other. For example, when one foot steps on a nail, the crossed extensor reflex shifts the body's weight onto the other foot, protecting and withdrawing the foot on the nail.
- The withdrawal reflex and the more-specific pain withdrawal reflex involve withdrawal in response to a stimulus (or pain). When pain receptors, called nociceptors, are stimulated, reciprocal innervations stimulate the flexors to withdraw and inhibit the extensors to ensure they are unable to prevent flexion and withdrawal.

Key Terms

- **golgi tendon reflex**: A normal component of the reflex arc of the peripheral nervous system. In this reflex, a skeletal muscle contraction causes the agonist muscle to simultaneously lengthen and relax. This reflex is also called the inverse myotatic reflex because it is the inverse of the stretch reflex. Although muscle tension is increasing during the contraction, the alpha motor neurons in the spinal cord that supply the muscle are inhibited. However, antagonistic muscles are activated.
- **alpha motor neuron**: These are large, lower motor neurons of the brainstem and spinal cord. They innervate the extrafusal muscle fibers of skeletal muscle and are directly responsible for initiating their contraction. Alpha motor neurons are distinct from gamma motor neurons that innervate the intrafusal muscle fibers of muscle spindles.

2.6.4: Motor Circuitry- Neural Structures and Pathways

Learning Objectives

- Identify the main structures of neural motor circuits at the cortical, subcortical, and spinal levels
- Describe the main functional roles of the basal ganglia, premotor area, and motor cortex
- Apply knowledge of functional cortical anatomy to the control of fine and gross body movements

Neuroanatomy of Motor Systems

The motor system controls all of our skeletal muscle movement and more. There are multiple levels of control. Within the spinal cord, simple reflexes can function without higher input from the brain. Slightly more complex spinal control occurs when central pattern generators function during repetitive movements like walking. The motor, premotor and supplementary cortices in the brain are responsible for the planning and execution of voluntary movements. And finally, the basal ganglia and cerebellum modulate the responses of the neurons in the motor cortex to help with coordination, motor learning, and balance.

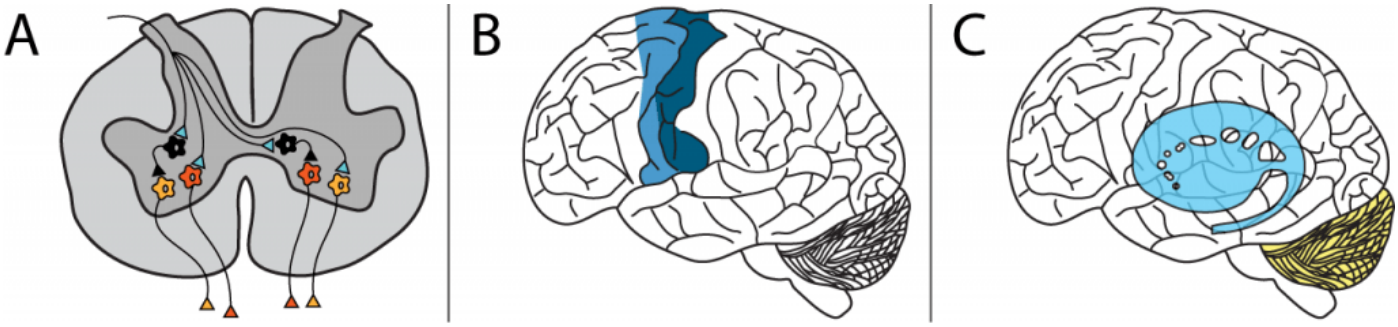

Figure 2.6.4.1: Motor output is controlled at multiple levels: A. Spinal cord and spinal neurons, B. Motor (dark blue) and premotor/ supplementary motor cortices (light blue with supplementary motor located in top portion), C. Basal ganglia (a subcortical structure shown in light blue) and cerebellum (yellow). 'Motor Control Levels' by Casey Henley is licensed under a CC BY-NC-SA 4.0 International License.

Cortical Anatomy of Movement

Much of the cortex is actually involved in the planning of voluntary movement. Sensory information, particularly the dorsal stream of the visual and somatosensory pathways, is processed in the posterior parietal cortex where visual, tactile, and proprioceptive information is integrated.

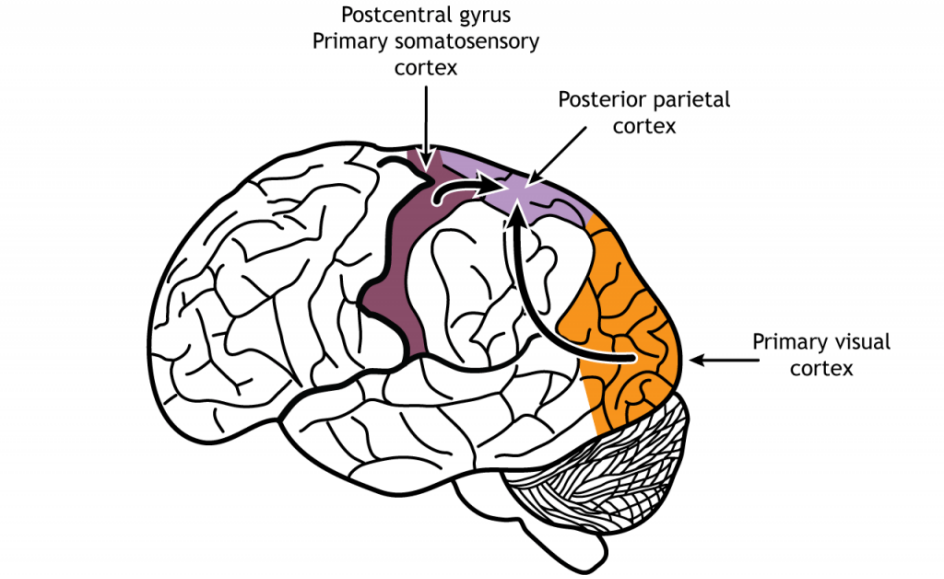

Figure 2.6.4.2: Information from multiple sensory systems is processed in the posterior parietal cortex. Projections are sent from the primary somatosensory and primary visual cortices. 'Posterior Parietal by Casey Henley is licensed under a CC BY-NC-SA 4.0 International License.

Connections from the posterior parietal cortex are then sent to both the premotor regions and the prefrontal cortex. The prefrontal cortex, which is located in the front of the brain in the frontal lobe, plays an important role in higher level cognitive functions like planning, critical thinking, and understanding the consequences of our behaviors. The premotor area lies just anterior to the primary motor cortex. This region helps plan and organize movement and makes decisions about which actions should be used for a situation.

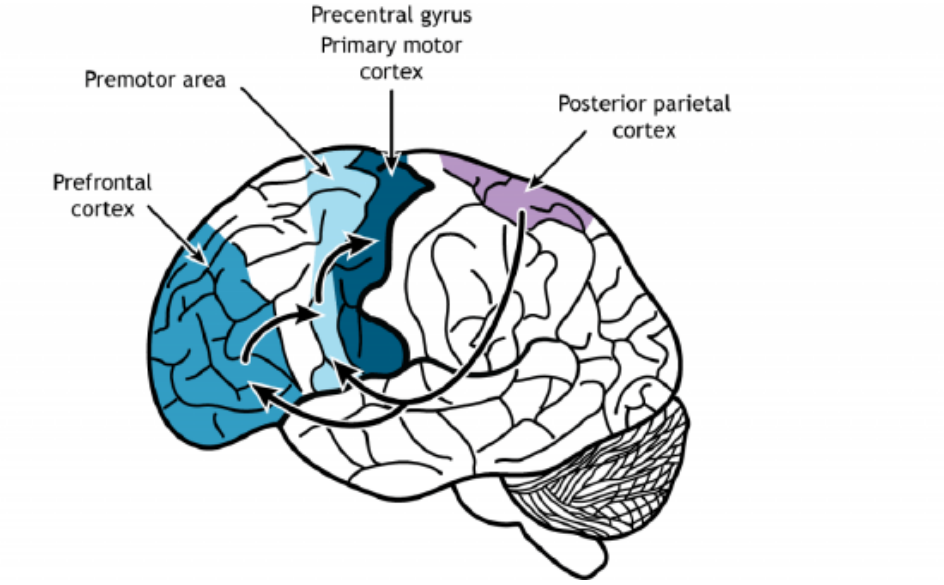

Figure 2.6.4.3: Sensory information from the posterior parietal cortex is processed in the prefrontal cortex and premotor area, both located in the frontal cortex. These areas then send information to the primary motor cortex located in the precentral gyrus. 'Motor Regions' by Casey Henley is licensed under a CC BY-NC-SA 4.0 International License.

Role of Premotor Area

The premotor regions send some axons directly to lower motor neurons in the spinal cord using the same pathways as the motor cortex. However, the premotor cortex also plays an important role in the planning of movement. Two experimental designs have demonstrated this role. Monkeys were trained on a panel that had one set of lights in a row on top and one set of buttons that could also light up in a row on the bottom. The monkeys would watch for a top row light to turn on. This would indicate that within a few seconds, the button directly below would light up. When the button turned on, the monkeys were supposed to push the

button.

Therefore, there were two light triggers in the experiment. The first required no motor movement from the monkey but did give the monkey information about where a motor movement would be needed in the near future. The second required the monkey to move to push the button. When brain activity was measured during this study, neurons in the premotor cortex became active when the first light trigger turned on, well before any movement actually took place (Weinrich and Wise, 1928).

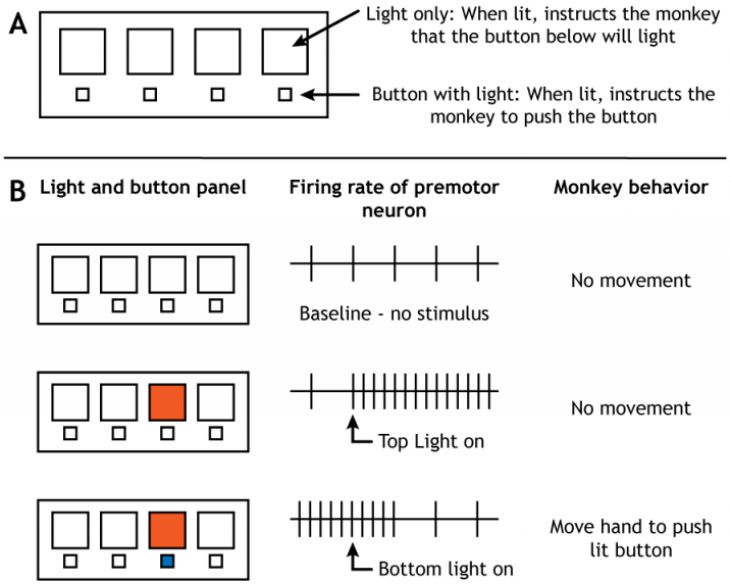

Figure 2.6.4.4: (A) Monkeys were trained to use a light panel. When lit, a light located in the top row informed the monkey that the button directly below would light up soon. Shortly after one of the top row lights turned on, the button directly below it would turn on, and the monkey would need to push that button for a reward. (B) When no lights are lit, premotor neurons fire at a baseline rate, and the monkey does not move. Neurons located in the premotor cortex increase action potential firing rate when the top row light turns on, even though the monkey makes no movement. The firing stops shortly after the monkey moves to push the bottom button after it turns on. (Based on Weinrich and Wise, 1928) 'Light Panel Experiment' by Casey Henley is licensed under a CC BY-NC-SA 4.0 International License.

In another experiment, people were trained to move their fingers in a specific pattern. Cerebral blood flow was then measured when they repeated the finger pattern and when they only imagined repeating the finger pattern. When the movement was only imagined and not actually executed, the premotor regions along with parts of the prefrontal cortex were activated (Roland, et al, 1980).

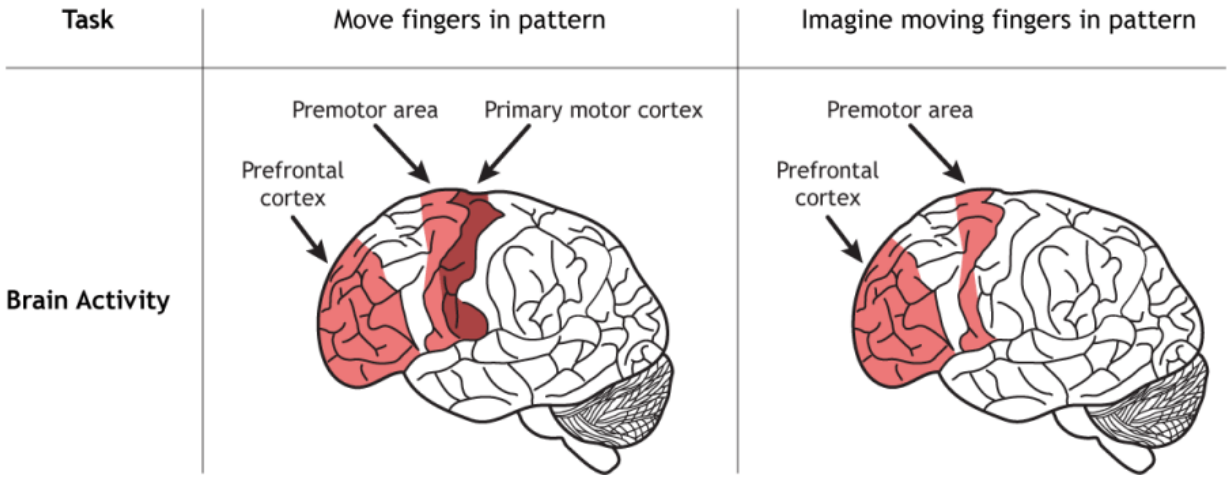

Figure 2.6.4.5: People were trained to move their fingers in a pattern. When the pattern was repeated, brain activity was seen in the primary motor cortex, along with the premotor area and prefrontal cortex. When the pattern was only imagined, and no finger movement took place, brain activity was seen in the premotor area and prefrontal cortex. (Based on Roland, et al, 1980) 'Finger Movement Experiment' by Casey Henley is licensed under a CC BY-NC-SA 4.0 International License.

These studies show that the premotor cortex is active prior to the execution of movement, indicating that it plays an important

role in the planning of movement. The posterior parietal, prefrontal, and premotor regions, though, also communicate with a subcortical region called the basal ganglia to fully construct the movement plan. The basal ganglia are covered in the next subsection.

Role of Motor Cortex

Once the plan for movement has been created, the primary motor cortex is responsible for the execution of that action. The primary motor cortex lies just anterior to the primary somatosensory cortex in the precentral gyrus located in the frontal lobe.

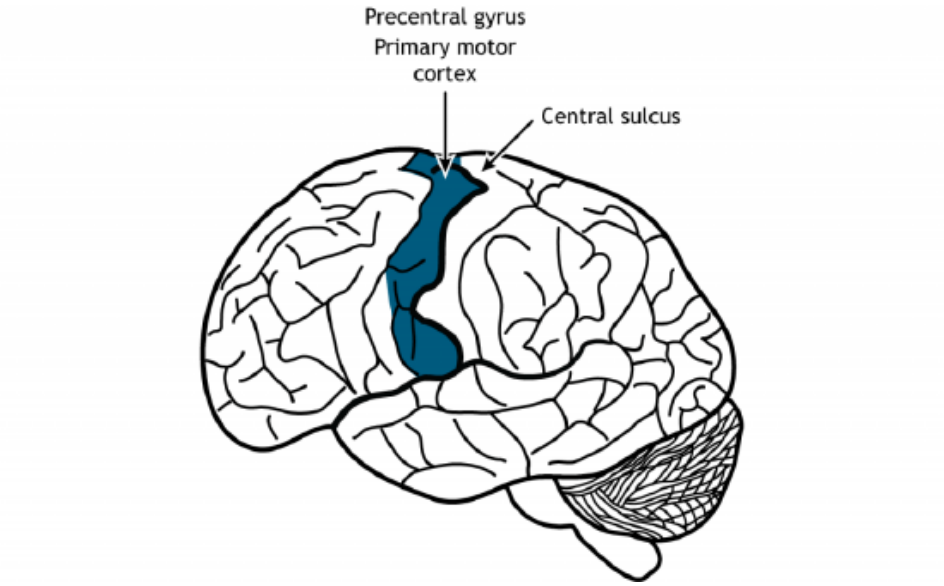

Figure 2.6.4.6: The primary motor cortex is located in the frontal lobe in the precentral gyrus, just anterior to the central sulcus. 'Primary Motor Cortex' by Casey Henley is licensed under a CC BY-NC-SA 4.0 International License.

Like the somatosensory cortex, the motor cortex is organized by a somatotopic map in that different areas of the body are controlled by distinct areas of the motor cortex. However, the motor cortex does not map onto the body in such an exact way as does the somatosensory system. It is believed that upper motor neurons in the motor cortex control multiple lower motor neurons in the spinal cord that innervate multiple muscles. This results in activation of an upper motor neuron causing excitation or inhibition in different neurons at once, indicating that the primary motor cortex is responsible for movements and not simply activation of one muscle. Stimulation of motor neurons in monkeys can lead to complex motions like bringing the hand to the mouth or moving into a defensive position (Graziano et al, 2005).

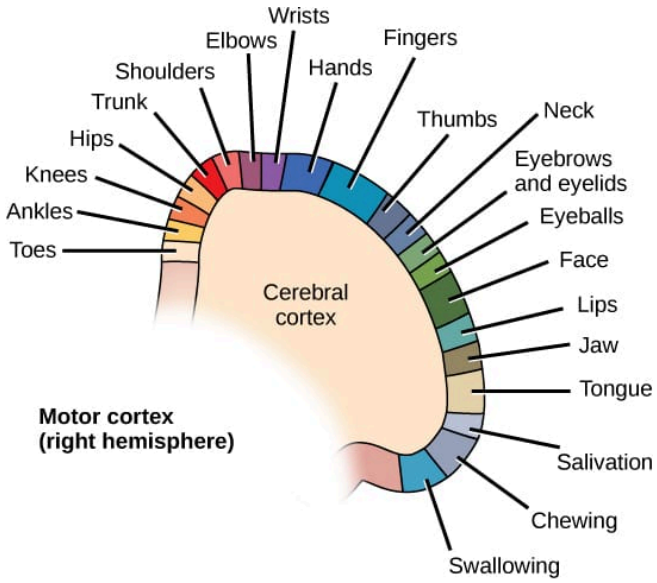

Figure 2.6.4.7: Different regions of the motor cortex control different muscle groups and their neighboring regions control neighboring muscle groups. Although the right hemisphere is shown, a mirror-image exists in the left hemisphere as well. Note that all areas of the body that have voluntary motor control are represented on the primary motor cortex. License: CC BY 4.0, via Wikimedia Commons

Basal Ganglia

The basal ganglia are a group of subcortical nuclei, meaning groups of neurons that lie below the cerebral cortex. The basal ganglia is comprised of several nuclei including the caudate nucleus, putamen, and the globus pallidus. Another nucleus typically associated with the basal ganglia is the subthalamic nucleus. The substantia nigra of the midbrain provides dopaminergic input to these areas.

The basal ganglia are primarily associated with motor control, since motor disorders, such as Parkinson's or Huntington's diseases stem from dysfunction of neurons within the basal ganglia. For voluntary motor behavior, the basal ganglia are involved in the initiation or suppression of behavior and can regulate movement through modulating activity in the thalamus and cortex. In addition to motor control, the basal ganglia also communicate with non-motor regions of the cerebral cortex and play a role in other behaviors such as emotional and cognitive processing.

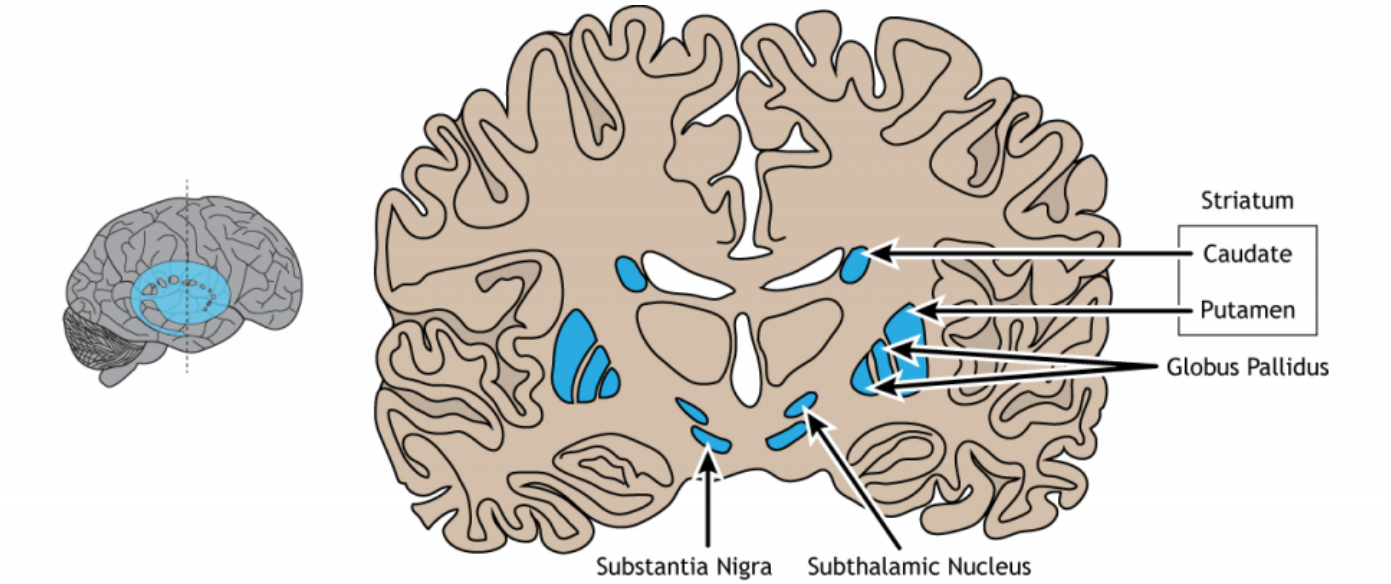

Figure 2.6.4.9: The basal ganglia are subcortical structures located at the base of the forebrain. They are comprised of the caudate and putamen, which both make up the striatum, as well as the globus pallidus, substantia nigra, and subthalamic nucleus. 'Basal Ganglia' by Casey Henley is licensed under a CC BY-NC-SA 4.0 International License.

Basal Ganglia Input

The majority of information processed by the basal ganglia enters through the striatum. The principal source of input to the basal ganglia is from the cerebral cortex. This input is glutamatergic (i.e. uses glutamate as its neurotransmitter) and therefore, excitatory. The substantia nigra is also a region with critical projections to the striatum and is the main source of dopaminergic input. Dopamine plays an important role in basal ganglia function. Parkinson's disease results when dopamine neurons in the substantia nigra degenerate and no longer send appropriate inputs to the striatum. Dopamine projections can have either excitatory or inhibitory effects in the striatum, depending on the type of metabotropic dopamine receptor the striatal neuron expresses. Dopamine action at a neuron that expresses the D1 receptor is excitatory. Dopamine action at a neuron that expresses the D2 receptor is inhibitory.

Basal Ganglia Output

The primary output region of the basal ganglia is the internal segment of the globus pallidus. This region sends inhibitory GABAergic projections to nuclei in the thalamus. This inhibitory output has a tonic, constant firing rate, which allows the basal ganglia output to both increase and decrease depending on the situation. The thalamus then projects back out to the cerebral cortex, primarily to motor areas.

2.6.5: Impact of Disease States and Neural Damage on Motor Control

Learning Objectives

- Describe the general symptoms of the major motor disorders of the nervous system
- Categorize motor disorders based on their underlying neuroantomical or neurochemical mechanisms
- Explain some of the treatments for some of the major disorders

Motor Disorders and Their Neuroanatomical/Neurochemical Mechanisms

Given that motor control involves such an extensive collection of structures and circuits throughout both the central and peripheral nervous systems, it is amazing how well and, often effortlessly, these systems function every second of our lives. However, the comprehensive nature of motor systems also allows for multiple avenues of potential damage or degeneration which can lead to profound consequences in one's ability to move or even survive.

Damage or disease can occur in regions of the forebrain associated with Upper Motor Neurons in the cortex or the basal ganglia, and/or Lower Motor Neuron regions of the medulla or spinal cord. These anatomical distinctions can be critical in the diagnosis and treatment of specific motor disorders.

Multiple Sclerosis

Multiple sclerosis (MS) is a progressive motor disease that attacks neurons in both the central and peripheral nervous systems. The main mode of this attack is the destruction of the myelin coating around the axon which ultimately will slow down action potential conductance. As axons are demyelinated, inflammatory patches called lesions are formed. As the disease progresses, the myelin-producing oligodendrocytes and, ultimately, the axons themselves are destroyed. There is compelling evidence that the destruction is caused by selective activation of the cellular immune system and inflammatory molecules, thus supporting the idea that MS is an autoimmune disease.

Findings from MRI studies indicate that an individual with MS may have abnormalities around sites like the lateral ventricle, optic nerve, brainstem, spinal cord, cerebellum and other areas (see Figure $2.6.5.1$ below).

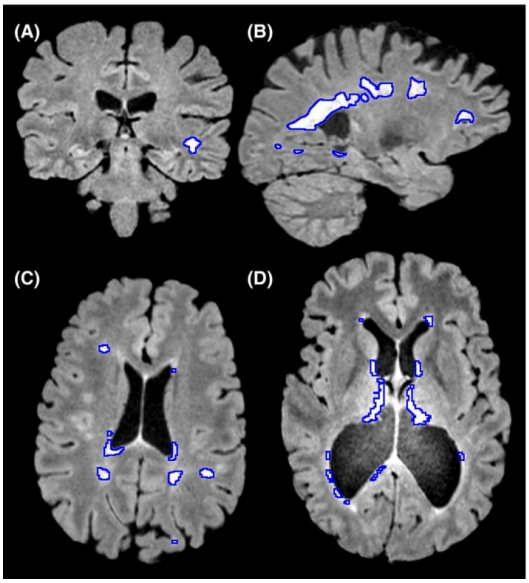

Figure 2.6.5.1: MRI images showing white hyperintensities in different areas of the brain of an individual experiencing symptoms of multiple sclerosis. (A) A coronal slice showing a lesion in peripheral white matter. (B) A sagittal slice showing large periventricular lesions. (C) An axial slice showing both periventricular and peripheral white matter lesions. (D) A case where severe atrophy caused midline false positives to not be removed, as they were further from midline than expected. Image from National Library of Medicine. License: CC BY 4.0.

Symptoms of MS

Multiple sclerosis also presents itself differently in acute and chronic phases. During the acute phase, the condition is associated with intermittent symptoms, whereas the chronic phase is associated with progressive forms of the disease and increased severity of symptoms.

Most people experience their first symptoms of MS between the ages of 20 and 40 with initial blurred or double vision, red-green color distortion, or even blindness in one eye. Most MS patients also experience muscle weakness in their extremities and difficulty with coordination and balance. These symptoms may be severe enough to impair walking or even standing. In the worst cases, MS can produce partial or complete paralysis.

Most people with MS also exhibit paresthesias, transitory abnormal sensory feelings such as numbness, prickling, or "pins and needles" sensations. Some may also experience pain. Speech impediments, tremors, and dizziness are other frequent complaints. Occasionally, people with MS have hearing loss. Approximately half of all people with MS experience cognitive impairments such as difficulties with concentration, attention, memory, and poor judgment, but such symptoms are usually mild and are frequently overlooked. Depression is another common feature of MS.

Potential Causes of MS

Currently, there is no known cause for MS although many different hypotheses have been put forward. Surprisingly, there are no known associative genes that have been implicated in causing MS, and scientists believe there might be a complex interaction between genes and environmental factors that produce demyelination. The most common theories about the cause(s) of multiple sclerosis include:

1. Viral infection resulting in an autoimmune reaction
2. Genetic factors: inherited predisposition possibly through the immune system, although a mutation in a gene has not been discovered
3. Environmental factor(s) which might work with genetics such as low vitamin D levels or smoking.

Although this is a well-characterized disorder, we still don't know much about its causes.

Parkinson's Disease

Parkinson's disease (PD) belongs to a group of conditions called motor system disorders, which cause unintended or uncontrollable movements of the body. The precise cause of PD is unknown, but some cases are hereditary while others are thought to occur from a combination of genetics and environmental factors that trigger the disease. In PD, brain cells become damaged or die in the substantia nigra which produces the neurotransmitter dopamine--a chemical needed to produce smooth, purposeful movement.

Symptoms of PD

The four primary symptoms of PD are:

- tremor--shaking that has a characteristic rhythmic back and forth motion
- rigidity--muscle stiffness or a resistance to movement, where muscles remain constantly tense and contracted
- bradykinesia--slowing of spontaneous and automatic movement that can make it difficult to perform simple tasks or rapidly perform routine movements
- postural instability--impaired balance and changes in posture that can increase the risk of falls.

Other symptoms may include difficulty swallowing, chewing, or speaking; emotional changes; urinary problems or constipation; dementia or other cognitive problems; fatigue; and problems sleeping.

PD usually affects people around the age of 70 years but can occur earlier. PD affects men more than women. Currently there are no specific tests that diagnose sporadic PD.

Potential causes of PD

The current model for most neurodegenerative conditions is that neurons die via apoptosis, a programmed form of cell death. Although this type of cell death occurs during normal development, neurodegenerative diseases such as Parkinson's Disease and Alzheimer's Disease are believed to use apoptotic pathways. This suggests that there is a component protein that is aberrantly folded to produce apoptosis. This has very important clinical implications as turning on or turning off specific genes/proteins is a method to stop or possibly reverse neurodegeneration.

Most cases of this disorder appear to be sporadic (i.e. non-genetic in origin) although a very few cases seem to have a genetic origin. Parkinson's Disease is most often associated with the loss of "pigmented" nuclei in the brain and typically involves the loss of a group of neurons found in the substantia nigra (see Figure 2.6.5.2). The substantia nigra neurons are dopaminergic and are pigmented because they contain the protein *melanin*.

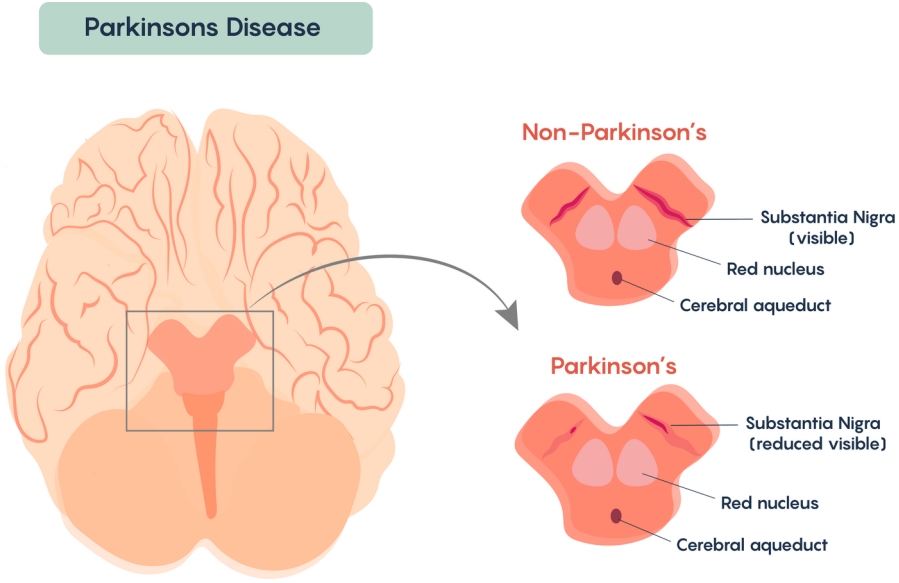

Figure 2.6.5.2: Loss of the pigmented dopaminergic neurons within the Substantia Nigra of individuals with Parkinson's Disease.

Loss of the substantia nigra cells affects the processing and execution of voluntary movement in individuals with Parkinson's Disease. Similar to MS, once diagnosed, the symptoms become continuous and progressive – i.e. the symptoms worsen over time. Again, there are many similarities with MS, and there is no known cure for Parkinson's Disease. The disease remains idiopathic although there are some known causes of Parkinson's Disease including loss of movement following cerebral atherosclerosis, viral encephalitis, and as the result of side effects from drugs such as phenothiazides and reserpine.

Alpha-synuclein is a naturally occurring protein within neurons. Mutations in the PARK1 and PARK4 genes which normally encodes for alpha-synuclein have been associated with Parkinson's Disease. As such, many animal models of Parkinson's Disease look for the production of the fibrillary form of alpha-synuclein as it misfolds and then accumulates within the substantia nigral neurons known as Lewy bodies (see Figure 2.6.5.3). The misfolding and accumulation of alpha-synuclein has been hypothesized to be the reason that neurons undergo apoptosis, although the exact mechanism for how this occurs remains to be elucidated.

Lewy bodies and alpha-synuclein – hallmark features of Parkinson's Disease

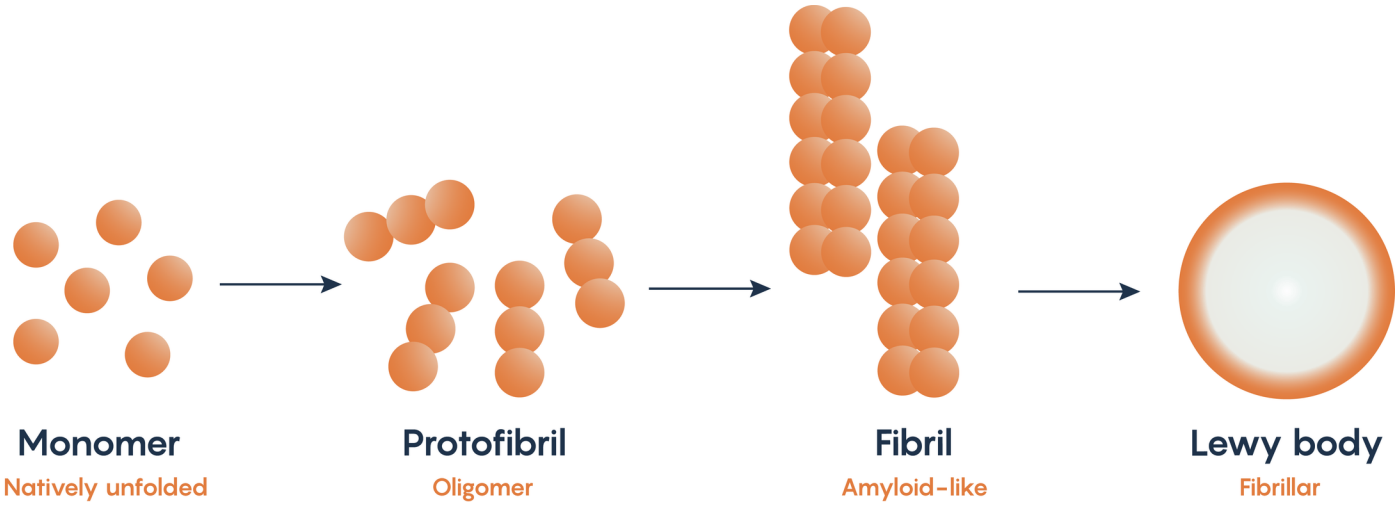

Figure 2.6.5.3:*Misfolding and subsequent accumulation of alpha-synuclein.*

Treatment of PD

At present, there is no cure for PD, but a variety of medications provide dramatic relief from the symptoms. Usually, affected individuals are given levodopa (l-dopa) combined with carbidopa. Carbidopa delays the conversion of levodopa into dopamine until it reaches the brain. Nerve cells can use levodopa to make dopamine and replenish the brain's dwindling supply. Although levodopa helps most people with PD, not everyone responds equally to the drug. The symptoms of bradykinesia and rigidity respond best, while tremor may be only marginally reduced. Problems with balance and other symptoms may not be alleviated at all.

There are a large variety of other drugs that affect the dopamine system and treat symptoms of PD. Some mimic the role of dopamine in the brain, causing the nerve cells to react as they would to dopamine, while others prolong the effects of levodopa by preventing the breakdown of dopamine in the brain. In addition to these dopaminergic drugs, anticholinergic drugs have been shown to help control symptoms of tremor and rigidity.

In some cases, surgery may be appropriate if the disease doesn't respond to drugs. One option is deep brain stimulation (DBS), in which electrodes are implanted into the brain and connected to a small electrical device called a pulse generator to painlessly stimulate the brain to block signals that cause many of the motor symptoms of PD. DBS is generally appropriate for people with levodopa-responsive PD who have developed dyskinesias or other disabling "off" symptoms despite drug therapy. However, DBS does not stop PD from progressing and some problems may gradually return.

Huntingtons Disease

Huntington's disease (HD) is an inherited disorder which causes the death of select populations of neurons. The affected neurons are located in various areas of the brain, including those in the basal ganglia which help to control voluntary (intentional)

movement.

Symptoms of HD

Symptoms of the disease, which gets progressively worse, include uncontrolled movements (chorea), abnormal body postures, and changes in behavior, emotion, judgment, and cognition. People with HD also develop impaired coordination, slurred speech, and difficulty feeding and swallowing.

HD typically begins between ages 30 and 50. An earlier onset form called juvenile HD occurs under age 20. Its symptoms differ somewhat from adult onset HD and include rigidity, slowness, difficulty at school, rapid involuntary muscle jerks called myoclonus, and seizures. More than 30,000 Americans have HD.

Huntington's disease causes disability that gets worse over time. Currently no treatment is available to slow, stop, or reverse the course of HD. People with HD usually die within 10 to 30 years following symptom onset, most commonly from infections (most often pneumonia) and injuries related to falls.

Causes of HD

Huntington's disease is caused by a mutation in the gene for a protein called huntingtin. The mutated gene includes an increased number of repeats of a select portion of it's normal genetic code. How these increased repeats lead to the disorder is still unclear. Each child of a parent with HD has a 50-50 chance of inheriting the mutated gene. A child who does not inherit the HD gene will not develop the disease and cannot pass it to subsequent generations. Since this is an autosomal dominant trait, a person who inherits the HD gene will eventually develop the disease. HD is generally diagnosed based on a genetic test, medical history, brain imaging, and neurological and laboratory tests.

Treatment of HD

There is no treatment that can stop or reverse the course of HD. The drugs, tetrabenazine and deuterabenazine can treat chorea associated with HD. Antipsychotic drugs may ease chorea and help to control hallucinations, delusions, and violent outbursts. Drugs may be prescribed to treat depression and anxiety. Side effects of drugs used to treat the symptoms of HD may include fatigue, sedation, decreased concentration, restlessness, or hyperexcitability, and should only be used when symptoms create problems for the individual.

Amyotrophic lateral sclerosis (Formally known as Lou Gehrig's Disease)

Amyotrophic lateral sclerosis (ALS) is a rare neurological disease that primarily affects the neurons responsible for controlling voluntary muscle movement. Voluntary muscles produce movements like chewing, walking, and talking. The disease is progressive, meaning the symptoms get worse over time. Currently, there is no cure for ALS and no effective treatment to halt or reverse the progression of the disease.

ALS belongs to a wider group of disorders known as motor neuron diseases, which are caused by gradual deterioration (degeneration) and death of motor neurons. As motor neurons degenerate, they stop sending messages to the muscles and the muscles gradually weaken, start to twitch, and waste away (atrophy). Eventually, the brain loses its ability to initiate and control voluntary movements.

Early symptoms of ALS usually include muscle weakness or stiffness. Gradually all voluntary muscles are affected, and individuals lose their strength and the ability to speak, eat, move, and even breathe. Most people with ALS die from respiratory failure, usually within three to five years from when the symptoms first appear. However, about 10 percent of people with ALS survive for 10 or more years.

Because people with ALS usually can perform higher mental processes such as reasoning, remembering, understanding, and problem solving, they are aware of their progressive loss of function and may become anxious and depressed. A small percentage of individuals may experience problems with language or decision-making, and there is growing evidence that some may even develop a form of dementia over time.

Possible Causes of ALS

The cause of ALS is not known, and scientists do not yet know why ALS strikes some people and not others.

Motor neuronal hyperexcitability potentially contributes to motor neuron death in ALS. Many previous studies support this hypothesis, including clinical trials of riluzole, a glutamate antagonist that delays ALS progression (Miller et al., 2012).

In addition to the possible role of motor neuron dysfunction, scientific evidence suggests that both genetics and environment play a role in motor neuron degeneration and the development of ALS.

In 1993, scientists supported by the National Institute of Neurological Disorders and Stroke (NINDS) discovered that mutations in the *SOD1* gene were associated with some cases of familial ALS. Since then, more than a dozen additional genetic mutations have been identified, many through NINDS-supported research.

Research on certain gene mutations suggests that changes in the processing of RNA molecules may lead to ALS-related motor neuron degeneration. RNA molecules are involved with the production of molecules in the cell and with gene activity.

Other gene mutations indicate there may be defects in protein recycling—a naturally occurring process in which malfunctioning proteins are broken down and used to build new working ones. Still others point to possible defects in the structure and shape of motor neurons, as well as increased susceptibility to environmental toxins.

Researchers are studying the impact of environmental factors, such as exposure to toxic or infectious agents, viruses, physical trauma, diet, and behavioral and occupational factors. For example, exposure to toxins during warfare, or strenuous physical activity, are possible reasons for why some veterans and athletes may be at increased risk of developing ALS. Ongoing research may show that some factors are involved in the development or progression of the disease.

2.7: Psychophysical Methods

Learning Objectives

Differentiate between experiments measuring absolute thresholds, difference thresholds, and magnitude estimations

Describe at least two different methods of estimating a threshold

Understand what a subliminal message is

Explain Weber's law (also called Weber-Fechner law)

Brief Overview

Psychophysics *quantitatively investigates the relationship between physical stimuli and the sensations and perceptions they produce. Psychophysics has been described as the scientific study of the relation between stimulus and sensation or, more completely, as the analysis of perceptual processes by studying the effect on a subject's experience or behaviour of systematically varying the properties of a stimulus along one or more physical dimensions.*

The sensitivity of a given sensory system to the relevant stimuli can be expressed as an **absolute threshold**. **Absolute threshold** refers to the minimum amount of stimulus energy that must be present for the stimulus to be detected 50% of the time. Another way to think about this is by considering how dim a light can be or how soft a sound can be and still be detected half of the time. The sensitivity of our sensory receptors can be quite amazing. It has been estimated that on a clear night, the rods (sensitive sensory cells in the back of the eye) can detect a candle flame 30 miles away (Okawa & Sampath, 2007). Under quiet conditions, the hair cells (receptor cells of the inner ear) can detect the tick of a clock 20 feet away (Galanter, 1962) see figure 8.4.1 below.

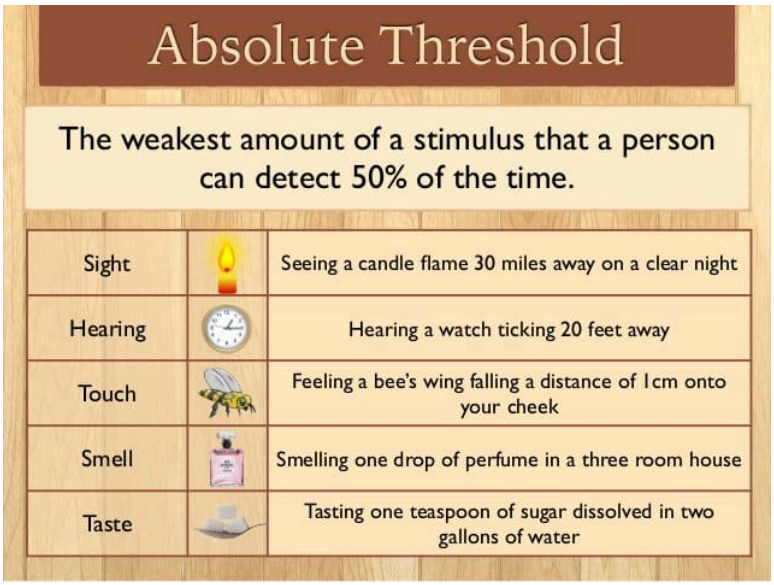

Fig 8.2.1 https://twitter.com/AP_Psychology/status/1094976965004705792/photo/1

It is also possible for us to get messages that are presented below the threshold for conscious awareness—these are called **subliminal messages**. A message below the absolute threshold is not strong enough to excite sensory receptors that send nerve impulses to the brain; when this occurs that threshold is said to be subliminal: We receive it, but we are not consciously aware of it. Over the years there has been a great deal of speculation about the use of **subliminal messages** in advertising, rock music, and self-help audio programs. Research evidence shows that in laboratory settings, people can process and respond to information outside of awareness. But this does not mean that we obey these messages or are heavily influenced by these messages; in fact, hidden messages have little effect on behavior outside the laboratory (Kunst-Wilson & Zajonc, 1980; Rensink, 2004; Nelson,

2008; Radel, Sarrazin, Legrain, & Gobancé, 2009; Loersch, Durso, & Petty, 2013).

Methods for estimating thresholds

When we design experiments, we have to decide how we're going to approach a **threshold estimation**. Here are three common techniques:

- **Method of Limits**. The experimenter can increase the stimulus intensity (or intensity difference) until the observer detects the stimulus (or the change). For example, turn up the volume until the observer first detects the sound. This is intuitive, but it is also subject to bias — the estimated threshold is likely to be different, for example, if we start high and work down versus starting low and working up.
- **Method of Adjustment.** This is very much like the Method of Limits, except that the experimenter gives the observer control of the stimulus adjustment with the instructions to: "adjust the stimulus until it's clearly visible" or "adjust the color of the patch until it matches the test patch."
- **Method of Constant Stimuli**. This is the most reliable, but also the most time-consuming. You decide ahead of time what levels you are going to measure, do each one a fixed number of times, and record percent correct (or the number of detections) for each level. If you randomize the order, you can get rid of bias.

Absolute thresholds are generally measured under rigidly controlled conditions in situations that are optimal for sensitivity. Sometimes we are more interested in how much difference in stimuli is required to detect a difference between them. This is known as the **just noticeable difference** (jnd) or **difference threshold**. Unlike the **absolute threshold**, the **difference threshold** changes depending on the stimulus intensity. As an example, imagine yourself in a very dark movie theater. If an audience member were to receive a text message on their cell phone which caused their screen to light up, chances are that many people would notice the change in illumination in the theater. However, if the same thing happened in a brightly lit arena during a basketball game, very few people would notice. The cell phone brightness does not change, but its ability to be detected as a change in illumination varies dramatically between the two contexts. **Ernst Weber** proposed this theory of change in **difference threshold** in the 1830s, and it has become known as **Weber's law**.

Weber's law is approximately true for many aspects of our senses — for brightness perception, visual contrast perception, loudness perception, and visual distance estimation, our sensitivity to change decreases as the stimulus gets bigger or stronger. However, there are many senses for which the opposite is true: our sensitivity increases as the stimulus increases. With electric shock, for example, a small increase in the size of the shock is much more noticeable when the shock is large than when it is small. A psychophysical researcher named **Stanley Smith Stevens** asked people to estimate the magnitude of their sensations for many different kinds of stimuli at different intensities, and then tried to fit lines through the data to predict people's sensory experiences (Stevens, 1967). What he discovered was that most senses could be described by a power law of the form $\mathbf{P \propto S^n}$ (where P is the perceived magnitude, $\propto$ means "is proportional to", S is the physical stimulus magnitude, and n is a positive number). If n is greater than 1, then the slope (rate of change of perception) is getting larger as the stimulus gets larger, and sensitivity increases as stimulus intensity increases. A function like this is described as being expansive or supra-linear. If n is less than 1, then the slope decreases as the stimulus gets larger (the function "rolls over"). These sensations are described as being compressive. **Weber's Law** is only (approximately) true for compressive (sublinear) functions; **Stevens' Power Law** is useful for describing a wider range of senses see Fig 8.4.2 below.

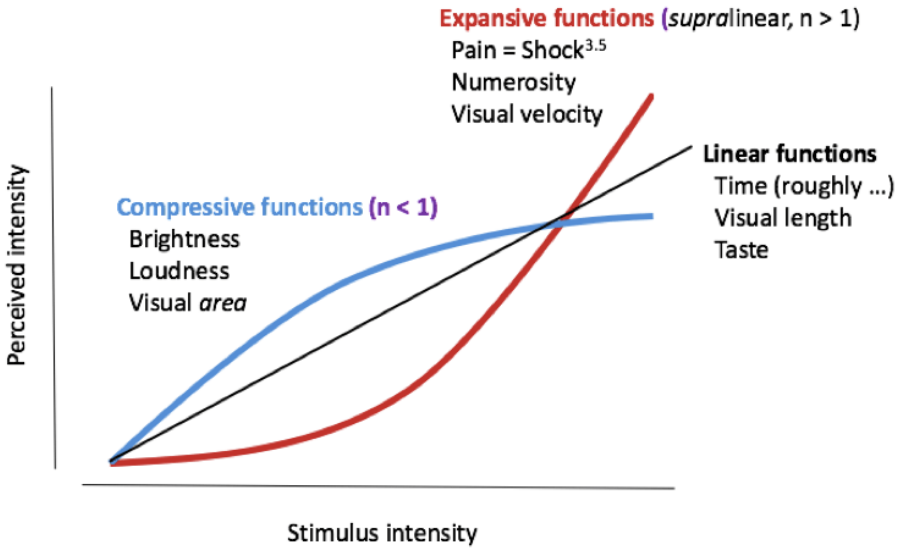

Fig 8.2.2 Different sensory systems exhibit different relationships between perceived magnitude and stimulus intensity. Sometimes, it makes the most sense to discount or ignore increases in stimulus intensity above a certain point; compressive sensory modalities with a power-law exponent less than 1 accomplish this. Other times, we need heightened sensitivity to stimuli with increased intensity; expansive sensory modalities, described by a power law with exponent greater than 1, accomplish this. Not all perception is non-linear, however; some senses are best described by a linear relationship between stimulus and perception.

Both **Stevens' Power Law** and **Weber's Law** are only approximately true. They are useful for describing, in broad strokes, how our perception of a stimulus depends on its intensity or size. They are rarely accurate for describing perception of stimuli that are near the absolute detection threshold. Still, they are useful for describing how people will expectably react to normal everyday stimuli.

Sensation and Perception Summary:

The world as we experience it is most often multimodal, involving combinations of our senses into one perceptual experience. The combination of senses that allow us to enjoy aspects of our everyday life requires our senses to be integrated. Interestingly, we actually respond more strongly to multimodal stimuli compared to the sum of each single modality together, an effect called the ***superadditive effect of multisensory integration****. This can explain how you're still able to understand what friends are saying to you at a loud concert, as long as you are able to get visual cues from watching them speak. If you were having a quiet conversation at a café, you likely wouldn't need these additional cues. Because we are able to process multimodal sensory stimuli, and the results of those processes are qualitatively different from those of unimodal stimuli, it's a fair assumption that the brain is doing something qualitatively different when they're being processed. There has been a growing body of evidence since the mid-1990's on the neural correlates of* ***multisensory integration****.*

2.8: Sensation vs Perception

Learning Objectives

- Distinguish between sensation and perception
- Distinguish between top-down and bottom-up contributions to perception
- Describe key principles, such as transduction and sensory adaptation

Brief Overview:

The topics of sensation and perception are among the oldest and most important in all of psychology. People are equipped with senses such as sight, hearing and taste that help us to take in the world around us. Amazingly, our senses have the ability to convert real-world information into electrical information that can be processed by the brain. The way we interpret this information-- our perceptions-- is what leads to our experiences of the world. In this module, you will learn about the biological processes of sensation and perceptions as well as key differences between these two processes.

Sensation and perception are often intertwined, however, there are important distinctions between the two. The *physical* process during which our sensory organs—those involved with vision and hearing, for example—respond to external stimuli is called **sensation**. Sensation happens when you taste noodles or feel the wind on your face or hear a car horn honking in the distance. During sensation, our sense organs are engaging in **transduction**, the conversion of one form of energy into another. Physical energy such as light or sound is converted into a form of energy the brain can understand: electrical stimulation (i.e. action potentials). After our brain receives the electrical signals, we make sense of all this stimulation and begin to appreciate the complex world around us. This *psychological* process—making sense of the stimuli—is called **perception**. It is during this process that you are able to *identify* a gas leak in your home or a song that reminds you of a specific afternoon spent with friends.

While our sensory receptors are constantly collecting information from the environment, it is ultimately how we interpret that information that affects how we interact with the world. Perception involves both bottom-up and top-down processing. Bottom-up processing refers to the fact that perceptions are built from sensory input, your eyes are not the only way to use bottom-up processing. Imagine you are in the forest walking and you are admiring the trees and nature around. As you continue to walk you hear crackling noises and you begin to smell burning wood. As you continue walking you hear people talking and the crackling and smell of burning wood becomes stronger, at some point you may realize you are entering campgrounds, you can't see the campgrounds but bottom-up processing with the help of your other senses tells you what is going on.

On the other hand, how we interpret those sensations is influenced by our available knowledge, our experiences, and our thoughts. This is called top-down processing. One way to illustrate these two concepts is with our ability to read. Read the following quote pictured in Figure 8.1.1 out loud:

Figure 8.1.1 An example of stimuli processing.

Did you notice anything odd while you were reading the text in the triangle? Did you notice the second “the”? If not, it’s likely because you were reading this from a top-down approach. Having a second “the” doesn’t make sense. We know this. Our brain knows this and doesn’t *expect* there to be a second one, so we have a tendency to skip right over it. In other words, your past experience has changed the way you perceive the writing in the triangle! A beginning reader—one who is using a bottom-up approach by carefully attending to each piece—would be less likely to make this error. The above demonstration illustrates how our experiences can influence the way our brain processes sensory information.

Another way to distinguish between perception and sensation is that sensation is a physical process, whereas perception is psychological. For example, upon walking into a kitchen and smelling the scent of baking cinnamon rolls, the sensation is the scent receptors detecting the odor of cinnamon, but the perception may be “Mmm, this smells like the bread Grandma used to bake when the family gathered for holidays.” Although our perceptions are built from sensations, not all sensations result in perception. In fact, we often don’t perceive stimuli that remain relatively constant over prolonged periods of time, which is known as **sensory adaptation.** Imagine entering a classroom with an old analog clock. Upon first entering the room, you can hear the ticking of the clock; as you begin to engage in conversation with classmates or listen to your professor greet the class, you are no longer aware of the ticking. The clock is still ticking, and that information is still affecting sensory receptors of the auditory system. The fact that you no longer perceive the sound demonstrates sensory adaptation and shows that while closely associated, sensation and perception are different.

When we experience a sensory stimulus that doesn’t change, we stop paying attention to it. This is why we don’t feel the weight of our clothing, hear the hum of a projector in a lecture hall, or see all the tiny scratches on the lenses of our glasses. Thus, when a stimulus is constant and unchanging, we experience sensory adaptation. This occurs because if a stimulus does not change, our brain quits responding to it. A great example of this occurs when we leave the radio on in our car after we park it at home for the night. When we listen to the radio on our way home, the volume seems reasonable. However, the next morning when we start the car, we might be startled by how loud the radio is. We don’t remember it being that loud last night. What happened? We adapted to the constant stimulus (the radio volume) over the course of the previous day and increased the volume at various times.

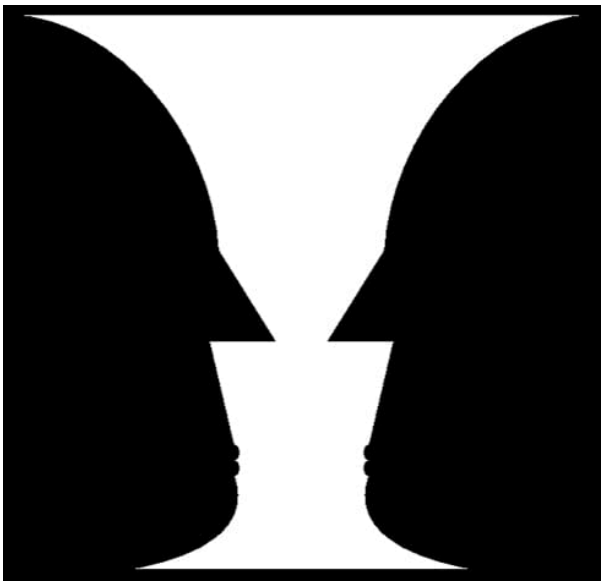
2.9: Gestalt Principles of Perception

Gestalt Principles

Learning Objectives

- Explain the figure-ground relationship
- Define Gestalt principles of grouping
- Describe how perceptual set is influenced by an individual's characteristics and mental state
- Understand the influence stereotypes or prejudice can have on perceptual bias

Brief Overview

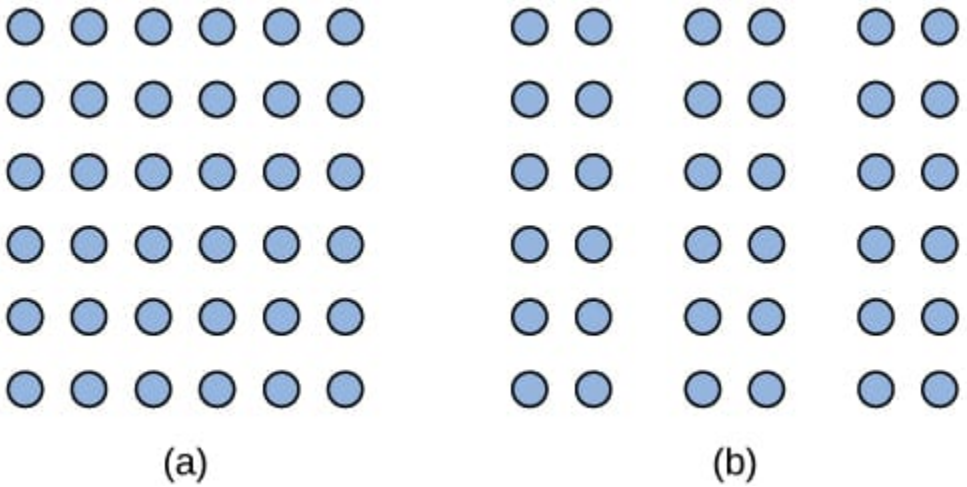


Gestalt theorists have been incredibly influential in the areas of sensation and perception. Gestalt principles such as figure-ground relationship, grouping by proximity or similarity, the law of good continuation, and closure are all used to help explain how we organize sensory information. Our perceptions are not infallible, and they can be influenced by bias, prejudice, and other factors.

Gestalt Psychology

In the early part of the 20th century, Max Wertheimer published a paper demonstrating that individuals perceived motion in rapidly flickering static images. Research conducted by Wertheimer and his colleagues proposed that perception involved more than simply combining sensory stimuli and led to a new field of psychology known as **Gestalt psychology**. The word **gestalt** literally means form or pattern, but its use reflects the idea that the whole is different from the sum of its parts. In other words, the brain creates a perception that is more than simply the sum of available sensory inputs, and it does so in predictable ways. Gestalt psychologists translated these predictable ways into principles by which we organize sensory information. As a result, Gestalt psychology has been extremely influential in the area of sensation and perception (Rock & Palmer, 1990).

Figure-ground relationship

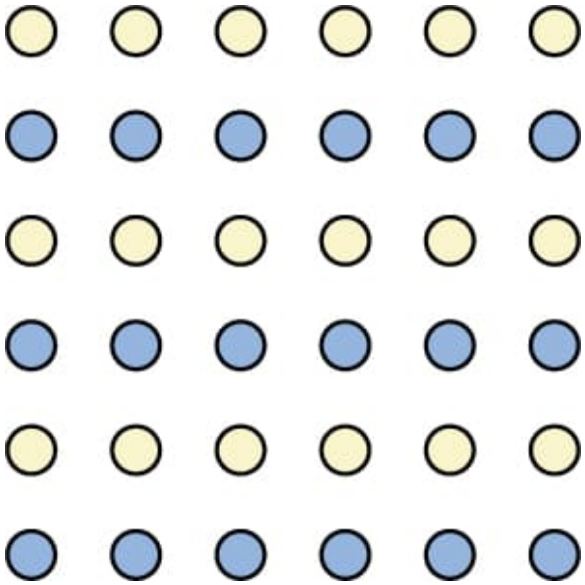


One Gestalt principle is the **figure-ground relationship**. According to this principle, we tend to segment our visual world into figure and ground. Figure is the object or person that is the focus of the visual field, while the ground is the background. As the figure below shows, our perception can vary tremendously, depending on what is perceived as figure and what is perceived as ground. Presumably, our ability to interpret sensory information depends on what we label as figure and what we label as ground in any particular case, although this assumption has been called into question (Peterson & Gibson, 1994; Vecera & O'Reilly, 1998). See figure 8.2.1 below.

8.4.1 The concept of figure-ground relationship explains why this image can be perceived either as a vase or as a pair of faces.

Principle of proximity

Another Gestalt principle for organizing sensory stimuli into meaningful perception is **proximity**. This principle asserts that things that are close to one another tend to be grouped together, as figure 8.2.2 below demonstrates.



8.4.2 The Gestalt principle of proximity suggests that you see (a) one block of dots on the left side and (b) three columns on the right side.

How we read something provides another illustration of the **proximity concept**. For example, we read this sentence like this, notl iket hiso rt hat. We group the letters of a given word together because there are no spaces between the letters, and we perceive words because there are spaces between each word. Here are some more examples: Cany oum akes enseo ft hiss entence? What doth es e wor dsmea n?

Principle of similarity

We also often use the **principle of similarity** to group things in our visual fields. According to this principle, things that are alike tend to be grouped together as Figure 8.2.3 below illustrates.

8.4.3 When looking at this array of dots, we likely perceive alternating rows of colors. We are grouping these dots according to the principle of similarity.

Another example is when watching an American football game, we tend to group individuals based on the colors of their uniforms. While watching an offensive drive (a series of plays which help the offense score), we can get a sense of the two teams simply by grouping along this dimension. Two additional Gestalt principles are the **law of continuity** (or good continuation) and the **principle of closure**.

Law of continuity

The **law of continuity** suggests that we are more likely to perceive continuous, smooth flowing lines rather than jagged, broken lines as illustrated in the figure below.

parts (Fig 8.2.4)

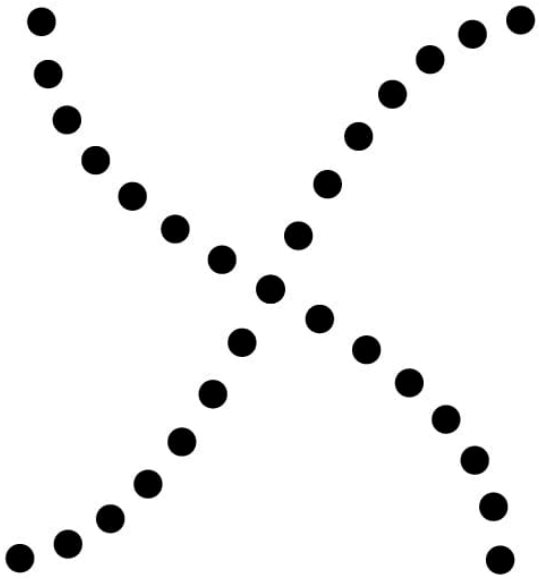


Fig 8.4.4 Good continuation would suggest that we are more likely to perceive this as two overlapping lines, rather than four lines meeting in the center.

Principle of closure

The **principle of closure** states that we organize our perceptions into complete objects rather than as a series of parts as illustrated in Fig 8.2.5

Fig 8.4.5 Closure suggests that we will perceive a complete circle and rectangle rather than a series of segments.

Pattern perception

According to Gestalt theorists, **pattern perception**, or our ability to discriminate among different figures and shapes, occurs by following the principles described above. You probably feel fairly certain that your perception accurately matches the real world, but this is not always the case. Our perceptions are based on **perceptual hypotheses**: educated guesses that we make while interpreting sensory information. These hypotheses are informed by a number of factors, including our personalities, experiences, and expectations. We use these hypotheses to generate our perceptual set. For instance, research has demonstrated that those who are given verbal priming produce a biased interpretation of complex ambiguous figures (Goolkasian & Woodbury, 2010).

Aspects of Bias, Prejudice, and Cultural Factors

In this chapter, you have learned that perception is a complex process. Built from sensations, but influenced by our own experiences, biases, prejudices, and cultures, perceptions can be very different from person to person. Research suggests that implicit racial prejudice and stereotypes affect perception. For instance, several studies have demonstrated that non-Black participants identify weapons faster and are more likely to identify non-weapons as weapons when the image of the weapon is paired with the image of a Black person (Payne, 2001; Payne, Shimizu, & Jacoby, 2005). Furthermore, White individuals' decisions to shoot an armed target in a video game is made more quickly when the target is Black (Correll, Park, Judd, & Wittenbrink, 2002; Correll, Urland, & Ito, 2006). This research is important, considering the number of very high-profile cases in the last few decades in which young Blacks were killed by people who claimed to believe that the unarmed individuals were armed and/or represented some threat to their personal safety. In the article *Stereotypes and Prejudice in the Perception of the "Other"* (Fedor, 2014), it is argued that **otherness** (that which is other than the concept being considered; often it means a person other than oneself) can lead to problematic interpersonal communication that often becomes permanent and may result in the prevention of community collaboration and development. The full article can be found here, https://www.sciencedirect.com/science/article/pii/S1877042814049702.

Do you typically wake up a few minutes before your alarm clock goes off? Do you get really sleepy in your classes that occur after lunch? On weekends, when you can set your own schedule, are you sleeping 2-3 hours later than on days when you work or go to class? When you fly somewhere on vacation do you experience jet lag? Each of these scenarios reflects how your internal biological clock is responding to timing cues in the environment. From a clinical standpoint, it is only recently that these daily circadian clocks have been considered important endpoints of relevance for both medical conditions as well as human

performance and efficiency. The study of circadian clocks has changed how airline flight crews are scheduled and how nursing shifts are organized. Even professional sports have been impacted by the consequences of biological clock disruptions. Across several professional sports in the U.S., teams traveling westward across time zones are at a significant disadvantage in away games as compared to those traveling eastward (Roy and Forest, 2018). Many studies have also found that high school students perform better when school start times are moved later to better match adolescent's biological clocks. When you consider all the myriad ways that humans can become out of synchrony with the standard day/night cycle, it is easy to understand how such disruptions could have a major impact on society. In this chapter, we will address these questions by exploring the field of Chronobiology, which studies biological clocks and biological rhythms within an organism.

Predictable rhythms exist in nearly every organism on the planet from bacteria to mammals. You have rhythms in your body that range from cycles of gene transcription, to hormone surges, to patterns of fatigue and alertness. The regulation of these rhythms and the coordination between different rhythms in an organism is managed by a "master clock" contained within a subset of cells within the hypothalamus of the brain. This master clock communicates with other brain areas which regulate your sleep stages.

Biological rhythms are critical in health and treatment of disease and disruption of these rhythms can be associated with an increase in cancers, diabetes, obesity, and heart disease. For example, people who participate in shift work such as police officers, medical personnel or those working a night shift in a factory often experience disrupted rhythms, making them particularly vulnerable to some diseases. On the other hand, knowledge of biological rhythms can lead to improvements in disease treatment; for example, administering asthma medication at the predictable time of day when symptoms are worst can result in better disease management.

Finally, consideration of the biological rhythms of individuals and its impact on our health has entered our society. You may have heard news stories about people who support, and are against, daylight savings time, or discussions of how school start times do not match appropriate sleep schedules for children. Disruption of normal sleep cycles can result in chronic sleep deprivation, which can have long term consequences for health.

3.1.2: What Are Circadian Rhythms?

Learning Objectives

By the end of this section, you should be able to

- 15.1.1 Name and define different biological rhythms.
- 15.1.2 Draw and label the components of a circadian rhythm.
- 15.1.3 Draw and label the components of a phase response curve.

Neuroscience Across Species: Why Are Rhythms Important?

The earth orbits the sun with a period of about 365 days and rotates on its axis every 24 hours. These rotations create a cyclical and predictable environment including rhythmic changes in light and dark, ambient temperature, and resource availability. Animals, plants, fungus and bacteria evolved during these predictable environments and have adapted their biological systems as a result. Thus, one significant benefit of biological rhythms is to synchronize the biology of an organism to environmental cycles in anticipation of recurring events. For example, organisms can increase their survival by avoiding predation, preparing for hibernation, gathering food, or finding mates when they can anticipate changes in the environment. Mammals increase their metabolism prior to the start of their active period when they eat their first meal of the day, mobilizing energy reserves in anticipation of increased demands on the body. Another example is that the mechanisms responsible for clearing out metabolic by-products from the brain go into high gear when we are sleeping, potentially helping create a neural environment conducive to new learning. Arctic mammals can prepare for a cold winter by reducing their metabolic rate and body temperature and hibernating for a portion of the year, and adult fruit flies emerge from their pupa in a timed manner, about 1-2 hours before dawn, which is the onset of their active period.

Examples of Rhythms

There are many different types of rhythms, with periods ranging in length from seconds to hours to days (Figure 15.2). Neuron electrical action potentials within the brain can occur at the level of milliseconds, neuronal firing rates can show spontaneous 24 hour rhythms, hormone surges such as the morning rise in cortisol can occur every 24 hours, and the reproductive or ovulatory cycle in laboratory rodents occurs every 4-5 days whereas it can occur around every 28 days in humans.

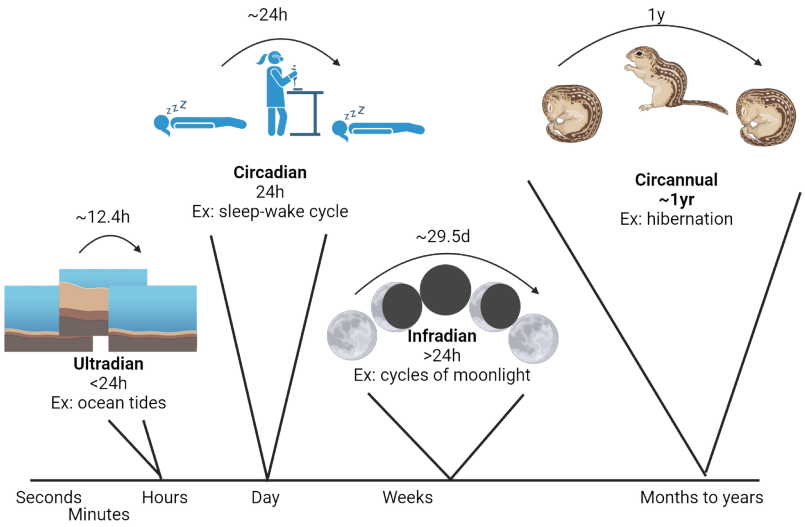

Figure 15.2 Types of rhythms

Circadian rhythms (circa = about, dia = day) describe rhythms with a period of about 24 hours and the best known of these is the daily rhythm of sleeping and wakefulness that many animals experience.

Ultradian rhythms have periods significantly shorter than 24 hours. An example of this would be heart rate, or the occurrence of multiple sleep cycles during the night (see below). Another type of ultradian rhythm are those that follow the cycles of tides; these are called circatidal and occur around every 12.4 hours. Marine organisms such as crabs time their locomotor activity to the occurrence of tides.

Infradian rhythms have periods significantly longer than 24 hours. For example, the reproductive rhythm (menstrual cycle) of women is a type of infradian rhythm. Circalunar rhythms are a type of infradian rhythm that follow the amount of moonlight that is available and last about 29.5 days. Examples of circalunar rhythms are seen in the reproductive cycles of marine animals. Circannual rhythms are another type of infradian rhythms—these are cycles that recur with a period of about 1 year. The onset of hibernation each year in Arctic ground squirrels would be a circannual rhythm.

Qualities of a Rhythm

A rhythm is a repeating event that occurs with a regular pattern (Figure 15.3). We can characterize the features of a rhythm by describing its period or the duration of time it takes one cycle of the rhythm to occur. The phase of a rhythm describes a marker or point in a daily rhythm. A phase could be measured at the peak of a daily rhythm, such as the peak of melatonin secretion, or a trough in a rhythm such as the time when your body temperature is the lowest. A phase relationship or phase difference is the timing of the phase of a rhythm in relation to another daily timing event. For example, we can talk about the phase difference between when you wake up each day (the phase) and the time when your alarm goes off. The mesor of a rhythm is the average level of the rhythm across a full cycle, and the amplitude of a rhythm is the difference between the peak and trough of that rhythm. Frequency describes how often the rhythm occurs within a period of time. For example, pulses of luteinizing hormone secretion might occur at a frequency of 4 per hour Chapter 11 Sexual Behavior and Development.

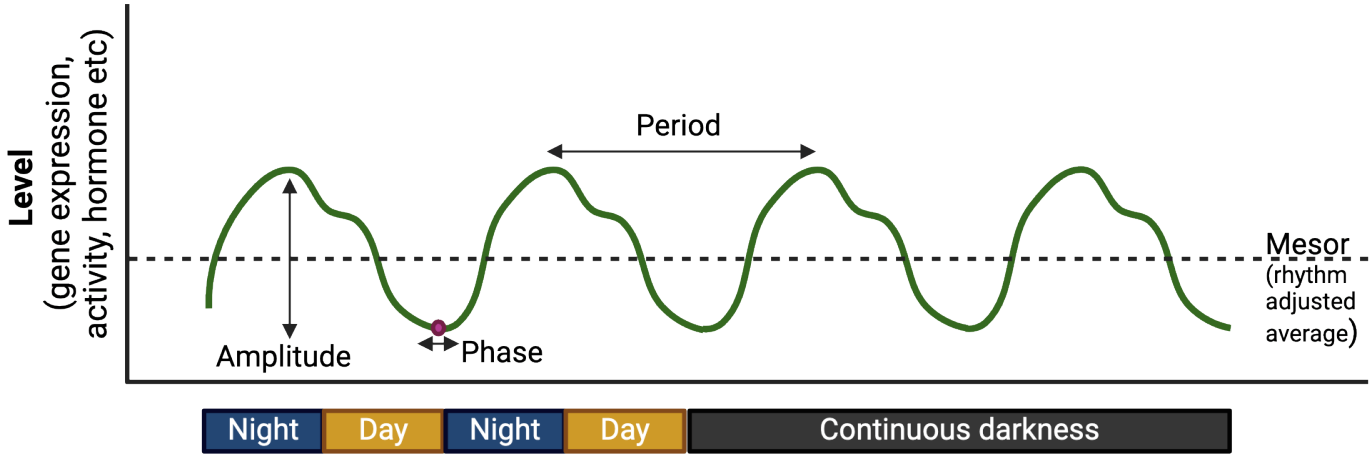

Figure 15.3 Circadian rhythm A biological rhythm has many independent components that can be analyzed.

One fascinating concept about biological rhythms is that they are endogenous, meaning that they are driven by internal physiology rather than being entirely generated by external or exogenous cues. This means that rhythms will continue to be expressed even if the organism is isolated from the environment. For example, a variety of circadian rhythms continue to be expressed, even when the organism is maintained in an environment with constant lighting conditions, which lack any cues as to the time of day. This experiment has been done with numerous species including placing humans in underground apartments, or housing laboratory rodents or fruit flies in constant darkness. These experiments demonstrate that biological rhythms continue to oscillate in a consistent manner, though this rhythm may not perfectly match the solar day or other rhythmic environmental cues such as temperature fluctuations. For example, if you were to live in dim light in a sleep lab for seven days and we measured the time when you woke up each day, we would learn that the period of your daily sleep-wake cycle may run slightly faster or slightly slower than 24 hours. Under these constant conditions the rhythm is described as free-running. Humans can have a free-running period that normally ranges from 23.5 to 24.7 hours. In nocturnal lab rodents, a typical free-running period can range from 23-25 hours long, and in fruit flies population rhythms in emergence from the pupa and individual activity rhythm is about 24.5 hours. Of course, most organisms do not live in environments absent of cues, thus when an organism's internally generated rhythm is synchronized to the rhythms of the external environment we refer to this as entrainment.

Chronotypes

Are you someone who tends to stay up late into the night? A "night owl"? Or perhaps you go to bed early and wake up early? A “lark”? The tendencies of your body towards sleeping at some hours of the day and being more alert at other times of day is called a chronotype. Chronotypes exist on a spectrum and can be influenced by age, gender, and genetics. Chronotype has been linked to health outcomes, mood such as anxiety and depression, and the time of day you are most productive. For example, evening types ("owls") are more likely to have depression, anxiety, obesity, and lower grades compared to morning types ("larks") (van der Merwe, Munch, and Kruger, 2022; Walsh, Repa, and Garland, 2022; Yeo et al., 2023). Individuals with severe morningness or eveningness chronotypes may be diagnosed with conditions such as advanced sleep-wake phase disorder or delayed sleep-wake phase disorder (see 15.4 Disorders of Sleep and Circadian Rhythms).

Your chronotype typically changes across your lifespan. Young children tend towards a morning preference and wake up and go to bed relatively early, whereas after adolescence, teenagers and young adults have difficulties falling asleep before 11 pm and may struggle to wake up for an early morning class or job. The peak in an evening chronotype occurs around age 19 after which the chronotype begins to shift to an earlier time. Thus, older individuals tend to be morning types, and this tendency to be a morning type continues to increase from age 35-80 (Roenneberg et al., 2007). Interestingly, there is also a sex difference in chronotypes, with women typically being earlier (larks) compared to men (Fischer et al., 2017). Some researchers hypothesized that these sex differences could be attributed to circulating hormones. This is supported by the fact that as women age and go through menopause and hormone depletion around the age of 40-50, the sex difference in chronotype goes away.

Although you can adapt your circadian rhythms to new environmental light cycles, such as would occur if you traveled to another time zone, it is difficult to intentionally change a chronotype. However, light therapy, melatonin treatment, and adherence to a sleep schedule (sleep hygiene) can help shift the timing of rhythms. People with an evening chronotype report that shifting their rhythms towards a morning chronotype can reduce depression and stress, improve mood, and improve cognitive performance (Facer-Child et al., 2019).

Neuroscience in the Lab

Photic Phase Response Curve

How does your internal clock adjust your sleep-wake pattern when you fly to a new time zone? How does your body stay entrained to your rhythmic environment without drifting? There are many types of environmental cues that can entrain a biological rhythm including cycling changes in temperature, humidity, food availability, and social cues. However, the strongest entraining cue for most animals is the light:dark cycle driven by the earth’s rotation. In mammals, the biological clock in our brains responds to light cues and helps synchronize it to the external rhythm. If the endogenous clock isn’t in alignment with the 24 hr day/night cycle, the clock needs to be adjusted to bring it back in synchrony with the environment. Both the magnitude of the response and the direction of that response depend upon when the light cue is perceived by the clock. To phrase this another way, your body can respond to light cues and "reset" the clock. However, the degree to which your clock is adjusted depends upon the time when you were exposed to a light cue.

Consider an experiment where we house a laboratory rodent in constant darkness and measure the onset of their daily bout of activity in a running wheel. This wheel running occurs during the animal’s active time of day, thus in this nocturnal animal wheel running would reflect its subjective night. When the rodent is sleeping, it would reflect the subjective day. We use the term “subjective” because it reflects the brain’s internal interpretation of time, not the actual environmental condition experienced. Figure 15.4 shows how we often represent the data from an experiment like this, where a single bar represents a 24h period and light and dark shading within that bar represent periods of low and high activity, which we learn by recording turns of the running wheel.

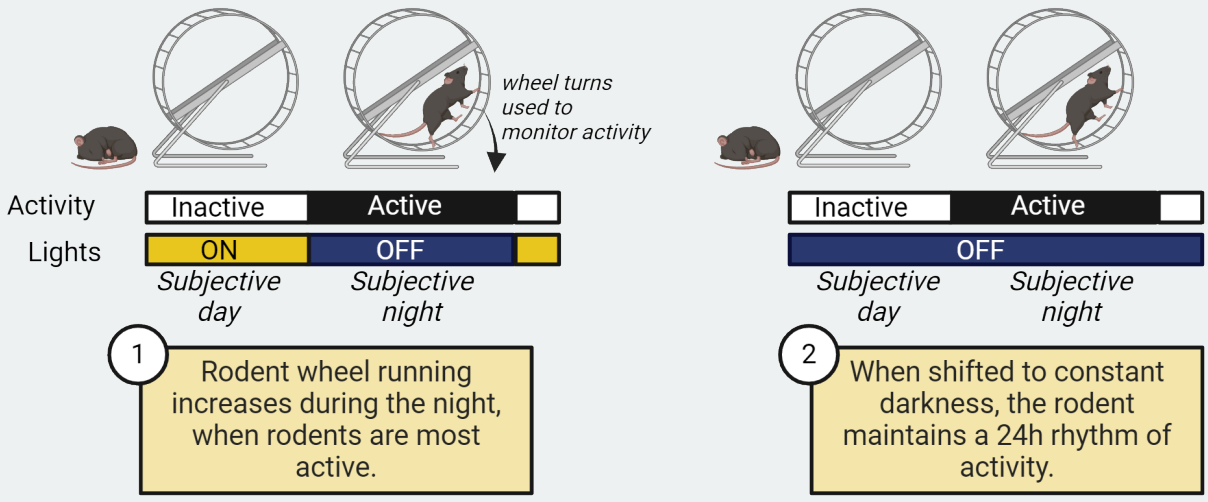

Figure 15.4 Measuring rhythms in rodents

In the lab, we can use rodent activity to study how biological clocks entrain to external cues depending on when they are given. For example, we can expose animals living in constant darkness to a 10-min pulse of light at various times across their subjective day and subjective night. We then measure the effect of that light cue on the timing of the wheel running onset. The observed change from the original activity onset to the new, adjusted onset is called a phase shift. We can plot phase shifts using a phase response curve (Figure 15.5).

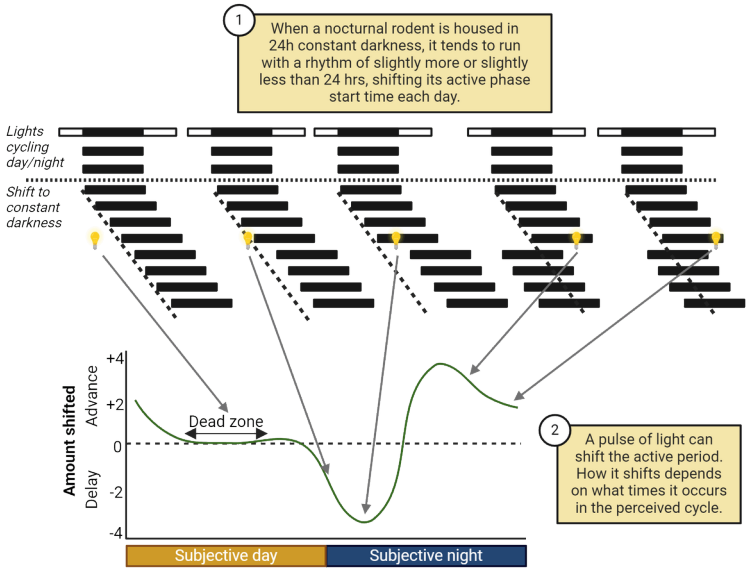

Figure 15.5 Circadian shift

Conventionally, we plot advances (waking up earlier) in the timing of activity as positive numbers and delays (waking up later) as negative numbers, against the time of day when the animals were exposed to the light pulse. By plotting the response to light pulses, we can see there is a pattern in sensitivity to the light cue. Generally speaking, if the animal was given a pulse of light during its subjective day there is little to no change in the onset of the wheel running the next day. This is to be expected because this is the time of day when light would normally be present. This part of the curve is referred to as a dead zone. However, when exposed to light in the early portion of the night, animals have a dramatic shift in the timing of wheel running or activity, such that it is delayed compared to when it was predicted to occur. Conceptually, think of this as the animal's brain interpreting the light as meaning that it is still daytime, the animal got up too early, and therefore tomorrow it should become active at a later time. Conversely, light pulses given in the second half of the evening result in advances in the timing of the wheel running onset (the animal stayed up too late—it should shift its activity to an earlier time). This light sensitivity that varies as a function of the time

of day is a critical function for how biological clocks synchronize to the environment. This same methodology has been used to determine the phase response curve in a variety of other species including fruit flies (Vinayak et al., 2013), sparrows (Binkley and Mosher, 1987), and flying squirrels (DeCoursey, 1960).

Interestingly, the shape of the phase response curve looks remarkably similar in diurnal and nocturnal organisms suggesting that there are similar clock processes underlying this response to light, despite behavioral rhythms having different patterns. Diurnal animals are those who are most active during the daytime hours whereas nocturnal animals are those who are active during the dark period of the day. Humans, and many species of primates, squirrels, and birds are diurnal. Similarly, there are birds such as owls, and primates such as lemurs that are nocturnal. Much of the basic research done on biological rhythms uses laboratory rodents which are either nocturnal or diurnal, or fruit flies, which are diurnal, but the principles of biological clock function are remarkably conserved across species and ecological niches.

People Behind the Science: Dr. Pat DeCoursey

The very first phase response curve has been credited to Dr. Pat DeCoursey. Dr. DeCoursey was always interested in science and while in high school conducted a census of songbirds in a tract in Long Island, NY. She entered her project into a science talent contest where she won scholarship money that helped her attend Cornell University. This was followed by graduate school at University of Wisconsin, Madison where she studied the emerging field of chronobiology. She was working with flying squirrels which have a precise free running period of nearly 24 hours and she was interested in asking questions about entrainment. She gave the animals light pulses and plotted their dramatic shifts in activity onset to create the first photic phase response curve. In her long career in biological rhythms, she worked with numerous species including Eastern chipmunks, antelope squirrels, hamsters, and golden mantled ground squirrels and she helped write and edit a textbook entitled *Chronobiology*. Later in her career, she performed exceptionally challenging experiments designed to examine the importance of a functional circadian clock to the survival of animals in the wild.

3.1.3: Where Are Rhythms in the Brain?

Learning Objectives

By the end of this section, you should be able to

- 15.2.1 Draw the pathway from light to the master clock in the brain and from the master clock to its targets.
- 15.2.2 Explain how the negative feedback loop of clock gene transcription and translation functions.
- 15.2.3 Explain the experiments and evidence that demonstrated that the master clock is contained in the SCN.
- 15.2.4 Explain the role of the SCN, retina, and the pineal gland in circadian rhythmicity.

Where in the body is the biological clock that regulates circadian rhythmicity? As we have described in the previous section, nearly all organisms possess circadian rhythms, including birds, mammals, plants, and single celled organisms. Across these various organisms you can find functional clock mechanisms within many different tissues. For example, the retina secretes melatonin in a rhythmic daily pattern in birds. Here we will focus on the clock in mammals, which is located in an area of the brain known as the suprachiasmatic nucleus (SCN) (Figure 15.6), but we will also note organismal variation. The SCN is often described as the master clock in mammals, as it drives rhythms in physiology and behavior that, in turn, synchronize the timing of clocks in other tissues. The SCN receives light input from cells in the retina, and in turn this brain structure regulates rhythms throughout the body.

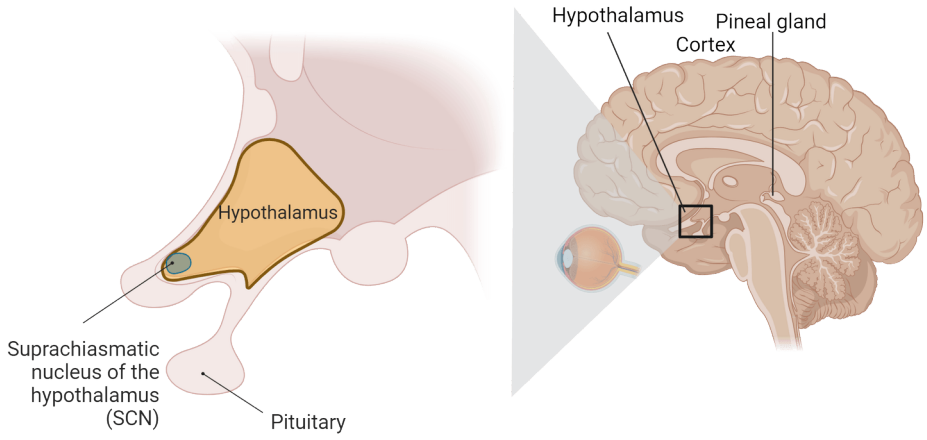

Figure 15.6 Suprachiasmatic nucleus of the hypothalamus

The Retina

In mammals, the retinas transmit photic information from the environment to the brain in order to synchronize internal rhythms with the external world. The retina possesses a multilayered structure designed to detect and process light and transmit that information to the brain, for both image forming and non-image forming purposes (see Chapter 6 Vision). Rods and cones are the primary photoreceptors for detecting light for image formation, but there is also a subset of retinal ganglion cells that contain photopigments and can detect light. These intrinsically photosensitive retinal ganglion cells (ipRGCs) send their long axons directly to the SCN in the hypothalamus. The SCN contains the master circadian clock which we will discuss next. The ipRGCs communicate to the SCN via the retinohypothalamic tract, providing a rod and cone-independent photoreceptive mechanism (Figure 15.7). The presence of these cells is a reason why some individuals with blindness caused by the degeneration of rods and cones can still show entrainment to light/dark cycles.

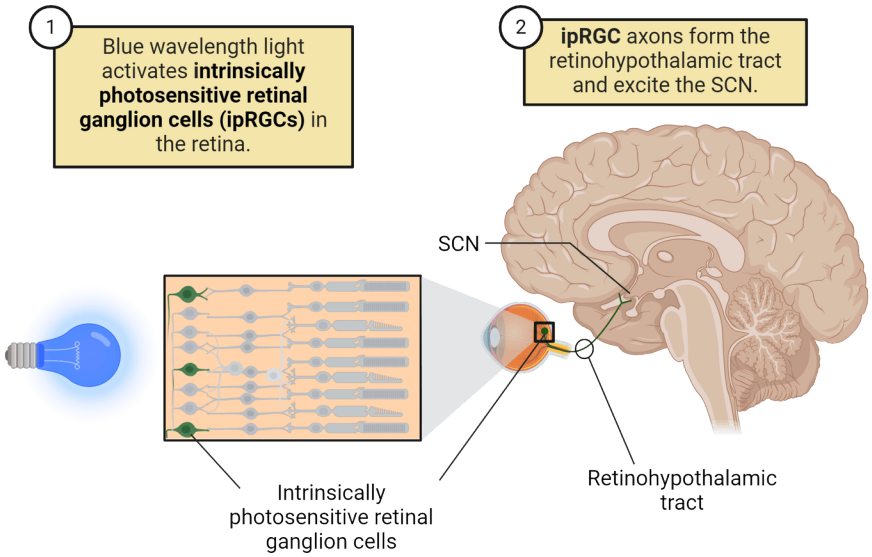

Figure 15.7 Non-image-forming retinal ganglion cells

ipRGCs use a novel photopigment called melanopsin for transducing energy from photons into chemical signals. Melanopsin is specifically found only in ipRGCs and, in its absence, ipRGCs lose their photoreceptive responses. Melanopsin is maximally sensitive to light at a wavelength of about 480 nm, which is in the blue part of the spectrum. Blue light is emitted by many common devices that you probably use everyday, including smart phones, computer screens, tablets, video game systems, and LED lights. Humans are sensitive to blue light and this sensitivity to blue light exposure is linked to the negative effects of artificial light at night on sleep and circadian rhythms. Specifically, blue light suppresses melatonin secretion (see below section on melatonin), which can disrupt rhythms and lead to reduced sleep, disrupted sleep quality and delays the timing of sleep (Silvani, Werder, Perret; 2022). The use of blue light (“night mode”) filters for cellular phones and screens, or wearing blue light filtered glasses at night when you are working on screens are two ways of mitigating the negative impacts of too much blue light exposure at night.

The Suprachiasmatic Nucleus of the Hypothalamus

The SCN are bilateral structures that are located in the ventral portion of the brain within the hypothalamus. They are medially located and are positioned next to the 3rd ventricle, a space where cerebrospinal fluid flows. They are also located above (supra) the optic chiasm, the location of the crossing of the optic nerves. They contain roughly 20,000 cells (in a rodent) that produce a variety of neurotransmitters including vasopressin, vasoactive intestinal polypeptide, gastrin-releasing peptide, somatostatin, and GABA.

There are numerous pieces of evidence that have established that the master circadian clock is located within these paired nuclei. First, when this area is removed by electrical lesioning, the animal loses any rhythmic patterns in physiology or behavior. For example, a hamster with a lesioned SCN will continue to exhibit wheel running, but this locomotor activity will no longer occur in a predictable schedule and the animal may have bouts of running throughout the day and night (Ralph et al., 1990). Second, when SCN tissue is removed from an animal and maintained in thin slices in a culture dish, the SCN continues to exhibit spontaneous free-running rhythms in electrical activity and in glucose metabolism for several days, similar to what would be seen if the SCN had remained in the animal (Newman and Hospod, 1986).

Lastly, the most conclusive evidence that the SCN contains the master clock was generated in experiments where the SCN was first removed and then replaced (Ralph et al., 1990). Hamsters had their SCN electrically lesioned, and as expected they had arrhythmic patterns of activity (Figure 15.8, steps 1 and 2). SCN tissue from the brains of fetal hamsters was then transplanted into the 3rd ventricle of the SCN lesioned animals. The ventricle is a space within the brain where cerebrospinal fluid flows, and the tissue was deposited near to the original SCN location. The lesioned animals began to express rhythms in locomotor activity again, that is, they began to have organized bouts of wheel running (Figure 15.8, step 3).

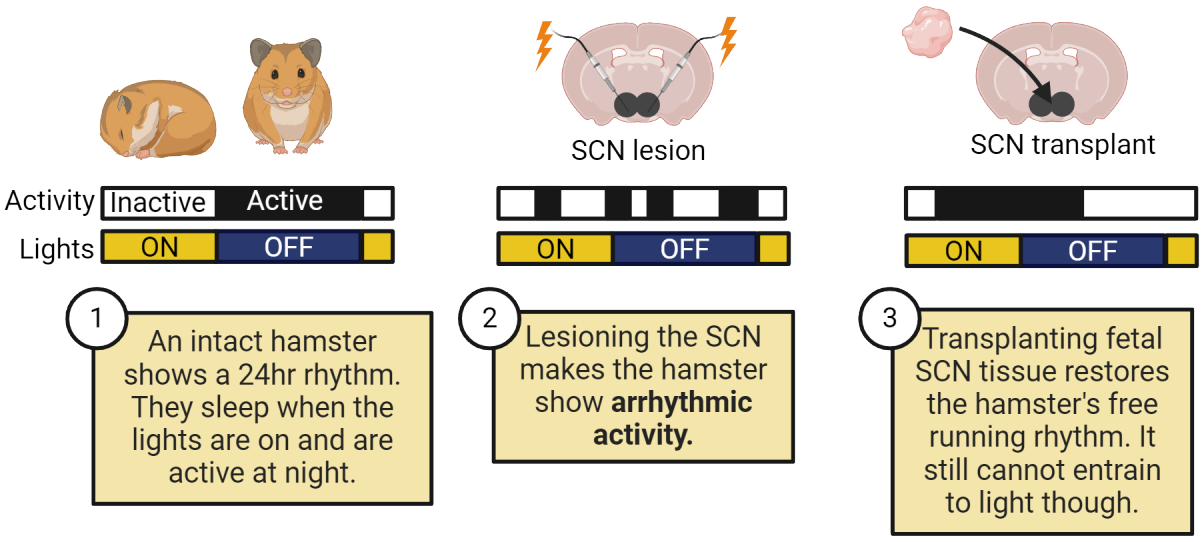

Figure 15.8 SCN lesion and transplant experiment

This study was extended by using hamsters that had a genetic mutation associated specifically with circadian clock function, such that animals that were homozygous for this mutation had a free-running period of 20 hours whereas wildtype hamsters without the mutation had a free-running period of 24 hours. The lesion-replacement experiment was repeated, but in this case the wildtype SCN lesioned animals received fetal SCN tissue collected from the mutant strain of hamsters. They also lesioned the SCN of animals with the mutant gene, and replaced their SCN with tissue from wildtype animals. The lesioned animals regained patterns of locomotor activity. However, the period of that activity matched that of the donor animals and not the host animal. That is, a wildtype animal exhibited wheel running patterns that had a period of 20 hours! Furthermore, through additional experiments investigators established that the implanted SCN tissue could generate rhythms in the host animal through the secretion of a neural factor, rather than by forming synapses with the recipient animal. However, implanted SCN tissue did not result in the recipients being able to entrain to light/dark cycles, indicating that neural connections were necessary for that function. These elegant experiments provided the strongest evidence that the SCN was the neural tissue generating daily rhythms that regulate physiology throughout the body (Silver et al., 1996; Ralph et al., 1990).

The SCN is also found to play a role in circadian rhythmicity in other organisms. In lizards, SCN lesion studies in two different species abolished circadian patterns of locomotor activity (Tosini, Bertolucci, and Foa; 2001). Further, studies in quail and sparrows revealed that there are two paired structures, the ventral SCN and medial SCN which also appear to play similar roles to the mammalian SCN (Cassone, 2014).

Rhythm Circuitry

Central circadian organization in vertebrates is composed of three major structures: the retina, the pineal gland, and the SCN. However, these tissues vary significantly in importance in different organisms. For example, the retina and the pineal gland secrete melatonin in vertebrates, an important hormone for sleep regulation. Additionally, if you take the retina from a non-mammalian vertebrate such as a bird, and incubate it in a dish (*in vitro*), melatonin continues to be released in a circadian manner. Thus, this structure can act as a daily pacemaker (Falcón et al., 2009). Furthermore, the pineal gland in fish and frogs contains photosensitive cells but these are absent in mammals. In this section, we will focus on the circadian clock circuitry in mammals.

As we have discussed, information about environmental light is transmitted to the SCN from the retina via the retinohypothalamic tract, a pathway of retinal ganglion cells that is not part of the image-forming visual system (Figure 15.9).

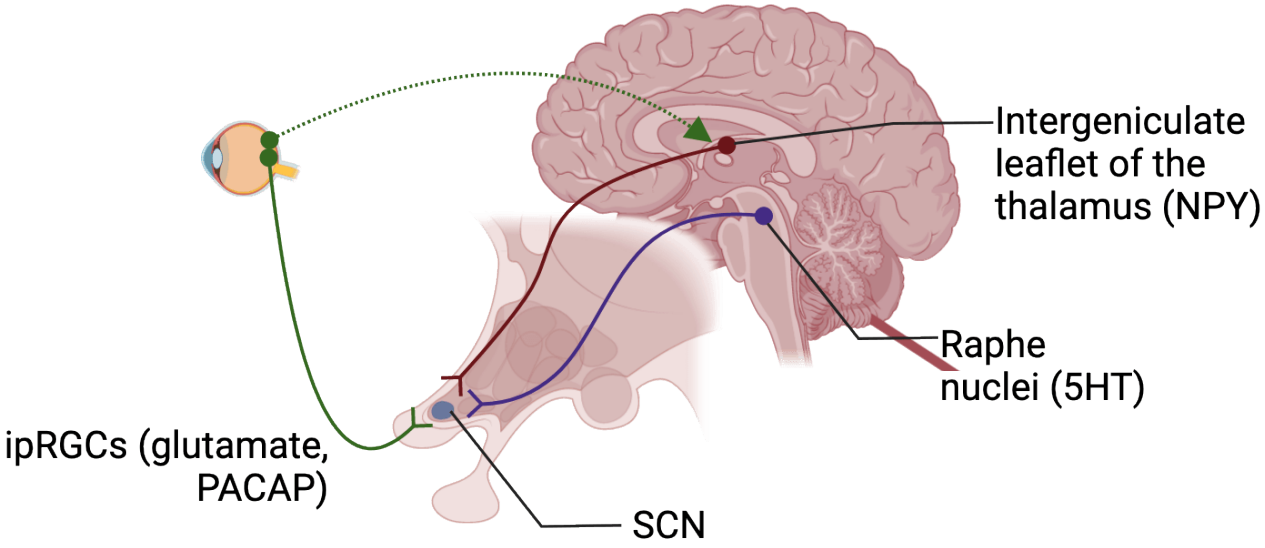

Figure 15.9 Inputs to the SCN The SCN receives several modulating inputs which contribute to entraining its activity to cues.

When light shines on the eyes, this pathway releases glutamate and pituitary adenylate cyclase-activated peptide (PACAP) into the SCN, producing an excitatory response. The influence of this input is modulated by a variety of neuropeptides and other signaling molecules, and its effects on circadian clock function vary with the time of day. The destruction of this pathway renders the circadian clock unable to entrain to light/dark cycles. However, the clock still runs as long as the SCN remains intact, with a period that reflects its own internal rhythm.

A second major input to the SCN is a pathway from the midbrain raphe nuclei which contains the neuropeptide serotonin (5HT). Neural activity in the raphe is highly reflective of the arousal state of an animal, with higher activity levels in the raphe associated with increased locomotor activity. Elevated locomotor activity increases serotonin release in the SCN. Increased locomotor activity and serotonin mimics (agonists) have inhibitory effects on the ability of light to shift the timing of the clock in the SCN. Light signals to the SCN can therefore be adjusted according to the behavioral context in which they are perceived. Thus, an animal exposed to light at night while resting may experience a phase shift, adjusting their clock timing for subsequent days, while one receiving similar light exposure while engaging in an intense activity bout may experience no shift or a lesser shift in timing.

A third pathway, called the geniculo-hypothalamic tract, is a multisynaptic connection from the retina to the intergeniculate leaflet of the thalamus, which in turn sends a Neuropeptide Y (NPY)-containing projection to the SCN. This pathway is thought to integrate both photic (light) and nonphotic information and is capable of regulating the entrainment of the SCN to both light/dark cycles and nonphotic signals. Nonphotic stimuli could be regular presentations of a running wheel, melatonin injections, or meals.

The SCN itself has its own structure of connectivity. This structure is characterized by overlapping subregions that are identified on the basis of synaptic connections or neuropeptide expression. While these divisions are often oversimplifications of the intricate structure of the SCN, they are helpful in understanding the general flow of information within the circadian clock mechanism. One of the most common constructs divides the SCN into a retinorecipient core region and a rhythmic shell. The core is generally located in the ventral part of the mammalian SCN, is heavily innervated by retinal afferents from the optic chiasm, and contains a dense plexus of neurons expressing vasoactive intestinal polypeptide. The shell is characterized by high amplitude rhythmicity in gene expression and is enriched in cells expressing the neuropeptide vasopressin. Regardless of their location within the nucleus and their neuropeptide expression, SCN neurons appear to uniformly express GABA as the primary classical neurotransmitter.

Neurons of the SCN project to a variety of other brain regions, mostly in the hypothalamus and thalamus. These projections are linked to rhythmic control of physiology and behavior, including variables such as body temperature, locomotor activity, the sleep/wake cycle, and various hormonal rhythms.

The Pineal Gland and Melatonin

Melatonin is a hormone produced primarily in mammals by the pineal gland, which is located in the roof of the diencephalon in humans. Melatonin secretion is directly tied to the circadian clock, with high levels during the night and very low levels during the day (Figure 15.10).

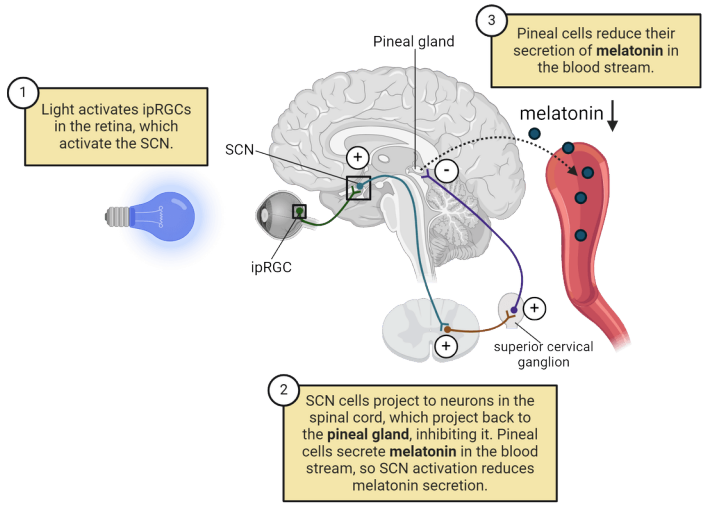

Figure 15.10 How light gets in the brain

Melatonin levels are directly suppressed by the presence of ambient light; thus, exposure to bright light during the night results in a very rapid decline in circulating melatonin. The melatonin rhythm is one of the casualties of screen use in the bedroom—exposing one's eyes to bright light from a phone or tablet screen in the middle of the night suppresses melatonin release and can have negative consequences for sleep quality. Melatonin is currently utilized as a therapeutic for a wide variety of conditions such as insomnia, jet lag, circadian rhythm and shift work sleep disorders, and to help support sleep in the elderly, who may suffer from reduced melatonin production.

Although melatonin's primary role with regard to human health is the treatment of rhythm disorders, it has a major role in the regulation of reproduction in seasonally breeding species such as sheep, deer, and golden hamsters. In these species, the duration of the nocturnal rise in melatonin serves as a measure of daylength, with long nights, and thus long period of melatonin secretion, indicating winter photoperiods and the suppression of reproductive physiology and behavior. Although humans are not considered to be seasonal breeders, there are melatonin receptors present in reproductive tissues in humans and there is some evidence that melatonin may play a role in a variety of reproductive processes (Olcese, 2020).

The pineal gland, through melatonin secretion, may have a more dominant role in circadian clock function in many non-mammalian species. In zebrafish, for example, the pineal gland functions as a central circadian pacemaker and directly regulates the sleep/wake cycle (Aranda-Martínez et al., 2022). Similarly, in pigeons, circadian rhythms in pineal melatonin directly regulate sleep and wakefulness (Phillips and Berger, 1992).

Rhythms in Clock Genes

Circadian rhythms at the level of the organism are ultimately driven by rhythms at the level of individual cells. Within each cellular clock, rhythms are generated and expressed at the level of gene and protein expression. Some genes and proteins may build up throughout the day and decrease during the night, while others may show the opposite pattern. An essential set of genes, known as the core clock genes, interact with one another to produce self-sustaining rhythms with periods close to 24 hours, and which can respond to external stimuli to adjust clock timing when necessary.

The molecular clock is generated by interlocking transcription/translation feedback loops, which function to produce robust rhythms of gene expression with a period of about 24 hours. These negative feedback loops are composed of a set of highly conserved core clock proteins that both participate in the central machinery of the clock and drive rhythmic expression of other

genes (Figure 15.11). Four core clock gene families sit at the center of the molecular clock: *Clock* and *Bmal1*, which code for activators, and *Per* and *Cry*, which are repressors. The proteins CLOCK and BMAL1 are subunits of a transcription factor that activate transcription of *Clock* and *Bmal1* and *Per* and *Cry* genes as well as other clock-controlled output genes (Step 1 in Figure 15.11). Essentially, these proteins turn on the production of the mRNA for *Clock* and *Bmal1*, which code for activators, and *Per* and *Cry*. These genetic mRNAs for *Clock* and *Bmal1*, which code for activators, and *Per* and *Cry* then leave the nucleus and travel to the cytoplasm where they are transcribed into their respective proteins (Step 2 in Figure 15.11). The PER and CRY proteins bind to each other (heterodimerize) in the cytoplasm and move (translocate) to the cell nucleus where they inhibit the transcriptional activation by the CLOCK/BMAL1 complex (Step 3 in Figure 15.11). In other words, the PER/CRY protein complex turns off the activity of the CLOCK/BMAL1 complex. Activity of these proteins are regulated by a variety of kinases, phosphatases, and other modulators. Mutations in many of these regulatory proteins can modulate the free-running period of the clock by changing the degradation rate of one or more of the clock proteins.

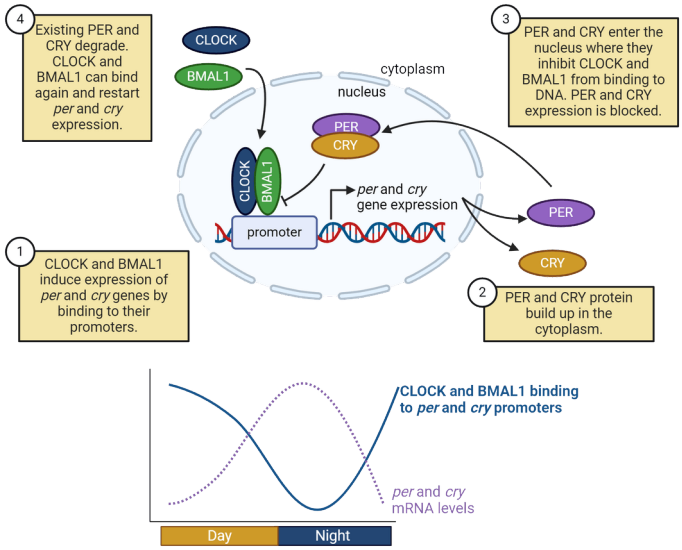

Figure 15.11 Rhythms in clock genes

The presence of interlocking feedback loops strengthens and maintains accurate circadian timing in the presence of noise and environmental disruptions. They also help to generate phase differences in circadian transcriptional output that optimally time gene expression which can differ depending upon the specific tissues or cell types.

The molecular clock mechanism also has a number of functional redundancies that maintain function in the event of genetic mutations. For example, in mice there are three homologues of the period gene called Per1, Per2, and Per3. A knockout of any one of these genes is not sufficient to eliminate circadian rhythmicity, but a mouse with a Per1/Per2 double knockout does lose rhythmicity. The only single gene knockout known to eliminate clock function in the SCN is the Bmal1 knockout. Such mice lack molecular and behavioral circadian rhythms, and have additional abnormal phenotypes such as decreased activity, decreased body weight, and shortened lifespan. Although the SCN is a network of thousands of neurons that together function as a circadian clock, many, if not most, individual cells have the cellular machinery necessary to function as a clock. That is, cells throughout the body have the same circadian clock gene components.

Neuroscience across Species: Discovery of Molecular Clocks

The molecular underpinning of the circadian clock owes much to the foundation that was done with work in fruit flies. In 1968, Ronald Konopka began to screen strains of fruit flies to determine if there was one that had problems with the timing of eclosion (emergence) of the mature fruit fly from the pupa. Eclosion has a circadian rhythm and flies hatch 1-2 hours before dawn. Three strains were identified, one that had a shorter period of 19 hours, one with a long period of 28 hours, and one that had individuals emerging across the day with no period. This led to a groundbreaking paper that identified the gene responsible for the three mutant strains, which they called *period* (Konopka and Benzer, 1971). This foundational work led to the discovery of additional genes that form a feedback loop within fruit flies, and also led to work in lab rodents, described above.

In fruit flies, the feedback loop is comprised of the CYCLE (CYC) and CLOCK (CLK) proteins which form a dimer. They enter the nucleus of the clock cells and turn on the transcription of the genes *timeless (tim)* and *period (per)*. These genes lead to the production of PER and TIM proteins which are formed in the cytoplasm. TIM is light sensitive and thus builds up at night. PER alone is unstable; it becomes phosphorylated by the protein DBT (encoded by the gene *doubletime*) which leads to its being degraded in the cytoplasm. However, when TIM and PER heterodimerize in the cytoplasm they become stable and increase in the cytoplasm, enter the nucleus, and block their own transcription. This is done by PER inhibiting CLK which prevents the PER/CLK dimer from binding to the DNA. Thus, PER negatively inhibits its own production (Rosato, Tauber, and Kyriacou; 2006, Bhadra et al., (2017).

A second feedback loop occurs where CLK protein has a peak in the daytime, opposite to that of TIM. CLK/CYC dimers initiate the transcription and translation of two proteins VRI (encoded by the gene *Vrille*) and PDP1e (encoded by the gene *Pdp1e*). VRI is a negative inhibitor of the transcription of *Clk* and PDP1e is a positive regulation of this gene, thus they act in opposite ways on the transcription of Clk (Rosato, Tauber, and Kyriacou; 2006). The initial characterization of these clock gene loops in fruit flies led to a Nobel Prize to be awarded to three circadian biologists in 2017, Drs. Hall, Rosbash, and Young.

Neuroscience across Species: Evolution of Clocks

Circadian rhythms do not require a brain. Well-regulated circadian clocks are found in plants, fungi, and even some types of bacteria. Further, they are found in animals that do not have an SCN such as fruit flies, honey bees, and roundworms. Circadian rhythms are found across vertebrates from fish to sloths, from rodents to humans. There has been much speculation as to how clocks evolved in such a diverse array of species and for what purpose. One foundational assumption is that possession of a daily clock confers an advantage to the organism. This has led to the idea that some fundamental advantage of having biological rhythms is so important that clocks may have evolved multiple times across varied species. Interestingly, another hypothesis speculates that biological clocks may have originated as a fundamental process for detoxifying cells from oxidative stress. Peroxiredoxin protein, which plays a role in eliminating reactive oxygen species, has a daily rhythm in mice, bacteria, flies, and fungus (Loudon, 2012). Thus, there is much to be determined as to when biological rhythms emerged.

In animals, overall control of rhythmicity is generally coordinated by a set of clock generating cells in the central nervous system. For example, in fruit flies, there are about 150 clock neurons in the brain. These neurons are subdivided into groups that regulate a variety of aspects of circadian rhythmicity, and the neuroanatomical organization of these cells is well known. In vertebrates, the primary circadian clocks are best represented by some combination of clocks located in the retinas, pineal gland, and the hypothalamus (Menaker, Moreira, and Tosini, 1997). This group of clocks has been best studied in birds, where all three of these areas contain circadian clocks, with the relative importance of each varying from species to species. For example, the pineal gland has circadian oscillations in some but not all bird species. In mammals, the SCN acts as a master circadian clock, driving rhythms of physiology and behavior. The pineal gland and retinas still have rhythmic activity, but the contribution of these clocks to overall circadian rhythms has diminished. The SCN has a structure that is remarkably conserved across mammalian species, and is characterized by direct retinal input and a separation of neurons into distinct groupings on the basis of neuropeptide content. The interaction of these clocks was appropriately described as a neuroendocrine loop, which maintains synchrony amongst independent circadian clocks in each tissue through hormonal and neuronal signals. Ultimately, additional research needs to be conducted across species to determine commonalities and differences.

3.1.4: Regulation of Sleep

Learning Objectives

By the end of this section, you should be able to

- 15.3.1 Describe several theories to explain why we sleep.
- 15.3.2 Differentiate between the different stages of sleep.
- 15.3.3 Differentiate between circadian and homeostatic regulation of sleep.
- 15.3.4 List several ways in which disruption of sleep (shift work, light at night) impacts human health.

Why Does Sleep Exist?

At first glance, the entire process of sleep seems maladaptive. While sleeping, organisms are not searching for food or mates and have reduced sensitivity to environmental stimuli, making them more vulnerable to predators or hazardous events. Despite this, almost all animals appear to sleep, even when they lack a central nervous system as is the case with Hydra (Kanaya et al., 2020). It therefore seems likely that sleep evolved in very primitive animals and gradually took on additional functions throughout the evolution of the animal kingdom.

In humans, sleep regulation can be modeled using the two-process model of sleep regulation. Process C refers to the circadian rhythms in the timing of sleep and wakefulness. There are endogenous rhythms to when you feel sleepy and when you feel most awake. For example, most of us feel fatigued and sleepy during the later hours of the evening, and we feel most alert in the morning hours. There is also a period of reduced alertness which occurs in the midafternoon. You may have experienced this as sleepiness after lunch. These cyclical rhythms in sleepiness and wakefulness are regulated by the circadian timekeeping system and the master clock found in the SCN. Process S refers to the homeostatic pressure to get restorative sleep. The more time it has been since you slept, the greater the pressure to fall asleep. After you have been awake for a while, a certain amount of sleep debt has accumulated, and you need a period of sleep to eliminate the debt. The interaction between these two processes determines the amount of sleep pressure at any given time and the likelihood of falling asleep.

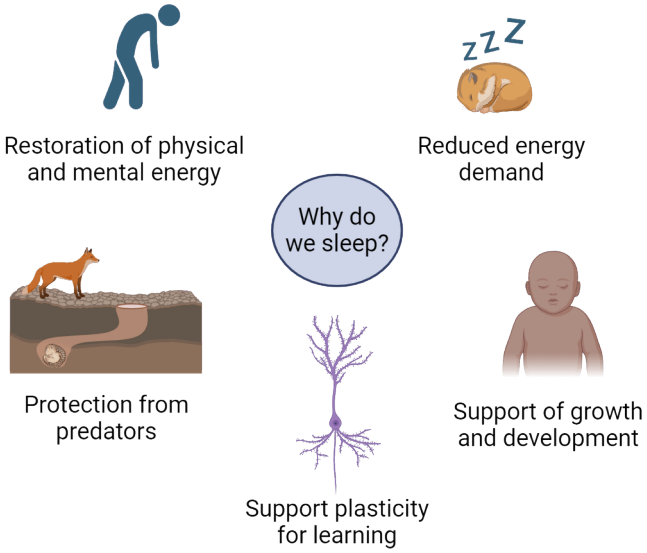

Figure 15.12 Why we sleep

One major theory of the function of sleep is that sleep performs a restorative function, without which an animal's performance is impaired in some fashion (Figure 15.12). In humans, when we don't sleep, we feel tired and our ability to function is decreased on both physical and mental tasks. After sleeping, we feel better. There is significant evidence in support of this function at the behavioral, physiological, and molecular levels. Sleep deprivation impairs, among other things, cognitive function, tissue repair,

attention to tasks, and even increases cancer risk.

One possible mechanism of the restorative function of sleep focuses on the neurotransmitter adenosine. Adenosine is released by neurons in response to excessive firing and metabolic exhaustion (Lovatt et al., 2012). During wakefulness, adenosine builds up in the brain, promoting sleepiness. It is then reduced during sleep. The impact of adenosine is counteracted by caffeine, giving coffee and other caffeinated beverages their ability to defer sleep onset. Caffeine has this effect by blocking action at the A2A adenosine receptor. This effect is temporary—once the caffeine wears off, a person is just as sleepy as if they had never had the caffeine.

Another possible mechanism for the restorative function of sleep is waste clearance. Metabolic waste products are removed from the brain at a higher rate during sleep than during wakefulness (Albrecht and Ripperger, 2018). One mechanism that clears this neural waste is known as the glymphatic system and this has been the subject of new and exciting research in neuroscience. In this system, cerebral spinal fluid (CSF) enters the brain then has an exchange with the brain tissue via the interstitial fluid. The byproducts of metabolism are collected and removed from the brain. The glymphatic system is active when animals are sleeping and it is largely quiet when animals are awake. Research has demonstrated that this rhythm in clearance is circadian in nature (Hablitz et al., 2020). Thus, sleep may serve as an active period when the brain is removing toxic waste (Jessen et al., 2015).

A second popular theory of sleep function is that it serves an energy conservation function. Energy usage is reduced during sleep, with the amount of savings varying from animal to animal. Animals spend a considerable amount of their energy budgets looking for food, and the reduction in energy usage during sleep could make a difference in evolutionary success. In fact, when we sleep our metabolism decreases by 10% (Sharma and Kavuru, 2010). Some species gain significant energy savings during sleep by reducing body temperature, but the reduction in muscle usage provides for significant savings. Many species also adopt sleeping postures that conserve heat, reducing the energy usage for body temperature homeostasis. At times when food is scarce, the reduction in metabolic rate during sleep could allow an animal to survive for a longer period of time than would otherwise be possible. While this theory is appealing, there are examples that do not support it. For example, some animals sleep a lot whereas others sleep very little. Lions and zebras both use relatively little energy; male lions do not hunt and grazing expends a small amount of energy. Yet lions sleep 15-18 hours a day and zebras sleep as little as 3-4 hours a day (Siegel 2005).

A third theory is that sleep enforces inactivity during periods of time when an animal's survival would be negatively impacted by active behaviors. Thus, animals with specialized adaptations for nocturnality sleep during the day, when they would be more vulnerable to predation, and diurnal animals dependent on vision are safer being inactive during the night. However, it is not clear whether sleep is really necessary to enforce this kind of behavior pattern, with the added cost of loss of responsiveness to sensory stimuli.

Finally, there is the idea that in animals with complex nervous systems sleep serves an important role in the growth, development, and plasticity of the brain, particularly as it relates to functions around learning and memory. As an example, sleep deprivation studies have confirmed that learning and memory are negatively impacted by insufficient sleep through effects on signaling in hippocampal neurons (see Chapter 18 Learning and Memory).

These theories are not mutually exclusive. It seems likely that sleep evolved in response to bioenergetic pressures that resulted from circadian rhythms of energy availability and took on additional functions as nervous systems developed and became more complex.

Neuroscience in the Lab

How We Measure Sleep

The gold standard for measuring sleep is by the use of a polysomnogram (PSG). Figure 15.13 shows a photo of someone undergoing polysomnography, along with some of the typical measures collected during the session. This is typically done within a lab setting or sleep clinic. Electrodes are attached to standardized locations on the scalp to measure brain electrical activity through electroencephalography (EEG) (see Methods: Sleep Studies and EEG Technology). Fluctuations in voltage are measured and compared between each of the sensors. Electrical signals from the brain vary between waking and sleeping, and between the different stages of sleep. Electrodes are also used to measure movement of the eye muscles through electrooculography (EOG). This detects ocular movement during wakefulness and the different sleep stages and is used to identify Rapid Eye Movement Sleep (REM or REM sleep). Sensors are also used to measure muscle movement through

electromyography (EMG). There are changes in muscle tone that occur as you move from wakefulness with continuous movement to REM sleep with muscle paralysis. Finally, oxygen saturation in your blood, respiratory rate, and heart rate may also be measured.

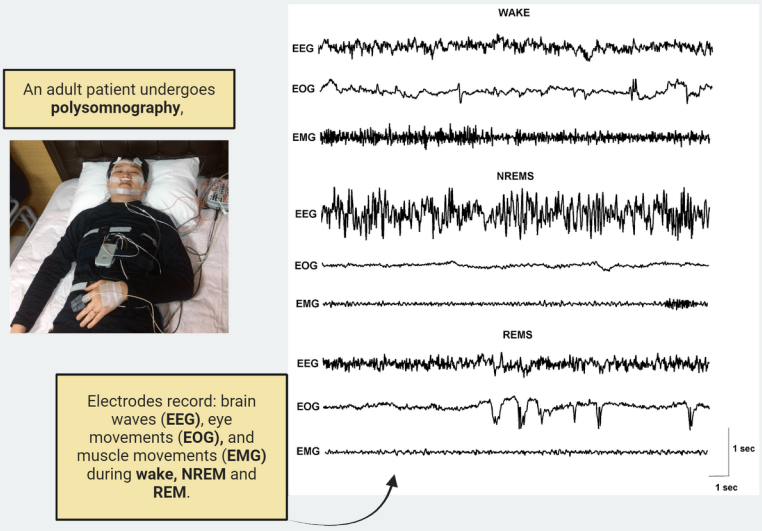

Figure 15.13 EEG measurement of sleep Image credit: Photo of person from: by Kuyohong/Wikimedia Commons, CC BY-SA 4.0. Electrode traces from Kumar, Ramaswamy & Mallick. 2013. "Local Properties of Vigilance States: EMD Analysis of EEG Signals during Sleep-Waking States of Freely Moving Rats." https://doi.org/10.1371/journal.pone.0078174. CC BY 4.0

PSG measures sleep in an objective manner. However, you can also give people surveys or diaries and ask them to describe their sleep. This is referred to as subjective measures. There are many sleep surveys and tools that are used to measure healthy sleep and to assess potential sleep disorders such as insomnia or sleep apnea. These surveys can probe how much an individual sleeps, their level of daytime sleepiness, the quality of their sleep, and their preference for activities at certain times of day. A doctor may also ask for a sleep diary or log where a patient records the time they go to bed, the time they fall asleep, the number of minutes they are awake after they fall asleep and the time they wake up.

In healthy patients, the subjective and objective measures of sleep have a high correlation, but in patients with conditions such as insomnia or depression, the correlation is not as strong. For example, patients with insomnia may report that it takes longer for them to fall asleep than the PSG records would indicate (Rezai et al., 2022). However, both objective and subjective measures of sleep are important for a medical professional to use as data for treating a patient. Recently, new tools using fitness trackers and smart watches have become available that purport to measure sleep time and even to identify the timing of deep and REM sleep. These devices can be very good at identifying periods of sleep but may somewhat overestimate sleep time because they aren't necessarily as good at identifying waking periods. In addition, accuracy in the measurement of sleep stages is not yet up to clinical standards.

Stages of Sleep

There is a clear distinction between your activity levels during sleep when compared to being awake. However, getting a good night of sleep is not a uniform process where you lay immobile in bed and your brain becomes quiet. In reality, your brain and your body cycle through 4 different stages and the whole cycle can take about 90 minutes (Figure 15.14). You may experience 3-5 cycles per evening.

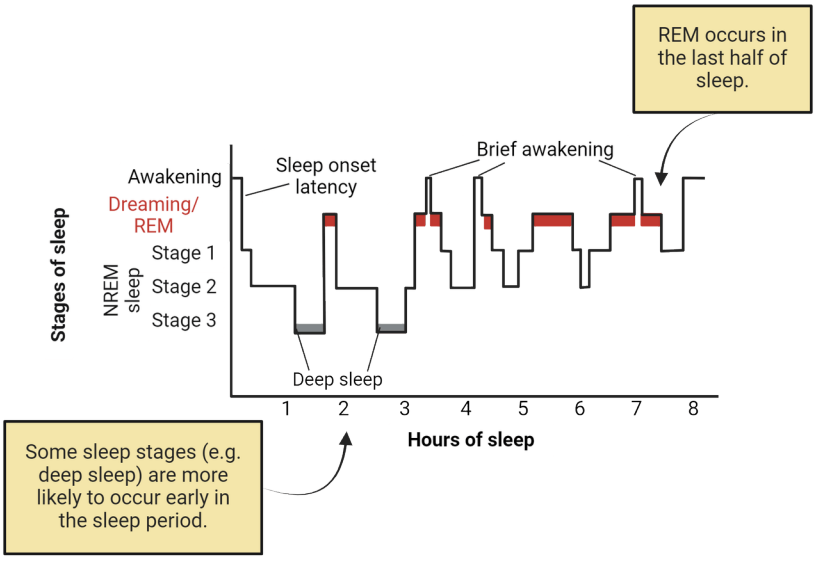

Figure 15.14 Hypnogram

The stages comprising a cycle can be divided into non-REM (3 stages) and REM sleep. Non-REM sleep (also referred to as NREM sleep) is characterized by large amplitude, slow oscillations on the EEG, representing synchrony of electrical activity in the cortex (Figure 15.13). Muscle tone is reduced and movement is limited (but not eliminated).

- Stage 1 non-REM sleep is a transitional stage that occurs as one moves from wakefulness into sleep. This period lasts less than 10 minutes and is considered the lightest stage of sleep because you are easily woken up during this stage.
- Stage 2 non-REM sleep is where the majority of your sleeping time is spent. Your body temperature drops, your breathing rate slows, and your brain electrical patterns exhibit sleep spindles (Figure 15.15). Spindles appear on the EEG as rapid and rhythmic bursts of activity. Spindles are associated with learning capacity. This period lasts about 25 minutes.
- Stage 3 non-REM sleep, or delta sleep, or slow wave sleep is a deeper sleep where it may be hard to wake up even if there are loud noises or stimuli in the environment. The body's breathing rate is slowed and muscles are relaxed. In the EEG, delta waves appear which are slow frequency and high amplitude waves of electrical activity (Figure 15.15). This is the deepest stage of sleep and is the critical stage for restorative sleep as it is a time when the body clears out waste, builds bone and muscle and the immune system is strengthened. Decreases in the amount of slow wave sleep is associated with more fatigue during the day. Importantly, this stage of sleep is critical for memory consolidation.

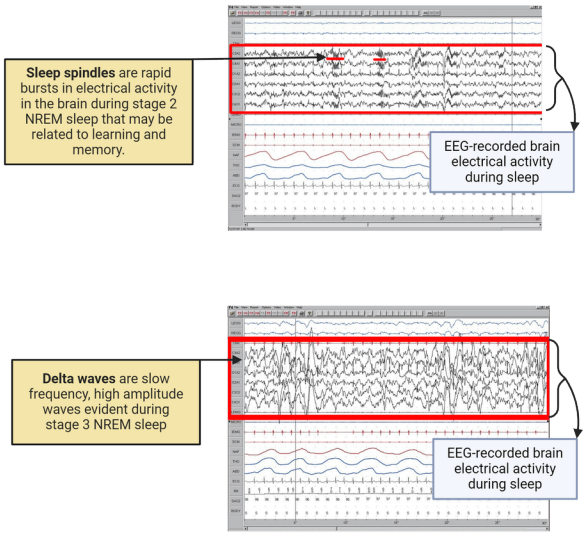

Figure 15.15 Sleep spindles and delta waves Image credit: Sleep spindles from EEG by MrSandman at English Wikipedia. Transferred from w to Commons by en., Public Domain, https://commons.wikimedia.org/w/inde...p?curid=453178. Delta waves from EEG Public Domain, https://commons.wikimedia.org/w/inde...p?curid=453193

Finally, about 90 minutes after you fall asleep you enter the REM sleep phase. Here your brain EEG has electrical activity that resembles wakefulness; as such, this stage is referred to as "paradoxical sleep". Despite brain activity that resembles the waking state, your muscles are immobilized, breathing is fast and irregular, and your eyes exhibit rapid movements. This stage can last 10 minutes in the first sleep cycle of the evening, but as the night progresses, you spend an increased amount of time in the REM portion of the sleep cycle, perhaps as long as 60 minutes by the end of the night. In a typical night of sleep, you do not progress through the sleep stages in order. Initially you may enter stage 1 through 4 in sequence before reaching REM sleep, but at the end of the night you may cycle between REM and stage 2 and stage 3 non-REM sleep.

Cramming for Exams

Have you ever pulled an all-nighter to complete a last-minute project or to study for an exam? This learning strategy is not ideal as research teaches us sleep is critical for optimal learning. We may not yet know the full reasons for why we sleep, but studies show that sleeping helps with our memory formation and retention. Getting enough sleep both before and after you learn material can help strengthen memories. In lab studies, people were allowed to have a full night's sleep, or even a 90-minute nap *prior* to having a memory task of learning face-name pairs. Those that slept had a significantly better learning capacity compared to those with no nap or less sleep. The polysomnogram (PSG) data from the participants were analyzed and it was found that the number of sleep spindles that occurred in the stage 2 non-REM sleep prior to learning was associated with an increase in learning ability. Sleep also helps you strengthen and retain memories after they have been formed. In studies where participants learned word pairs, then took a nap, or slept overnight, it was found that they recalled more words than those that did not sleep. An additional important finding was that the amount of deep non-REM sleep was strongly associated with the amount of information that was retained. We get more deep non-REM in the early part of our sleep cycle, thus, getting a full night's sleep is critical for learning (Walker, 2017).

Regulating Sleep

When we are awake there are multiple brain areas that are actively responsible for keeping us in an awake state. However, you may not realize that when we are asleep our brains are not in an "off" state; instead, our brains remain engaged in active processes. While we sleep there are specific brain areas that are turned "on" to help regulate our sleep. During our waking period there are multiple brain areas, working together as part of the ascending arousal system, that secrete neurotransmitters which then maintain wakefulness (see Chapter 3 Basic Neurochemistry (Figure 15.16). The neurotransmitters that are secreted go to a sleep-promoting brain area to turn off its activity. This brain area, known as the ventrolateral preoptic area (VLPO, a region of the hypothalamus), communicates back to the wake-promoting system, and inhibits these structures in order to maintain a quiescent state. Thus, there is a brain area that promotes sleep, a second set of structures that promotes wakefulness, and these two systems inhibit one another. This is referred to as the flip flop switch.

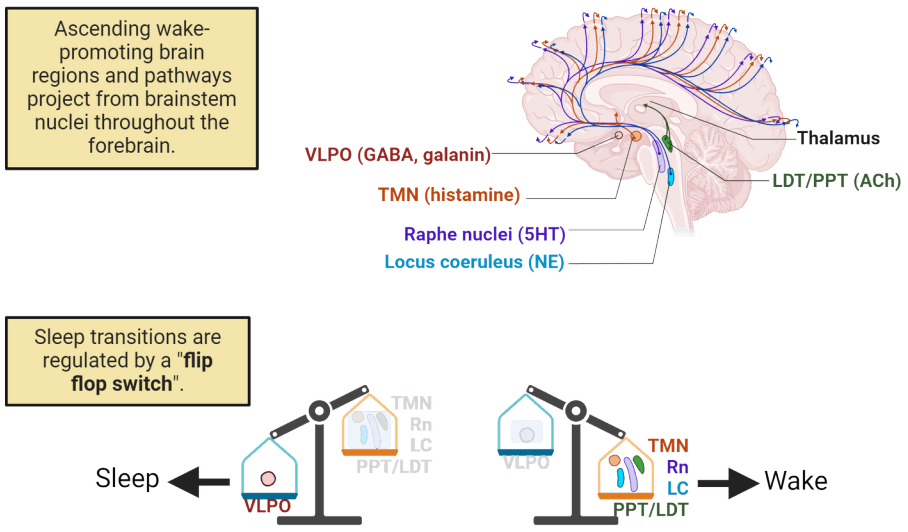

Figure 15.16 Sleep circuitry

To be more specific, during wakefulness, in the brainstem, the locus coeruleus (LC) secretes norepinephrine and the raphe nuclei secretes serotonin. In the hypothalamus, the tuberomammillary nuclei (TMN) secrete histamine. Additionally, in the brainstem, near the pons are two groups of cells that secrete acetylcholine. These cells are located in the lateral dorsal tegmentum (LDT) and the pontine peduncular tegmentum (PPT). Together, these wake-promoting areas send projections through the rest of the brain to help maintain wakefulness. In contrast, there is a group of cells in the VLPO of the hypothalamus which promotes sleep. As mentioned above, there is a mutual inhibition between the sleep-promoting regions of the VLPO and the wake-promoting regions of the brainstem and hypothalamus. Specifically, the VLPO is inhibited by norepinephrine and serotonin via connections from LC and raphe nuclei; this occurs during wakefulness. The cells of the VLPO send neuronal projections containing the inhibitory amino acid GABA and the inhibitory neurotransmitter galanin to the aforementioned sleep-promoting brain areas. The VLPO thus inhibits these areas and as a result maintains sleep. These connections are diagrammed in Figure 15.17.

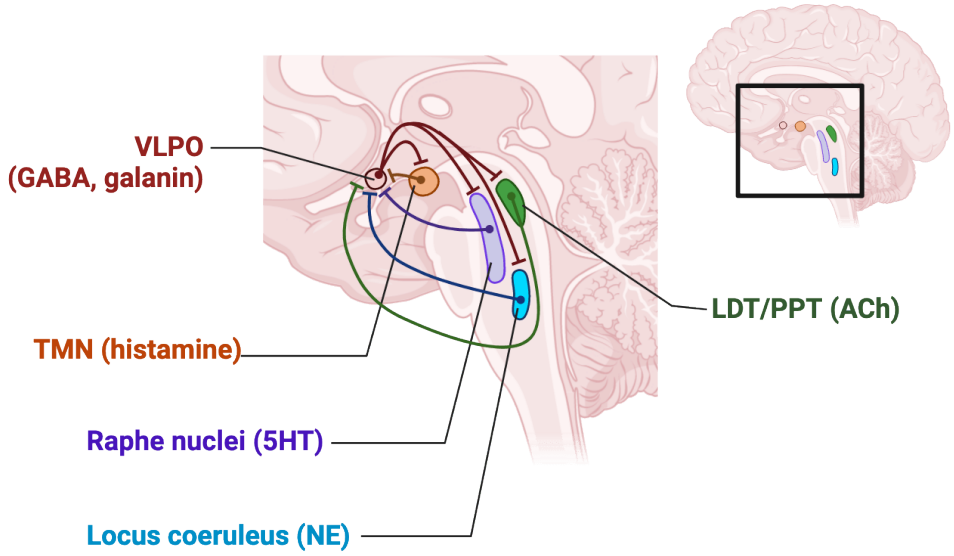

Figure 15.17 Reciprocal inhibitory connections of sleep areas Wake and sleep promoting regions inhibit each other.

Neuroscience across Species: Comparative Sleep

Adaptation to a variety of ecological niches has resulted in a wide range of sleep strategies and some unusual variations in sleep physiology. Just across mammals, sleep duration can vary from 4-20 hours per day, and length of time spent sleeping represents just one way in which sleep differs between species. Sleep may confer an advantage to remain quiet when predators are present, or to conserve energy for when food (prey) is abundant. For example, in sloths in the wild, predation appears to determine when they are sleeping and when they are awake (Voirin et al., 2014). The little brown bat sleeps for up to 20 hours a day, which might be due to the fact that its food source of moths and mosquitos is only present in a small window of time at dusk (Siegel, 2022).

Some mammals (whales, dolphins, fur seals, and sea lions) exhibit an unusual pattern of sleep called unihemispheric sleep. When in this state, one half of the brain is in a state of slow wave sleep at a time. Given the requirements of living in an aquatic environment, this makes sense: aquatic mammals must retain voluntary muscle control because they need to swim and surface to breathe, and maintain contact with conspecifics and be alert for threats. Behaviorally, the animals generally keep one eye open and one closed, with the open eye connected to the cerebral hemisphere that is awake. The open eye is usually the one directed towards other members of the group, rather than looking outward for threats, suggesting that these animals are utilizing unihemispheric sleep, in part, to maintain group cohesion. Unihemispheric sleep is also thought to occur in some birds and eared seals.

Sleep-like states can also be measured in other organisms that do not have an SCN, such as fruit flies. In this versatile lab model, circadian rhythms are controlled by about 150 cells which are clustered into groups (reviewed by Dubowy and Sehgal, 2017). Together these groups function like the mammalian SCN. Further, these clusters also have differences in neurotransmitter expression, much like the different subregions of the SCN. Fruit flies have states of rest (quiescence) which resemble sleep. These periods of resting are circadian regulated and therefore occur rhythmically. Further, there is a homeostatic drive and flies can be deprived of this rest period after which they show sleep recovery periods. These recovery periods have longer and deeper sleep, indicating a potentially restorative function. Lastly, during the sleep period the fly requires a stronger stimulus to arouse it, much like you would require a stronger stimulus to get your attention when you were sleeping compared to when you were awake

(Dubowy and Sehgal, 2017). This laboratory model has proven to be extremely useful in dissecting the genetic underpinnings of sleep, since the genes and behaviors underlying sleep are conserved.

Sleep qualities have been examined in humans from industrialized areas and compared to hunter-gatherer tribes that have little outside contact and no electricity (Siegel, 2022). Interestingly, in both types of cultures, humans do remain awake after the sun has set. In the tribal communities, humans remain awake for about 3 hours after dark, and further, they acquire about 7 hours of sleep a night. An additional interesting result is that there are relatively low reports of insomnia in individuals from hunter gatherer societies (2% compared to 10-30% in industrialized societies).

Ultimately, sleep can vary within or between species due to mating opportunities, season, food availability and predation. A comparative approach investigating sleep between various species, may lead to a common factor or factors which may determine why sleep is important.

Sex as a Biological Variable: Sex Differences in Sleep Variables

Polysomnography studies both at home and in the sleep lab indicate that women have better objective sleep quality when compared to men. Women fall asleep faster, stay asleep longer, have less wakefulness during their sleep period, and have a greater percentage of slow wave sleep than men. Women also tend to have an earlier bedtime and earlier wake time than men. Men have lighter sleep and spend more time in non-REM stages 1 and 2 and are more easily woken compared to women. Men have less slow wave sleep than do women. Some of these sex differences in sleep variables may be caused by changes in circulating gonadal hormones in males and females. For example, sleep changes and sleep complaints occur in women as they experience fluctuations in hormones such as occurs at the onset of puberty, across menstrual cycles, during pregnancy, and during menopause.

There are studies in men that examine the relationship of testosterone with sleep. Generally, we can suggest that low levels of testosterone are associated with reduced sleep; although not all reports support this conclusion. In healthy males, testosterone peaks around the time that REM sleep stage begins. If a male individual has fragmented sleep or sleep deprivation, then testosterone is reduced. Men with androgen deprivation therapy, which is a treatment for prostate cancer, report an increase in insomnia (Gonzalez et al., 2018). In a study of men 65 years old and older, there was a relationship between low levels of testosterone, increased waking during the night, and less time spent in the restorative slow wave sleep stage (Barrett-Conner et al., 2008). In contrast, high levels of testosterone replacement in older men or young men taking androgenic steroids have a decrease in the amount of total sleep (Liu et al., 2003).

There is still a relative lack of research into how and why sleep is regulated differently in women compared to men. Some of this lack of information may exist because of differences in how sleep is measured, how hormone profiles are determined, and males and females report sleep problems (Mallampalli and Carter, 2014). However, we can describe some consistent changes that are associated with ovarian hormones in sleep in healthy women (see Chapter 11 Sexual Behavior and Development). During the follicular phase of the menstrual cycle, estradiol is rising. When it reaches a threshold, it triggers a surge of luteinizing hormone and this is followed by ovulation. The period after ovulation is called the luteal phase and this is when progesterone begins to rise. One conclusion that can be made from the literature is that during the luteal phase women experience more awakenings during the night and there is a reduction in slow wave sleep (Baker and Driver, 2007). Furthermore, sleep spindles increase during the luteal phase. Some, but not all, studies have found that the amount of REM may be reduced, REM may start earlier, and there is increased slow wave sleep during the luteal phase. However, when the follicular phase is compared to the luteal phase, PSG studies have found no difference in the time it takes to fall asleep, the time spent awake after falling asleep, or sleep efficiency (time spent asleep/time spent in bed).

Interestingly, changes in hormones such as occurs during menopause are associated with an increase in sleep complaints. As women transition through menopause, they have difficulty falling asleep and they have increased events of waking up during the night. This may be related to the decrease in estradiol and rise in follicular stimulating hormones which occurs at this time. However, some studies also found the speed at which these hormones changed also played a role (Baker et al., 2018). Additionally, women that take birth control report that this affects their sleep patterns. For example, they report more daytime sleepiness and insomnia (Bezarra et al., 2020). Relatively few studies have examined objective sleep measures in women on oral contraceptives. However, in one study, healthy women on oral contraceptives had disrupted sleep; they experienced less slow wave sleep and had a shorter latency to enter REM sleep (Burdick, Hoffmann, and Armitage, 2002).

There are also sex differences in sleep disorders. Insomnia can be defined as difficulty falling asleep and staying asleep, waking up too early, and having poor sleep quality. Insomnia is common in the general population with an estimate that approximately 30% of the population reports at least one insomnia symptom (Sateia et al., 2000). There is a striking difference in men and

women with respect to the occurrence of insomnia: women are nearly twice as likely to report insomnia compared to men, and the risk of reporting insomnia increases with age. In fact women have a 40% greater risk for insomnia in their lifetime compared to men (Mong and Cusmano, 2016). This predisposition for women to have insomnia has been found consistently across studies. Interestingly, the sex difference in the number of complaints about poor sleep and insomnia in women begins at puberty, suggesting that ovarian hormones may be playing a role in this perception.

There are self-reported sleep disruptions that occur during the menstrual cycle, pregnancy, postpartum period, and when women are experiencing the transition to menopause. Sleep disturbances can have a significant impact on quality of life, mood, and health thus identifying how they may occur could lead to therapies. We have already discussed the findings that sleep is more disrupted in the luteal phase of the menstrual cycle. In pregnant women, subjective data indicates total sleep time increases in the first trimester but is dramatically reduced in the third trimester. Women in the last trimester also have more nighttime awakenings (Salari et al., 2021). This disrupted sleep is related, in part, to discomfort due to an increase in pain or decrease in bladder volume. However, treating insomnia in the third trimester can help alleviate postpartum depression (Khazaie et al., 2013). Objective measures of sleep using polysomnography confirmed that sleep variables are changed in pregnant women. Pregnant women had less total sleep, a longer latency to fall asleep, more awakenings, and less slow wave sleep. In the initial postpartum period sleep was significantly disrupted with total sleep time at night being reduced but there was an increase in daytime napping. As the postpartum period progresses, however, sleep quality does improve somewhat. Clearly, there are many factors influencing sleep during pregnancy including the dramatic shift in hormones, the physical discomfort experienced, and the needs of a newborn.

In menopausal women, the decline in sleep quality is one of the most common and problematic symptoms that women report. In this population, declining concentrations of estradiol and rising levels of follicular stimulating hormone are associated with more frequent awakenings and reduced sleep quality. While endocrine changes are likely playing a role in the sex differences seen in insomnia prevalence in all stages of life, we cannot rule out the influence of other factors including aging, quality of health, anxiety, depression, and hot flashes.

In conclusion, there is evidence that sleep in healthy individuals is regulated in part by circulating gonadal hormones and changes in hormones across the lifespan may contribute to sex differences observed in insomnia.

3.1.5: Disorders of Sleep and Circadian Rhythms

Learning Objectives

By the end of this section, you should be able to

- 15.4.1 Describe how damage to the retinal input pathway to the SCN can lead to problems with entrainment.
- 15.4.2 Describe the difference between narcolepsy, non-24 sleep/wake disorder, and delayed sleep-wake phase disorder.
- 15.4.3 Describe how an understanding of the timekeeping system helps one develop therapies for sleep or circadian disorders.

Inadequate or disrupted sleep is increasingly being recognized as a serious public health issue (Medic et al., 2017), impacting tens of millions of people in the U.S. alone. There are a wide variety of sleep disorders, which have physiological consequences on their own as well as exacerbating comorbid conditions. Disruption of sleep can come in a variety of forms, including inadequate duration, fragmentation of sleep periods, sleepiness at inappropriate times of day, and inability to fall asleep at a time that fits an individual's lifestyle. Disruption of sleep or circadian rhythms can be conditions on their own, or be comorbid with diseases or other disorders. Examples include Alzheimer's disease and Parkinson's disease (Ju et al., 2017). We have already heard about insomnia, so here we will expand on some other conditions.

Non-24 hour Sleep/wake Disorder

Normally, internal rhythms are synchronized to the external environment through the process of entrainment. An organism's internal clock naturally has a period that might be slightly less than or greater than 24 hours, but is kept synchronized to the 24-hour rotational period of the earth by photic cues present in the daily light/dark cycle. In humans, it is possible that internal (endogenous) rhythms do not get properly synchronized to the 24-hour day (exogenous rhythms). When this happens, the symptoms of non-24 hour sleep/wake disorder can manifest. Non-24 hour sleep/wake disorder is most commonly caused by blindness; in fact it occurs in greater than 50% of all blind people. This condition can occur in people that have blindness caused by the loss of the eye or damage to the retina and the photosensitive retinal ganglion cells (ipRGCs). This damage would eliminate any perception of light and darkness and would prevent such signals from reaching the SCN. If the clock can't set itself to daily cycles of light and darkness, then the body's internal clock remains cyclic but gradually drifts out of phase with the normal light and dark cycle of the day. This is referred to as free-running when the internal and external rhythms are not synchronized. As a result, a person may desire to sleep at 10:30pm, but their internal clock may interpret the time as 3:00pm. As such, they will find it difficult to sleep at bedtime and they may remain alert despite the clock time. If they have school, or a job, that requires them to be active at a consistent time each day, they may find that they are excessively tired due to sleep deprivation. Over the long term, such a condition can also lead to other health problems, including depression. Attempts to use alternative mechanisms to entrain, such as forced sleep schedules or exercise, are not very successful. Non-24 hour sleep/wake disorder is often treated with melatonin or drugs that act on melatonin receptors.

Narcolepsy

Narcolepsy is a sleep disorder in which people feel excessively sleepy at inopportune times throughout the day, even after adequate nocturnal sleep. People can fall asleep even while engaging in activities such as eating or driving, and the normal structure of sleep stages are altered, with an unusually rapid entry into the phase of REM sleep. Figure 15.18 shows polysomnograms of someone with narcolepsy during night sleep and daytime naps where you can see this rapid REM entry along with frequent night wakenings.

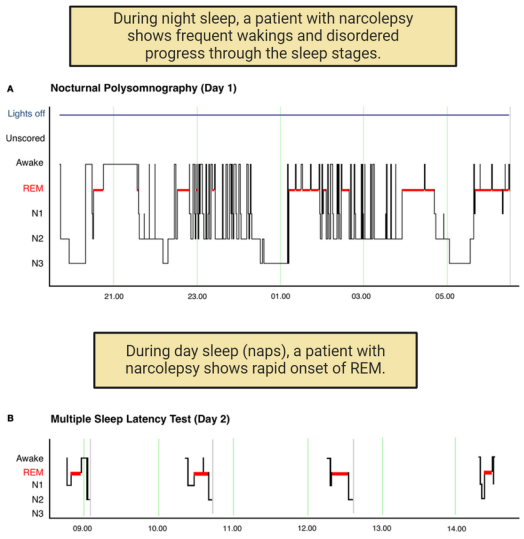

Figure 15.18 Hypnogram of narcolepsy Image credit: Hypnograms from: Rosch RE, Farquhar M, Gringras P and Pal DK (2016) Narcolepsy Following Yellow Fever Vaccination: A Case Report. Front. Neurol. 7:130. doi: 10.3389/fneur.2016.00130. CC BY

Narcolepsy is characterized by 1) excessive daytime sleepiness, 2) a reduction or loss of muscle tone which is known as cataplexy, 3) visual and auditory hallucinations at the time of waking or falling asleep, and 4) sleep paralysis which is a temporary period in which you cannot move or speak. This occurs at waking or onset of sleeping (Tisdale, Yamanaka, and Kilduff; 2021). Narcolepsy is often treated with stimulants and lifestyle adjustments.

One type of narcolepsy is caused by specific gene mutations that alter a neuropeptide called orexin or its receptor. Orexins, also known as hypocretins, are hypothalamic-specific peptides found in the lateral hypothalamus and surrounding nuclei, and have primarily excitatory effects on neurons. They appear to be important in gating the transition between the waking and sleep states, such that when the system is defective it becomes more difficult to sustain wakefulness. Evidence in support of the important role of orexins in this condition comes from animal studies. Mice missing the gene for orexins or its receptors show narcolepsy-like symptoms, and narcolepsy in dogs is the result of a mutation in the orexin receptor 2 gene (Hypocretin receptor 2).

Narcolepsy in Dogs

How did Doberman dogs help sleep research? Narcolepsy was first described in the medical literature in 1877 and 1880 (Mignot, 2014) but it wasn't until the 1980s that scientists began to identify molecular factors that may be playing a role. The Stanford University Sleep Disorders Clinic was studying people with narcolepsy and other diseases in the 1970s. At that time, researchers were also traveling to veterinary colleges and visiting with veterinarians in order to identify dogs that had narcolepsy. A colony of dogs including Beagles and Poodles was established but the researchers were unable to successfully breed additional dogs with the disease. In 1975, they acquired Dobermans that had episodes that resembled human narcolepsy. Furthermore, they were successful at breeding these animals and thus generated more dogs that also expressed narcoleptic-like symptoms (Mignot, 2014). Beginning in the late 1980s, the researchers applied numerous genetic techniques to identify candidate genes for narcolepsy in canines. Finally, in 1999, the team determined that canine narcolepsy was caused by a mutation in the hypocretin receptor 2 gene (HcrtR2). After learning that the hypocretin/orexin system is important to sleep regulation, additional studies were undertaken in human narcoleptic samples. A study in narcoleptic people found that 7 of 9 patients had undetectable levels of the peptide hypocretin 1 in their cerebrospinal fluid, (Nishino et al., 2000) and in samples of postmortem brain tissue, a loss of hypocretin/orexin was found in narcoleptic patients (Peyron et al., 2000). Thus, animal research, particularly in dogs, helped move the field of sleep research forward. A short video describing some of this work in dogs can be found here.

Delayed Sleep-Wake Phase Disorder (DSWPD)

In delayed sleep-wake phase disorder (DSWPD) an individual has difficulty falling asleep at socially appropriate and/or desired times. For example, a person might need to go to bed at 11 pm so that they can get enough sleep for school or work the following

day. However, an individual with DSWPD struggles to fall asleep or wake up at the correct times of day. Sleep in individuals with DSWPD is delayed 2-6 hours later than conventional bed times (Micic et al., 2016). The amount of sleep is compromised, and, when they do wake up, they have sleep inertia or decreased alertness and excessive daytime sleepiness. To diagnose this condition, a patient must keep a prospective sleep diary for at least 7 days and have a discussion with a doctor. In some cases, a patient may wear a wrist device that records the timing of their sleep schedule. This condition may be diagnosed as insomnia. However, if the individual is allowed to set their own sleep and wake schedule then they have no trouble falling asleep or staying asleep, they have normal sleep quality, and they have no daytime sleepiness (Meyer et al., 2022). Thus, it appears that an individual with DSWPD has a circadian rhythm that is delayed relative to the environmental light cycle. The prevalence of this disease is estimated between 0.17-1.54% in children and in adolescent and young adults this can increase to 3.3%-7.3%. However, only about 0.7% of middle aged patients are diagnosed with this disease (Micec et al., 2016). This increase in the number of teenagers that are diagnosed with DSWPD maps onto the "night owl" chronotype that begins to emerge at adolescence (Meyer et al., 2022). While an advancement in the timing of circadian rhythms typically occurs in individuals as they progress through adulthood, some people will retain this significant delay in the timing of their sleep onset. DSWPD can be treated by addressing the underlying biological clock. Specifically, treatments include melatonin, bright light therapy, and light avoidance through the use of blue light blocking glasses at specific times of the day. However, more treatments need to be developed.

3.1.6: Circadian Rhythms and Society

Learning Objectives

By the end of this section, you should be able to

- 15.5.1 Describe how human biological rhythms of individuals intersect with societal demands and policies.
- 15.5.2 Describe how deficits in sleep impact on different measures of human performance.
- 15.5.3 Describe how knowledge of biological rhythms of diseases has influenced how we develop therapeutics (chronotherapeutics).

Our biological rhythms can influence our ability to work at certain times of day, the effectiveness of medication, our health, societal practices such as daylight savings time, and educational policies. Disruptions to rhythms such as sleep deprivation have consequences to our health and society.

Daylight Savings Time

In the United States, Canada, Australia, the United Kingdom and the European Union, there is a practice to advance clocks by 1 hour during the warmer months. In the US, we refer to this as Daylight Savings Time (DST) and the concept is to align human activities (and the time on their watch) to the presence of daylight. The change in clock time results in people waking up an hour earlier and conducting their work during an additional daylight hour during the summer. In the cooler months, we return the clocks back to Standard Time.

Recently there has been much debate about DST and its consequences on human health and society. There are numerous reports that in the days following the transition to DST, there is an increase in ischemic strokes and myocardial infarction compared to the week before the time change (Sipila et al., 2016). Following the DST change, there is also a 6% increase in fatal traffic accidents, with the largest increases occurring in the morning hours, although this impact on traffic has not been found in all studies (Fritz et al., 2020). There is also an increase in workplace injuries. The underlying cause for these health consequences and increased risk of accidents is likely due to sleep deprivation. The DST transition typically results in 40 min less sleep the following day and this results in a decrease in sleep quality, fatigue, and a decrease in vigilance. As a result of these negative consequences, there are position statements from the Society for Biological Rhythms and the American Academy of Sleep Medicine that support abolishing DST and maintaining our watches on Standard Time, based on the idea that this clock time best matches the time of day represented by the sun.

Shift Work

In our modern society, shift work has become a necessity and between 18 and 26% of the United States population (26-38 million people) participates in shift work. Shift work can be defined as any work that occurs outside the hours of 7 am to 6 pm. Shift workers are thus working at times when their internal biological clock says they should be sleeping. People work around the clock in transportation and airline travel, health care and medicine, security, hospitality, and manufacturing. Shift work schedules vary widely. Some people may be on a regular schedule even if those working hours occur at night or very early morning; some individuals may have a rotating schedule where they work night shifts in some weeks and day shifts in others. Shift workers are at a higher risk than the general population for a variety of diseases including obesity, metabolic disorder, cancer, insulin resistance, heart disease, and systemic inflammation.

The misalignment between scheduled work times and the internal rhythms may result in restricted sleep times. This sleep deprivation can result in consequences on the job including increased fatigue, decreased alertness, and cognitive decline. This can lead to an increase in mistakes and accidents that occur on the job. One estimate is that night shift workers have a 30-50% increase in the chance of having an accident in the workplace compared to workers on other shifts. Furthermore, night shift workers are significantly more likely to have a fatal accident at their place of employment compared to non-night shift workers (Harrison, 2013).

Endocrine rhythms are also misaligned in shift workers. Normally cortisol (a stress hormone, see Chapter 12 Stress) has a surge

at the beginning of the day and melatonin peaks at night during the dark. These rhythms in hormone secretions are reduced in amplitude or their pattern is altered in shift workers. In fact, there is no sign that these rhythms adapt to the shift work schedule and thus the peak of melatonin, even though reduced, still occurs during the night shift while the individual is at work.

In addition to sleep deprivation, another consideration of shift work is that meals are mistimed relative to internal rhythms. In simulated night shifts in a lab setting, in human studies with light at night, or in studies of a cross section of shift workers, there is increased insulin and disrupted leptin concentrations (see Chapter 16 Homeostasis). The alterations in these hormones can even be detected when the blood is sampled on a day when the individual is not working. These critical hormones are associated with metabolism, glucose homeostasis, and food intake. In animal studies where they model circadian misalignment, these results are duplicated and mice with perturbed rhythms have an increased body weight and altered leptin concentrations. These disruptions to metabolism may be an important factor underlying the increased risk of metabolic disease and obesity that occurs in populations of shift workers.

Sleep Schedules and School Start Times for Adolescents

What time did you wake up to go to High School? What time did school begin? Chances are that your school started between 7 and 8:30 am. In fact, a report by the National Center for Education Statistics finds that over 80% of public high schools in the United States have a start time before 8:30 am (Sawyer & Taie, 2020). Despite having to wake up early for school, teenagers tend to fall asleep relatively late due to underlying circadian biology, homework requirements, job and sports schedules, and distractions from screens. These late bedtimes and early school times mean that teens are not getting enough sleep. A National Sleep Foundation study reveals 56% of teens age 15-17 get less than 7 hours of sleep a night (NSF, 2014). Teens with sleep deprivation experience higher rates of depression, obesity, and daytime sleepiness as well as having lower grades and reduced alertness in school. To increase the amount of sleep teens are getting, The American Academy of Pediatrics and The American Academy of Sleep Medicine recommend that school start times occur at 8:30 am or later. School districts that have adopted a later start time have seen benefits such as improved grades, increased attendance, and reduced tardiness (Dunster et al., 2018). In fact, one school county found that starting school 1 hour later resulted in a greater than 16% reduction in motor vehicle accidents involving teens (Danner and Phillips, 2008). In July of 2022, California passed a law requiring that middle schools start no earlier than 8 am and high schools start no earlier than 8:30 am. Florida passed a similar law in 2023 that will go into effect in 2026. This movement to delay school start times in order to improve student wellbeing is gaining traction. As of May 2023, an additional eight states are considering laws to move school start times later. To read more about these laws, read these press releases.

Long Term Impact of Sleep Deficits on Health

Chronic sleep deprivation refers to a state in which an individual has an insufficient amount of sleep over an extended period of time. According to the American Academy of Sleep Medicine, sleep deprivation becomes chronic when the period of insufficient sleep persists for more than three months. Chronic sleep deficiency is another term that includes sleep deprivation but also covers the case where sleep is fragmented or otherwise disrupted. Such conditions have a direct impact on both cognitive and physical performance and can contribute to an elevated risk of a wide variety of disorders from diabetes to elevated pain sensitivity to several mental health disorders. Fortunately, many types of sleep disorders that cause sleep deprivation or insufficiency are treatable through behavioral interventions.

Naps as Therapy

One theme of this chapter is how disruptions to your circadian clock or sleep cycle can have a negative impact on your health. Can napping during the day alleviate some of these issues? There is a change in the amount of napping which occurs across the lifespan and a change in the type of sleep that occurs during the nap. In infants, naps resemble nighttime sleep because they both contain REM sleep. Naps in young children consist of more non-REM sleep than REM sleep. In young adults, longer naps will contain both REM and non-REM sleep; however naps in older adults consist of lighter sleep stages with a bout of slow wave sleep (non REM stage 3). Napping can be done to counteract sleepiness or recuperate from a reduction in sleep, in anticipation of extended sleep loss such as might occur with a night shift worker, or just for enjoyment or boredom.

There are many documented benefits to naps, with the first being that napping reduces the homeostatic sleep pressure that accumulates with wakefulness. Individuals that nap have both objective and subjective improvement in alertness, enhanced cognition, improved short term memory, and improved mood. The best time to take a nap is in the early afternoon, between 1 and

3 pm (Dutheil et al., 2021). Naps later than this can interfere with your ability to fall asleep that evening. There is an effect of nap duration on cognitive function after waking. If you take a nap in the afternoon following a normal night of sleep then a short nap is beneficial. Specifically, naps 10-30 min long result in an immediate improvement in alertness and performance on cognitive tasks upon awakening and this effect can last for up to 2 hours (Leong et al., 2023). These shorter naps typically contain stage 1 and stage 2 non-REM sleep. However, longer naps, particularly those that contain slow wave sleep (stage 3 non-REM sleep), result in an initial decrease in alertness that is described as sleep inertia. This grogginess upon waking is associated with a decline in motor performance, cognition, and mood and may last between 30 and 60 minutes. However, after this period passes, there is an increase in alertness and a decrease in fatigue that lasts for several hours. Additionally, longer naps may be more beneficial in individuals that are experiencing sleep deprivation.

Sleep Hygiene and College Students

Being a young adult is an exciting and stressful time with educational, extracurricular, work, and social opportunities. As a result, it may be hard to find the time to get everything accomplished without sacrificing some sleep. In fact, college-aged individuals require about 8-9 hours of sleep a night but between 70-96% report getting less than 8 hours a night. Around 50% of college students report excessive daytime fatigue and sleepiness at least 3 times a week. This sleepiness can be caused by acute lapses in sleep ("all nighters") or chronic partial sleep deprivation. Partial sleep deprivation occurs when students routinely get less sleep than they require, for example college students report getting between 5.7-6.5 hours a night.

What is the consequence of eliminating sleep that you need? It's unlikely that the occasional all-nighter will have significant consequences, but being chronically tired and not getting enough sleep can be detrimental to academic success and mood. For example, students that had a total sleep time of 9 or more hours had an average GPA of 3.24 whereas those with 6 hours or less a night had an average GPA of 2.74 (Kelly, Kelly, and Clanton, 2001). In other studies, sleep patterns played a larger role than total sleep time. Specifically, later bedtimes or later wake up times were associated with lower GPAs (Trockel, Barnes, and Egget, 2000). There is also a relationship between irregular sleep patterns, poor sleep quality and increased anxiety symptoms in university students. In a study of 462 university students, insomnia severity was associated with anxiety severity (Choueiry et al., 2016). Furthermore, when colleges have wellness classes or incentive programs that improve the amount of sleep and sleep schedule, anxiety decreases, and grades improve or stay the same, indicating that students can increase their sleep while maintaining their same GPA.

You can take daytime and evening steps to promote healthy sleep. This is called sleep hygiene. These steps include having a consistent bedtime and wake time, resisting the use of screens in the hour before bed as the blue light emitted by your phone can disrupt your circadian clock, having a period of time before bed where you wind down and relax, and maintaining a dark and cool bedroom. If you have a roommate, this can be difficult but you can try earplugs and eye masks to help. It is also advised that you are careful with alcohol and caffeine use. Alcohol can help you fall asleep but disrupts your restorative sleep, and studies show that caffeine use even 6 hours before bedtime causes problems with sleep quality.

Social Jetlag

As we have described in a previous section, people can exhibit chronotypes such as "night owl" or "lark". These preferences for specific times for sleep/activity can be in conflict with external timing requirements such as work and school. Social jetlag occurs when an individual fits their sleep/wake schedule to match their requirements during the week, but then they allow their internal clock to dictate their sleep/wake schedule on weekends (Figure 15.19). There is a discrepancy between the schedule of sleep during the week and weekend. For example, a college student may get up at 9 am and go to bed at midnight Sunday-Thursday. But on Friday and Saturday they may stay awake until 2 am and get up at 11 am. When Monday morning rolls around, the student would have to readjust their schedule again and wake up 2 hours sooner than they would prefer, as if they were adapting to a new time zone. This phenomena can be worse in night owl chronotypes, as they may experience difficulty falling asleep early, yet they still have to wake up early for school or work.

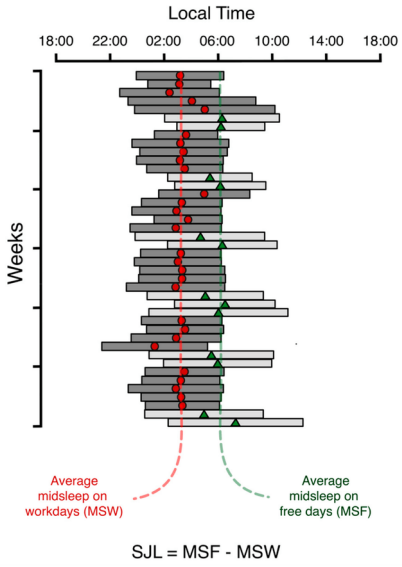

Figure 15.19 Social jet lag Sleep timing varies by days of the week in humans. Image credit: Roenneberg et al., 2019, "Chronotype and social jetlag: A (self-) critical review." Biology, 8(3), 54. https://doi.org/10.3390/biology8030054. CC BY 4.0

Social jet lag can generate poor sleep quality and chronic partial sleep deprivation. As a result, people experiencing social jet lag have reduced attention, increased fatigue, and poor performance at school or work. A variety of studies also find that people experiencing social jet lag have an association with obesity, diabetes, and depression as well as risk factors for metabolic disorder such as high total cholesterol and triglycerides (Castilhoa Beauvalet et al., 2017). As described above, getting healthy sleep on a consistent schedule is key to helping correct social jet lag.

Chronotherapeutics

Chronotherapy, also called chronomedicine, is based on the idea that medicine may be more effective, have fewer side effects, and have higher tolerability, if it is administered at an optimal time of day matching the rhythms of the disease. As we have emphasized throughout this chapter, physiology has many daily rhythms as seen in biochemical reactions, gene changes, and hormone secretion patterns. It makes sense that medication should be administered at a time of day when disease symptoms are expressed at their highest levels. Furthermore, there is evidence that people with consistent and strong circadian rhythms are more likely to have better health than those with rhythms that are disrupted or have low amplitude rhythms. Strengthening rhythms in sleep/wake cycles, mealtimes, or endocrine secretion patterns such as melatonin signaling can reduce health problems and improve health.

Asthma and Bronchodilators

Asthma is a chronic disease characterized by difficulty breathing caused by inflammation and constriction of the airways. Up to 75% of asthma sufferers have "nocturnal asthma" where they report having more significant symptoms during the nighttime hours. Sometimes these symptoms cause disruptions to sleep. Studies of asthma sufferers in the lab reveals that there is a circadian rhythm in pulmonary function, airway resistance, and airway inflammation independent from the influence of sleep, posture, or locomotor activity. Further, there is a daily rhythm in discomfort which peaks at night which corresponds to the daily rhythm in the use of rescue-based inhalers at this time (Litinski, Scheer, and Shea, 2009). In addition to rescue inhalers, people with asthma may also be prescribed a once-daily use of inhaled corticosteroids to help with airflow. In a large meta-analysis of over 1200 patients, it was found that use of this treatment at night led to better pulmonary function compared to use of it in the morning (Song, Park, and Lee, 2018). Asthma is just one example of how therapies for ailments can be optimized by basing the timing of delivery on biological rhythms.

Cancer Therapies

Circadian rhythms have a bidirectional relationship with the development and growth of cancers. Epidemiological studies in humans and laboratory studies using rodent models have linked circadian disruptions to cancer. In fact, this link of disruption of

your clock to cancer prevalence led to the World Health Organization to declare shift work as a "likely carcinogen". In humans, chronic jet lag, shift work, or exposure to light at night are associated with an increased risk for many types of cancer including colon, breast, prostate, and lung. Humans with polymorphisms in the clock genes *Clock* and *Bmal1* have increased susceptibility to certain types of cancers. In animal studies, circadian rhythm disruption can be induced by lesioning the SCN or putting animals in chronic jet lag conditions. When these mice are inoculated with cancer cells that develop into a tumor, the tumor grows both faster and larger in the animals with circadian perturbations. Similarly, mice with mutations in clock related genes also have an increased susceptibility to spontaneous cancers and radiation induced cancers.

Treatment of cancer can be improved by incorporating circadian rhythms into the therapy. Patients that maintain more regular daily patterns of activity have a longer survival rate, and respond to drug treatment better than those with disrupted daily rhythms. In patients with colorectal cancer, time of day of administration of the chemotherapy drug influenced the efficacy of the treatment as well as the ability of the patient to tolerate high doses of the drug (Levi et al., 1994). Interestingly, the time of day of drug effectiveness varies for each drug. Understanding circadian biology of the patient, tumor cell type, and medication effectiveness can be used to tailor cancer therapy that has the maximal anticancer effects, the lowest side effects, and a resultant increase in survival rates.

Endogenous biological rhythms are found in nearly every organism on the planet. Internal clocks can help an organism anticipate changes in their environment. There are many types of biological rhythms that can range from seconds to hours to years; circadian rhythms are those that take about 24 hours to complete a cycle. We can characterize the components of a rhythm by analyzing their period, phase, amplitude, mesor and frequency. Furthermore, we can determine how an internal clock responds to the environment by constructing a phase response curve.

15.2 Where Are Rhythms in the Brain?

Your brain contains a master clock which regulates your daily rhythms from your gene and protein changes in cells to your sleep patterns. In mammals, this clock is found in the SCN, a collection of cells that express clock genes, neurotransmitters and neuropeptides. Elegant lesion and replacement experiments established the SCN as the site of the master clock. The retina sends information to the SCN via a number of connecting pathways, including ipRGCs that contain melanopsin. The SCN also expresses clock genes that have a feedback loop that regulates daily rhythms. There is a diversity of species that exhibit biological rhythms, and thus additional research is needed to determine when, how, and why these rhythmic processes emerged.

15.3 Regulation of Sleep

There are several overlapping hypotheses for why sleep exists including energy conservation, restoration of energy, and aiding growth and development. Sleep can be measured in the lab using a PSG which detects changes in the phases of sleep. There are non-REM (3 stages) and REM sleep stages that are differentiated by different types of brain wave activity patterns. The flip flop model of sleep-promoting neurons in the VLPO have a mutual inhibition with wake promoting cell populations in the brainstem and hypothalamus. This is referred to as a flip flop switch and is maintained in part by a variety of neurotransmitters including acetylcholine, norepinephrine, serotonin and GABA. Finally, there are sex differences in sleep that may be influenced in part by circulating hormones.

15.4 Disorders of Sleep and Circadian Rhythms

Disorders of sleep and circadian rhythms can have a serious impact on the lives of those suffering from such conditions. Such conditions are common but often go untreated. Examples discussed in more detail are non-24 hour sleep/wake disorder, narcolepsy, and delayed sleep-wake phase syndrome.

15.5 Circadian Rhythms and Society

We can become sleep deprived due to shift work, daylight savings time changes, or reducing our sleep to gain study time. Sleep deprivation and disruptions to the circadian system can have a major negative impact on human health, but treatment of many conditions is effective through behavioral interventions. Furthermore, relief of circadian and sleep symptoms can contribute to improvement in underlying comorbid conditions.

3.1.8: Key Terms

15.1 What Are Circadian Rhythms?

Chronobiology, circadian, ultradian, circatidal, infradian, circannual, circalunar, rhythm, period, phase, phase difference, amplitude, mesor, frequency, endogenous, exogenous, free running, entrainment, chronotype, sleep hygiene, subjective day, subjective night, phase response curve, dead zone, diurnal, nocturnal

15.2 Where Are Rhythms in the Brain?

suprachiasmatic nucleus, photoreceptors, intrinsically photosensitive retinal ganglion cells (ipRGCs), retinohypothalamic tract, melanopsin, arrhythmic, geniculo-hypothalamic tract, nonphotic, retinorecipient core, rhythmic shell, melatonin, transcription/translation feedback loop, clock genes, heterodimerize, translocate

15.3 Regulation of Sleep

Process C, Process S, homeostatic, glymphatic system, Polysomnography, electroencephalography, electrooculography, Rapid Eye Movement Sleep (REM), electromyography, non-REM (NREM), Stage 1 non-REM, Stage 2 non-REM, Stage 3 non-REM, sleep spindles, delta sleep, slow wave sleep, delta waves, flip flop switch, insomnia

15.4 Disorders of Sleep and Circadian Rhythms

non-24 hour sleep-wake disorder, narcolepsy, cataplexy, sleep paralysis, orexin, delayed sleep wake phase disorder, sleep inertia

15.5 Circadian Rhythms and Society

Daylight savings time, shift work, chronic sleep deprivation, chronic sleep deficiency, sleep hygiene, social jet lag, chronotherapeutics, chronomedicine

This page titled 3.1.8: Key Terms is shared under a CC BY-NC 4.0 license and was authored, remixed, and/or curated by Ivette Merced via source content that was edited to the style and standards of the LibreTexts platform.

3.1.10: Multiple Choice

15.1 What Are Circadian Rhythms?

1.
Female rats have an estrous cycle that determines when they are sexually receptive to a mate. This cycle repeats every ~4 days. What kind of biological rhythm is this?

a. Ultradian
b. Circadian
c. Infradian
d. Circannual

2 .
Biological rhythms can have a period of:

a. a few hours.
b. ~24 hours.
c. more than 24 hours.
d. All of these

3.
Every day, Eli's alarm goes off at 6am. He hits snooze and usually does not wake up until 8am. The 2h difference between his alarm and when Eli wakes up is called a:

a. phase difference.
b. period.
c. amplitude.
d. phase.

4 .
Biological rhythms are regulated by:

a. endogenous cues.
b. exogenous cues.
c. both endogenous and exogenous cues.
d. neither endogenous nor exogenous cues.

5.
When laboratory rodents are shifted to live in constant darkness, they still show a 24h rhythm in their activity levels. We call their rhythm in these conditions:

a. entrained.
b. free-running.
c. chronotype.
d. photically shifted.

6 .
When laboratory rodents are shifted to live in constant darkness, they still show a 24h rhythm in their activity levels. If we were to expose an animal like this to a pulse of light in the first half of their subjective night, what would happen to their activity rhythm?

a. Their activity rhythm would shift earlier a bit
b. Their activity rhythm would shift later a bit
c. Not much would happen
d. Their rhythm would become disorganized

7.
Which of the following species show a circadian rhythm?

a. Rats
b. Bacteria
c. Plants
d. All of these

15.2 Where Are Rhythms in the Brain?

8 .
Entrainment of the biological clock by light requires which of the following?

a. Photoreceptors
b. Intrinsically photosensitive retinal ganglion cells
c. Red light
d. The lateral geniculate nucleus of the thalamus

9.
Imagine a rodent has a small stroke that destroys their bilateral SCN. What would happen to their activity rhythm?

a. Their activity rhythm would shift earlier a bit
b. Their rhythm would continue but would no longer entrain to changes in external light cues
c. Not much would happen
d. Their rhythm would become disorganized

10 .
Increased locomotor activity:

a. increases serotonin release in the raphe nuclei.
b. decreases serotonin release in the raphe nuclei.
c. stimulates the SCN.
d. stimulates intrinsically photosensitive retinal ganglion cells.

11.
Which of these people likely has the highest melatonin levels in their blood?

a. Someone deep asleep in the middle of the night
b. Someone wide awake in the middle of the day
c. Someone taking a late afternoon nap
d. Someone who just woke up in the morning

12 .
Among the Clock genes, high levels of Per and Cry will do what to CLOCK and BMAL1?

a. High Per/Cry will suppress expression of CLOCK and BMAL1
b. High Per/Cry will prevent CLOCK/BMAL1 from binding to Per/Cry promoters
c. High Per/Cry will promote expression of CLOCK and BMAL1
d. High Per/Cry will facilitate CLOCK/BMAL1 binding to Per/Cry promoters

15.3 Regulation of Sleep

13.
Jax has stayed up all night working on an essay for class. The next day, they are exhausted and fall asleep at 9 in the morning. Which process is driving them to sleep?

a. Process C
b. Process S
c. The glymphatic system

d. Metabolic wakefulness

14 .
Sleep is often measured by polysomnography. Which tool used in polysomnography measures brain activity?

a. EOG
b. EMG
c. EEG
d. EKG

15.
During which stage of sleep are frequent eye movements observed?

a. Stage 1
b. Stage 2
c. Stage 3
d. REM

16 .
During which stage of sleep is muscle activity low?

a. Stage 1
b. Stage 3
c. REM
d. All of these

17.
The flip flop switch of sleep-wake systems means that when the pontine peduncular tegmentum (PPT) is active, which system is inhibited?

a. VLPO
b. TMN
c. Raphe nuclei
d. Locus coeruleus

18 .
When a person is asleep, which brain region should be the most active?

a. TMN
b. Raphe nuclei
c. VLPO
d. Locus coeruleus

15.4 Disorders of Sleep and Circadian Rhythms

19.
What is the name of the sleep disorder characterized primarily by a failure to entrain to the 24-hour day?

a. Narcolepsy
b. Non-24hour sleep/wake disorder
c. Laziness
d. Insomnia

20 .
Which of the following is common in narcolepsy?

a. Falling asleep at inopportune times
b. Resolution of symptoms if the patient can set their own sleep and wake times
c. Excessive time in NREM sleep

d. Fewer nighttime awakenings than healthy sleepers

21.
What are things in common between people suffering from narcolepsy and delayed sleep-wake phase disorder?

a. Excessive daytime sleepiness
b. Both suffer primarily from too little sleep
c. Both suffer primarily from disorganized sleep phase progression, falling into REM sleep too rapidly
d. All of these

22 .
Sleep problems can arise from:

a. inadequate sleep time.
b. disorganized sleep phase patterns.
c. inability to fall sleep at socially appropriate times.
d. All of these

15.5 Circadian Rhythms and Society

23.
Which of the following represent good sleep hygiene?

a. Going to bed at the same time every night
b. Using your phone to wind down right before bed
c. Keeping your bedroom warm
d. Having a loud night owl roommate

24 .
What is the term for the negative health consequences of regularly keeping a different sleep schedule on weekends than weekdays?

a. Sleep hygiene
b. Daylight savings time
c. Narcolepsy
d. Social jetlag

3.1.11: Fill in the Blank

15.1 What Are Circadian Rhythms?

1.
The field of _____ studies biological clocks and biological rhythms within an organism.
2 .
Sleep cycles during the night are an example of _____ rhythms and have periods significantly shorter than 24 hours.
3.
_____ is a term used to describe how an organism's internally generated rhythm is synchronized to the rhythms of the external environment.

15.2 Where Are Rhythms in the Brain?

4 .
The _____ of the hypothalamus and is considered to be the master clock of the brain.
5.
In the presence of light, the pineal gland will reduce secretion of _____ into the bloodstream.

15.3 Regulation of Sleep

6 .
Stage _____ non-REM sleep is characterized by deep sleep, muscle relaxation, slowed breathing, and EEG delta waves.

How long can you hold your breath? Most people can comfortably hold their breath for about 30-60 seconds. Trained athletes and people who regularly regulate their breathing (for example, musicians who sing or play wind instruments) can hold their breath for several minutes. The world record for holding the breath is over 20 minutes!

No matter how long you can hold your breath, at some point, everyone feels the overwhelming compulsion to finally breathe in and out. Because all living cells require a steady source of oxygen, animals must constantly measure and maintain optimal internal oxygenation levels to survive. In response to a low oxygenation state, animals engage in response mechanisms to correct for the deficiency—in this case, taking in a deep breath of air.

Indeed, to survive and flourish, all animals must maintain optimal levels of many life-sustaining factors. In addition to oxygen, animals thrive within an optimal temperature range such that they are not too hot or cold. Animals must ingest an optimal amount of calories from food to provide for their daily metabolic energy needs. Animals must also regularly ingest an optimal amount of water to keep their cells and tissues properly hydrated. Failure to obtain appropriate levels of these factors can lead to unhealthy or even lethal outcomes.

Homeostasis (from the Greek roots *homeo*, meaning “similar,” and *stasis*, meaning “stable”) is the maintenance of a stable internal environment. To maintain an optimal range of oxygen, temperature, calories, and water, the nervous system must sense the internal environment and ultimately influence physiology and behavior to motivate an animal to take a breath, to move to a

warmer/cooler environment, to eat a meal, or to take a drink of water (Figure 16.2). Our sensations of being hot/cold, hungry/full, and thirsty/satiated are all manifestations of our central homeostatic systems attempting to keep us alive.

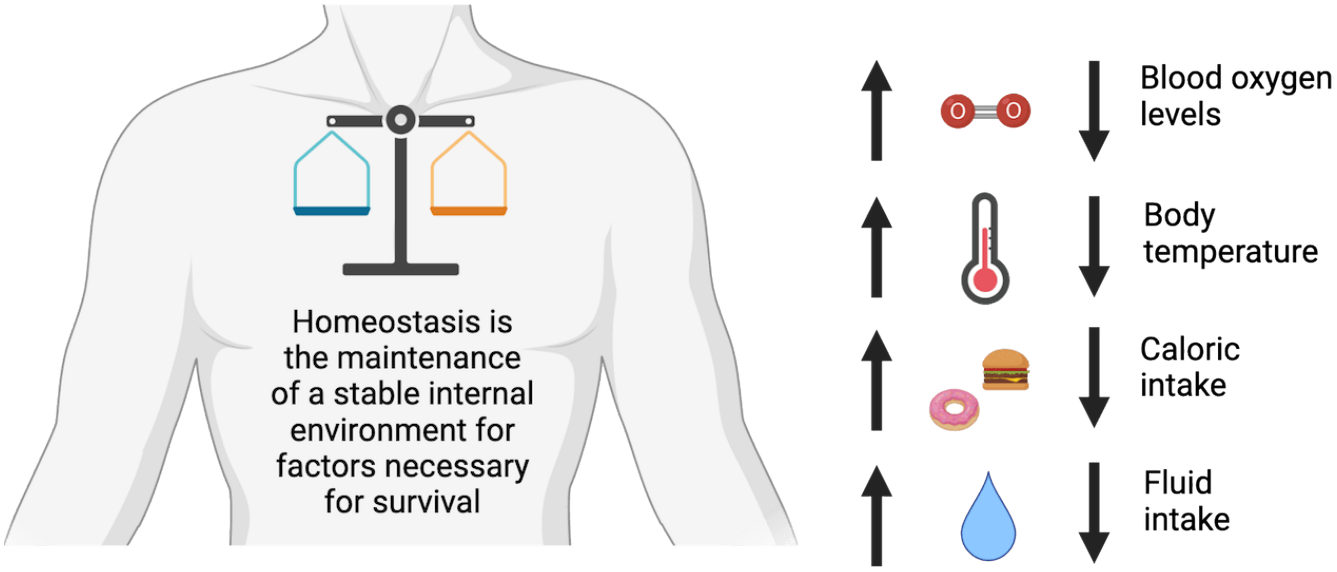

Figure 16.2 Homeostasis

The purpose of this chapter is to describe the neurobiology of homeostasis. First, we will discuss fundamental principles of homeostasis and the general mechanisms by which the nervous system measures and maintains internal states. Then, we will survey the mechanisms by which the nervous system maintains homeostasis for oxygen, temperature, calories, and water. Some behaviors, not described in this chapter, are also homeostatically regulated. For example, sleep (see Chapter 15 Biological Rhythms and Sleep) is a behavior under homeostatic control–the more an animal is sleep deprived, the more the nervous system increases the drive to sleep to make up for the deficiency. In some animals, social behavior is thought to be homeostatic, as isolation from peers for too long produces a stronger desire to engage with others.

In addition to the systems described in this chapter, there are other mammalian homeostatic systems that are not regulated by the nervous system. Instead, these systems are predominantly regulated by endocrine glands throughout the body that release hormones to cause physiological effects. For example, the amount of sugar in the blood (glucose homeostasis) is regulated by the release of the hormones insulin and glucagon from the pancreas. Details on these homeostatic mechanisms can be found elsewhere–for this chapter, we will focus on homeostatic systems regulated by the nervous system.

3.1.13: Principles of Homeostasis

Learning Objectives

By the end of this section, you should be able to

- 16.1.1 Describe the major principles of homeostasis including set points and negative feedback mechanisms.
- 16.1.2 Explain the components of a generic homeostatic system including sensors, control systems, and effectors.

Animals maintain a stable internal environment using multiple homeostatic systems that each regulates a distinct, life-sustaining factor. For example, the neurons and organs that regulate hunger and energy balance are distinct from those that regulate thirst and water balance. Although distinct, these homeostatic control systems all utilize the same fundamental principles.

Homeostatic systems maintain life-sustaining factors at optimal set points

Animals maintain homeostasis for a particular biological parameter by maintaining values at an optimal set point. For example, most humans maintain a blood oxygen level of 75-100 mmHg (the partial pressure of oxygen in the bloodstream), a core body temperature of 37 °C, a caloric intake of 2000-2500 calories per day, and a blood osmolarity of 300 mOsm/L (the concentration of solutes in fluids). Set points are not necessarily a specific value, but rather a narrow range of values by which an animal can survive in good health. Individuals within a species may have slightly different set points based on their genetics and their environment.

Set points for specific factors can change over a 24-hour circadian period. For example, human core body temperature is approximately 36.5 °C at night when we are sleeping compared with 37.5 °C during the day when we are more active (see Chapter 15 Biological Rhythms and Sleep). Set points can also change throughout the life of an animal. For example, as animals develop from juveniles to adults (such as humans during puberty), they require a much higher caloric intake than when they were younger. Later in life, as animals age, metabolism slows down and daily caloric needs decline.

Sometimes, during certain environmental challenges, it is temporarily beneficial to maintain factors outside normal set point values. Allostasis (from the Greek root allo, meaning “other”) is the temporary maintenance of internal physiological conditions outside the normal range. These changes in set points allow an organism to respond to an immediate threat to survival. For example, when we are sick, one response is to develop a “fever” in which our set body temperature increases by 1-2 °C to combat the infection (Figure 16.3). When we experience a stressful environmental condition, such as taking an exam, speaking in front of an audience, or undergoing something truly life-threatening, we undergo a temporary elevation in body temperature and heart rate while simultaneously undergoing a temporary decrease in hunger and thirst (see Chapter 12 Stress). While these allostatic responses help to temporarily persevere against short-term challenges, it is not optimal to be in a state of allostasis for too long. For example, being in a state of chronic stress can ultimately lead to cardiovascular disease and aberrations in body weight.

Figure 16.3 Allostasis example: Fever An increased body temperature can help fight infection, an example of allostasis. Image credit: CDC - www.cdc.gov/vhf/ebola/resour...ographics.html, Public Domain, https://commons.wikimedia.org/w/inde...curid=41517131

Homeostatic systems maintain set points using negative feedback mechanisms

Animals maintain set points by utilizing negative feedback mechanisms. In these systems, a deviation from a set point causes a response that counteracts the change, thereby restoring optimal set point values (Figure 16.4). There are three components of a negative feedback loop: A sensor detects the initial deviation from the normal set point. A control system receives and processes information from the sensors, ultimately causing an effector system to produce a response that counteracts the change.

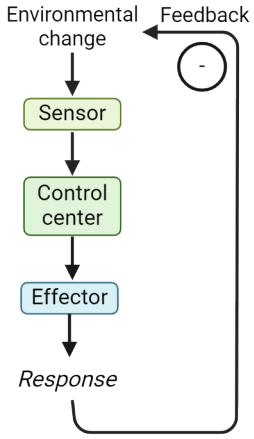

Figure 16.4 Homeostatic negative feedback loop

A familiar example of a negative feedback mechanism is the cooling system of a laptop computer (Figure 16.5). If a laptop becomes too hot, the high temperatures could damage the circuits and hardware. Small thermometers within the laptop serve as sensors, detecting temperatures higher than an optimal value. These thermometers signal to the central processing unit that the computer is too hot. The central processing unit then turns on an effector system—fans within the computer—to blow out the hot air. Once the computer cools down, the thermometers detect the cooler temperatures, the central processing unit turns off the fans, and an optimal temperature is achieved.

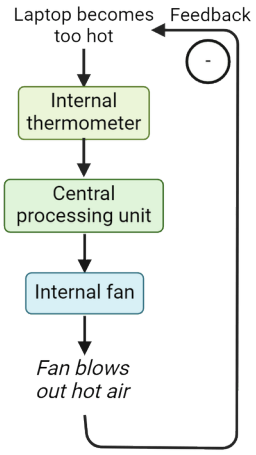

Figure 16.5 Unidirectional negative feedback loop

A computer fan is an example of a unidirectional homeostatic system, a feedback mechanism in which a factor is regulated in only one direction—in this case, whether the computer becomes too hot (but not if the computer becomes too cold). In contrast, bidirectional homeostatic systems regulate deviations from a set point in two directions. For example, consider a home thermostat system that maintains an optimal temperature range so that a home does not become too hot or too cold (Figure 16.6). An increase in temperature is sensed by a thermometer inside the home and is relayed to the control system, the thermostat. The thermostat then causes an effector system, an air conditioner, to blow cool air into the home to decrease the temperature. If the home becomes too cold, this decrease is also detected by a thermometer and relayed to a thermostat. The thermostat responds to this change by turning on the home furnace to increase heat. Therefore, the home thermostat system functions as a bidirectional homeostatic system to keep the temperature within a narrow range.

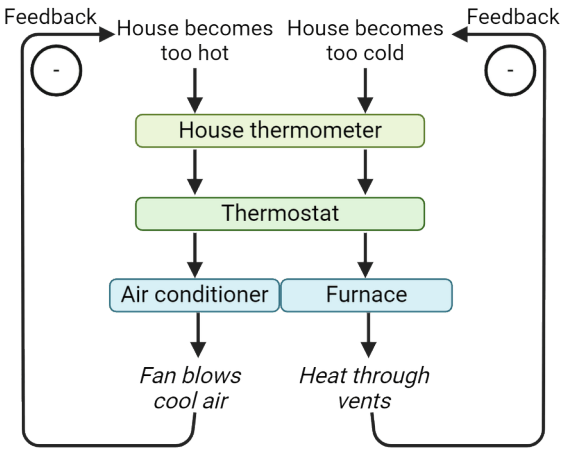

Figure 16.6 Bidirectional negative feedback loop

Just as engineers design unidirectional and bidirectional homeostatic mechanisms in computers, home thermostats, and other technology, animals have evolved homeostatic mechanisms of their own that work in the same way. Instead of electrical circuits in wires, these homeostatic mechanisms depend on neural circuits throughout the brain and body to precisely sense a deviation from a set point, to integrate and process these changes in control systems, and to effect physiological and/or behavioral effector systems to counteract the change.

The nervous system regulates homeostasis using different effector systems

Many homeostatic systems throughout the body, such as those that regulate blood oxygenation levels, body temperature, caloric intake, and fluid intake, are regulated by the nervous system. The challenge for neuroscientists interested in studying the neurobiology of homeostasis is to understand the biological substrates of these homeostatic mechanisms. How do animals sense changes in their internal environments, integrate this information within control centers, and ultimately cause changes in physiology and behavior to maintain homeostasis? What and where are the relevant neurons and cell types, and how do they communicate information with each other?

The nervous system detects changes in set points via sensory cells within the central and peripheral nervous systems (Figure 16.7). These specialized cells express unique ion channels and membrane-bound proteins to detect changes in blood chemistry, body temperature, stretch of visceral organs, blood osmolarity, and hormones released throughout the body. In response to deviation from a set point, these sensory cells communicate with other cells in the brain, typically in the brainstem or hypothalamus, that function as control centers (see Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy). These control centers integrate information and regulate effector systems that counteract the deviation from the set point.

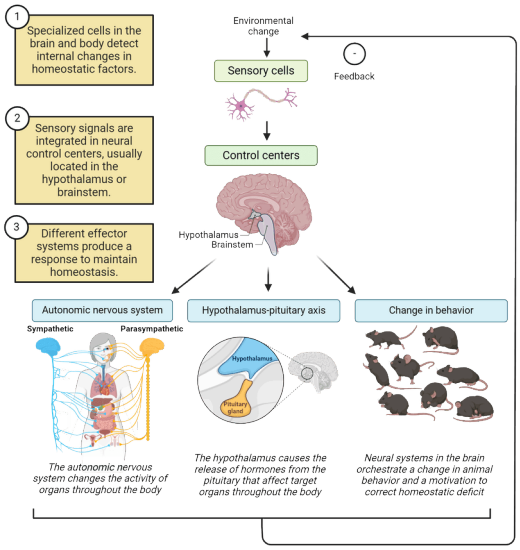

Figure 16.7 Neural mechanisms of homeostasis

In general, these effector systems modulate changes in life-sustaining factors in one of three ways (Figure 16.7):

- Some effector systems cause a physiological change via the autonomic nervous system (see Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy). The autonomic nervous system regulates physiological functions, such as heart rate or respiratory rate, that are typically not under conscious control. The autonomic nervous system can be anatomically and functionally divided into the sympathetic nervous system and the parasympathetic nervous system, two distinct neural networks that often cause opposing effects on target neurons. The sympathetic division typically facilitates an increase in activity necessary for a “fight or flight” response in which an animal is alert and active. For example, when the sympathetic nervous system is preferentially activated, heart rate increases and digestive functions decrease. In contrast, the parasympathetic nervous system typically facilitates a non-emergency, energy-replenishment state that can be characterized as more of a “rest and digest” response, for example by decreasing heart rate and increasing digestion. Therefore, the autonomic nervous system can cause changes in physiological states that affect the maintenance of homeostasis for physiological factors. These changes are often involuntary and automatic, occurring without any conscious realization by the animal undergoing these changes.
- Some effector systems cause a physiological change via the neuroendocrine system. This system causes the release of hormones that affect target organs throughout the brain and body. Most of these hormones are released via the hypothalamus-pituitary system, a parallel series of fibers that originate from the hypothalamus and cause hormone release from the pituitary gland. Like regulation by the autonomic nervous system, homeostatic regulation by the neuroendocrine system is involuntary and unconscious.
- Some effector systems regulate homeostasis by changing motivational drive and animal behavior. For example, if there is

insufficient calories/nutrients or insufficient water within an animal, the nervous system can correct for these deficiencies by increasing the drive for food or water. We describe these increases in motivation as “hunger” and “thirst,” and they ultimately cause a change in behavior that can maintain homeostatic set points. Unlike regulation by the autonomic nervous system and neuroendocrine systems, behavioral responses are voluntary and conscious. Although an animal cannot voluntarily choose to be hungry or thirsty, an animal can choose how to behave during these motivational states. However, the longer the animal goes without eating or drinking, the stronger the motivational drive, and animals gradually feel more uncomfortable until they ultimately act on their homeostatic needs.

3.1.14: Neural Control of Blood Oxygenation Levels

Learning Objectives

By the end of this section, you should be able to

- 16.2.1 Describe the reasons why animals need to maintain homeostasis for blood oxygen and carbon dioxide.
- 16.2.2 Describe the neural components of homeostatic systems that regulate blood oxygenation levels.

Consider some of the changes that occur in your body as you go for a run. Soon after you begin, you feel yourself breathing much faster. Your respiratory rate—the frequency with which you inhale and exhale—increases rapidly. Most people also experience a 2-2.5x increase in heart rate. When you eventually stop running and "catch your breath," your respiratory rate and heart rate slowly return to normal. These increases in respiratory rate and heart rate accompany most forms of physical activity, from aerobic exercise to weightlifting, eventually returning to normal levels at rest.

Vertebrate animals increase respiratory rate and heart rate to increase blood oxygen levels and decrease carbon dioxide. Oxygen is required for cellular respiration, the process by which cells generate energy from the reaction of oxygen with molecules derived from food. Cells that are more active require more oxygen. Skeletal muscle cells, the cells that make up muscles throughout the body under voluntary control, greatly increase their activity during exercise and therefore greatly increase their need for oxygen from the bloodstream. At the same time, they release more carbon dioxide, which the bloodstream circulates to the lungs to exhale.

To ensure an optimal amount of oxygen and swift removal of carbon dioxide, homeostatic mechanisms detect changes in the levels of these gases in the bloodstream and respond by modulating respiratory rate. Increasing the respiratory rate increases the diffusion of oxygen from the air into the lungs and, in turn, the removal of carbon dioxide from the lungs to the air. In parallel, these homeostatic mechanisms also modulate heart rate to increase or decrease the flow of oxygenated blood to cells throughout the body.

Homeostatic regulation of respiratory rate

You're out for a jog and your respiratory rate increases. How does the nervous system measure the need for oxygen and ultimately regulate breathing?

Blood oxygenation levels are indirectly sensed by a population of neurons in the brainstem collectively known as the medullary respiratory control center (MRCC) (Figure 16.8). These neurons do not actually sense oxygen directly—instead, they measure the pH (acidity) of the blood. Why pH? When cells consume more oxygen, they release more carbon dioxide as a waste product. Carbon dioxide is not very soluble in the blood, so it is converted to another molecule called carbonic acid. Therefore, increases in carbon dioxide cause a very slight increase in the acidity of blood, which can be detected by the specialized cells in the MRCC. These cells therefore serve as *sensors* for oxygen homeostasis. The pH scale inversely correlates with acidity–the lower the pH, the more the blood is acidic. Therefore, if the blood becomes slightly more acidic due to an increase in carbonic acid, the pH decreases and activity in MRCC neurons increases.

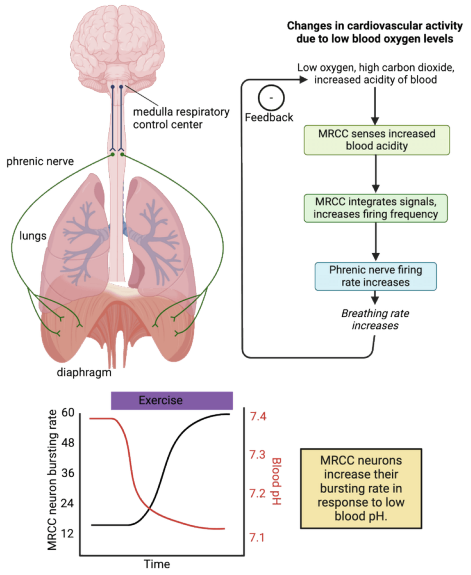

Figure 16.8 Control of blood-oxygen levels by the medullary respiratory control center pH data based on findings of Ball D, Burrows C, Sargeant AJ. Human power output during repeated sprint cycle exercise: the influence of thermal stress. Eur J Appl Physiol Occup Physiol. 1999 Mar;79(4):360-6. doi: 10.1007/s004210050521. PMID: 10090637. https://link.springer.com/content/pd...4210050521.pdf

The MRCC also integrates information from other parts of the brain, such as from neurons that regulate the conscious choice to inhale or exhale. Therefore, the MRCC also serves as a *control center* that ultimately regulates breathing patterns based on the homeostatic need for oxygen and the conscious choice to take a breath. Interestingly, MRCC neurons collectively exhibit a rhythmic, bursting firing pattern of action potentials that correlates with the degree of oxygen in the blood. At rest, the MRCC exhibits bursts of activity approximately 12-16 times per minute. As oxygen levels decline, carbon dioxide levels rise, and the pH of the blood becomes slightly more acidic during a vigorous run, the MRCC oscillatory activity can increase to around 40-60 bursts per minute.

Cells in the MRCC ultimately regulate respiratory rate by releasing neurotransmitter onto specialized *effector* neurons in the spinal cord (Figure 16.8). These neurons, in turn, project axons (in a nerve called the “phrenic nerve”) to muscle cells of the diaphragm. Each time the MRCC neurons exhibit a burst of activity, the diaphragm contracts downward, causing a negative pressure to build in the lungs. This pressure causes an animal to inhale, sucking oxygen-rich air from the environment into the lungs where it can diffuse into the bloodstream. Conversely, when the diaphragm relaxes, it pushes against the lungs, causing an animal to exhale and force carbon dioxide-rich air out to the environment.

Therefore, in response to relatively low blood oxygen levels, the MRCC serves as both sensor and control center to regulate contraction and relaxation of the diaphragm. When blood oxygen levels start to increase, such as at the end of a run, the frequency of MRCC bursting activity decreases, and respiratory rate returns to normal. Changes in respiratory rate can also be observed during a change to high or low altitude. A person who lives at sea level and travels to a high-altitude environment, such as on a ski trip, may exhibit an increased respiratory rate due to a decrease in oxygen at higher elevations. Eventually, over several days, the body compensates in other ways (such as producing more red blood cells, the cells that carry oxygen throughout the body), and respiratory rate returns to normal.

Homeostatic regulation of heart rate

If low blood oxygenation levels only caused an increase in respiratory rate, the blood lining the lungs would become oxygenated much more quickly, but the rate at which this blood was delivered to the cells throughout the body would not be any faster. Therefore, low blood oxygenation levels also cause an increase in heart rate to pump oxygen-rich blood to cells in need.

Low blood oxygen levels affect heart rate by causing a change in neural activity within a population of neurons in the brainstem called the medullary cardiovascular control center (MCCC) (Figure 16.9). These neurons are adjacent to the MRCC, but unlike the MRCC, they do not exhibit a rhythmic firing pattern. Instead, they exhibit a low frequency, stable firing pattern of action potentials at rest. These cells also sense blood oxygen levels indirectly via a change in blood pH. When the blood becomes slightly acidic (the pH decreases) due to decreases in oxygen and increases in carbon dioxide, the MCCC senses these changes, and the action potential firing frequency slightly increases. These cells also receive incoming synaptic input from other areas of the brain that

regulate heart rate, such as populations that regulate wakefulness and stress. For example, the thought of an upcoming exam or public speaking event might cause an increase in heart rate as the body prepares itself to survive the stressor (see Chapter 12 Stress). These MCCC cells therefore serve as both a *sensor* and a *control center* because they integrate information from multiple sources to ultimately affect heart rate.

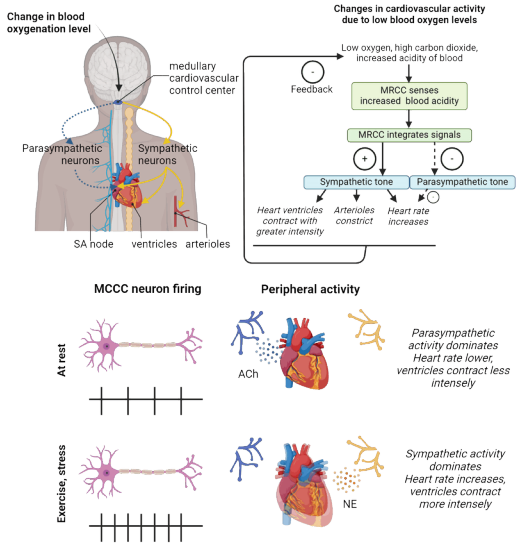

Figure 16.9 Control of heart rate by the medullary cardiovascular control center

MCCC neurons regulate heart rate by controlling the relative activity of sympathetic and parasympathetic nerves that synapse onto the heart (Figure 16.9). The sympathetic nerve releases the neurotransmitter norepinephrine onto the heart and causes an increase in heart rate, an increase in the forcefulness of the heart muscular contractions, and even causes vasoconstriction of arterioles to force more blood into the body. In contrast, the parasympathetic nerve releases the neurotransmitter acetylcholine onto the heart, which decreases heart rate. Therefore, if you go for a run and blood oxygen levels decrease, the MCCC ultimately causes an increase in sympathetic nerve activity and a decrease in parasympathetic nerve activity to increase heart rate. When the run ends and blood oxygen levels are restored, sympathetic tone decreases and parasympathetic tone increases such that heart rate returns to resting levels.

Because the MRCC and MCCC both regulate oxygen homeostasis, an increase in respiratory rate and heart rate almost always coincides. Exceptions can occur if sympathetic or parasympathetic activity changes due to reasons other than fluctuations in blood oxygen levels, such as the allostatic response to stress.

3.1.15: Neural Control of Core Body Temperature

Learning Objectives

By the end of this section, you should be able to

- 16.3.1 Describe the reasons why animals need to maintain homeostasis for core body temperature.
- 16.3.2 Describe the neural components of homeostatic systems that regulate core body temperature.

Although we don't often think about it, modern day humans routinely make behavioral choices to regulate their body temperatures. Our homes and other buildings have thermostats to ensure that our living environments are not too hot or cold. We wear warm jackets in the winter and dress light in the summer—especially in warm places like the beach. We almost always prefer to take warm showers instead of cold showers and enjoy warm visits to the sauna or hot tub. It feels great to warm up with a cup of hot chocolate on a chilly afternoon or to drink a cool glass of lemonade on an especially hot day.

Other animals aren't so lucky—they must generate warmth from their own metabolism and/or find appropriate shelters and life-sustaining environments to meet their thermoregulatory needs. Mammals (including humans), birds, and some species of fish are endotherms, deriving heat primarily from metabolism (Figure 16.10). Producing heat from within the body is energetically "expensive," and therefore endothermic animals need to consume a sufficient amount of calories just to maintain their core body temperatures. Other animals, including lizards, amphibians, and other species of fish, are ectotherms, deriving heat primarily from their environment. They do not need to consume as many calories as endothermic animals with similar body weights, but they tend to stay in places that allow a constant source of heat, such as near a body of water or on structures that face the sun.

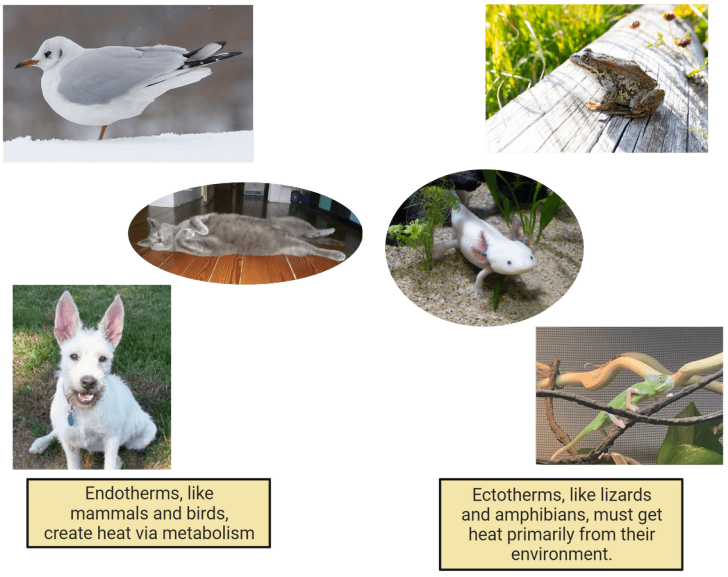

Figure 16.10 Endotherms vs ectotherms Cardinal By Jocelyn Anderson - Imported from 500px (archived version) by the Archive Team. Cat reproduced with permission from Elizabeth Kirby. Dog reproduced with permission from Bryon Smith.

Body temperatures also increase in response to increases in physical activity, such as going for a run or lifting weights. During strenuous physical activity, the body must respond to increases in core body temperatures via changes in physiology and behavior to release excess heat and cool down.

Regulation of core body temperature is highly important for survival. Maintaining core body temperatures within a narrow range is necessary for the structural integrity of cells and optimal biochemical dynamics throughout the body. All animals employ homeostatic mechanisms to ensure that their core body temperatures do not rise or fall outside an optimal range. Mammals

have evolved the ability to sense temperature both throughout their outer body surfaces and within their inner core and, when necessary, engage in a variety of physiological and behavioral mechanisms to restore homeostasis.

Neural sensation of body temperature

The feeling of warmth from sitting by a fire or the feeling of cold from stepping outside on a windy, winter day seems so natural and instinctive… it can be easy to forget that the nervous system must measure these temperatures and cause the sensations of "hot" and "cold." How does the nervous system measure external temperatures?

Specific neurons measure body temperature by expressing specialized ion channels that only open and allow ion flow in response to narrow temperature ranges. These temperature-gated ion channels are a subset of a family of ion channels called "Transient Receptor Potential (TRP)" channels, commonly referred to as thermoTRPs (Figure 16.11) (see Chapter 9 Touch and Pain).

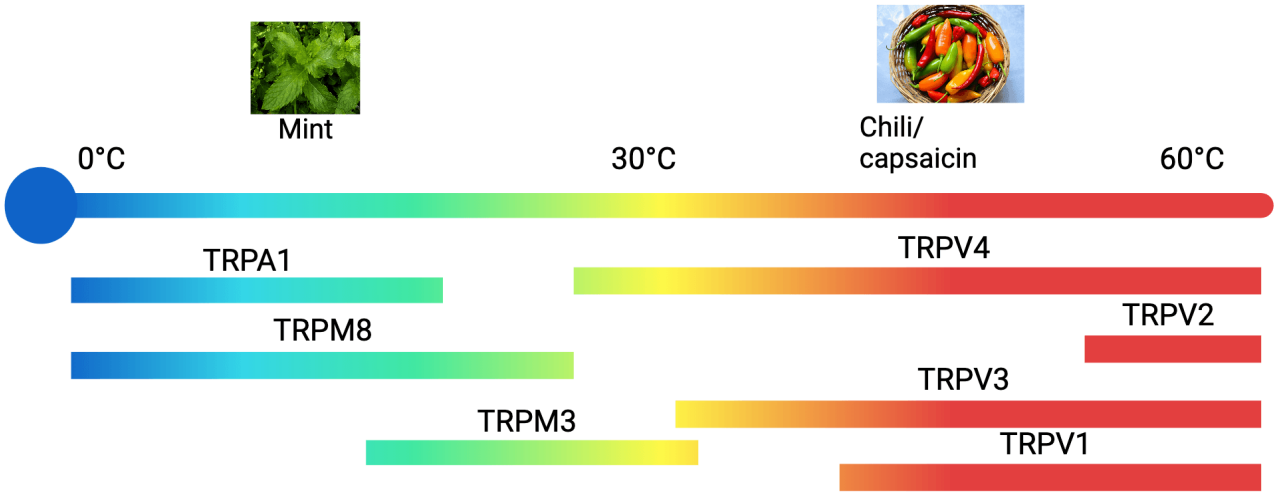

Figure 16.11 TRP ion channels that regulate body temperature TRP ion channels open in response to different ranges of temperature (and some chemicals from plants). Image credit: Mint: By Arjot, CC BY-SA 4.0, https://commons.wikimedia.org/w/inde...curid=92119526. Chili: By Kmtextor, CC BY-SA 4.0, https://commons.wikimedia.org/w/inde...curid=83424742

Once open, these ion channels allow positively charged cations to pass through the membrane and cause depolarization within neurons. For example, the TRPV1 ion channel opens at temperatures around 42 °C. Therefore, neurons that express TRPV1 alert the nervous system that a nearby stimulus is above a core body temperature of 37 °C. In contrast, the TRPM8 ion channel opens in response to temperatures at and below 22 °C, indicating the presence of a stimulus much cooler than core body temperature. Multiple TRP channels have been discovered that exhibit their own temperature ranges for activation, and the combination of these thermoTRPs allow the nervous system to determine environmental and internal temperatures.

Amazingly, many of these TRP channels can also open upon exposure to certain chemical compounds that are naturally produced by plants (see Chapter 8 The Chemical Senses). For example, TRPV1 channels open in response to capsaicin, a chemical naturally produced by chili peppers. Because neurons that express TRPV1 cannot distinguish between a naturally warm stimulus and capsaicin, foods with chili peppers cause the sensation of heat whether they are actually warm or not. Likewise, TRPM8 channels open in response to menthol, a chemical produced naturally in mint leaves. Therefore, foods and products (such as mouthwashes) containing menthol feel cold even if they are at room temperature.

Neural systems that sense and control thermoregulation

Temperature in mammals seems to be sensed via two independent systems. One system senses changes in temperature along the external surface of the body (such as the skin and mouth) and functions primarily in the conscious detection of hot or cold stimuli from the environment. The other system senses changes in core body temperature and functions primarily in regulating the temperature of the internal environment.

Temperature at the body surface is measured by specialized neurons in the dorsal root ganglia (for the lower body) or trigeminal ganglia (for the head). These neurons send sensory projections to the body surface that express thermoTRP ion channels in the skin (Figure 16.12). When specific thermoTRP ion channels open in response to environmental temperatures, the neurons that express them increase action potential firing frequency, ultimately releasing excitatory neurotransmitter onto neurons in the spinal cord. This information is relayed to the somatosensory cortex for the conscious perception of temperature. Using these neural circuits, animals can detect changes in temperature at specific body locations. For example, picking up a hot mug of coffee or a cold glass of water causes the perception of temperature change specifically on the hand. If you step into a warm shower or jump into a cold lake, peripheral sensors will indicate a change in environmental temperature from all over the body surface.

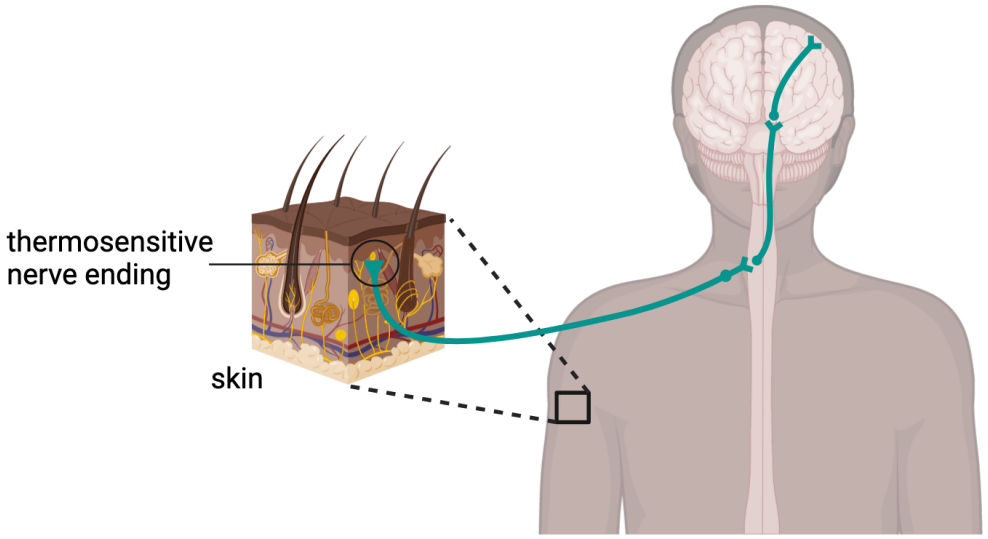

Figure 16.12 Sensation of body temperature in the skin Peripheral nerve endings with thermosensitive channels send information to the spinal cord and then to the brain.

Core body temperature, the temperature of the internal environment of an animal, is measured directly in the brain by neurons in a region of the hypothalamus called the pre-optic area (POA) (Figure 16.13). The POA is sensitive to the temperature of the blood that flows within the blood vessels surrounding these neurons. Because blood travels throughout the internal organs before reaching the POA, the blood temperature within the POA is likely to be indicative of the overall body temperature. Some POA neurons increase action potential frequency in response to relatively warm core body temperatures—the warmer the blood, the greater the action potential frequency. A separate group of POA neurons increase activation in response to colder core body temperatures.

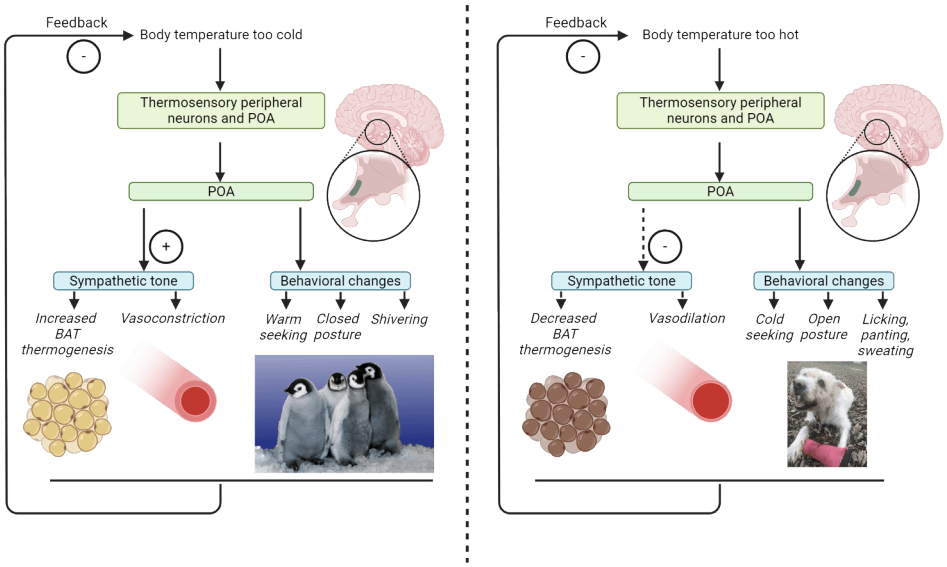

Figure 16.13 Neural regulation of body temperature Penguins image: Image by Struthious Bandersnatch, 1988. Emperor penguin chicks at Sea World, by Jose Lopez Jr. U.S. Air Force, Public Domain; Dog reproduced with permission from Bryon Smith.

Neurons that measure body temperature from specific parts of the periphery also send information to the POA. Therefore, the POA senses information about core body temperature and peripheral body temperatures to ultimately function as a control center that maintains temperature homeostasis. Interestingly, some POA neurons also function in the allostatic increase of body temperature experienced during a fever to overcome a virus or bacterial infection (see the feature box on Investigating allostasis of body temperature during illness).

Effector systems that regulate thermoregulation

If core body temperature deviates from a set point, how does the nervous system cause a change that restores a healthy value? Mammals employ numerous physiological and behavioral mechanisms to regulate body temperature. Both the warm-sensitive and cold-sensitive neurons within the POA project axons throughout the brain that, in response to an increase in action potential frequency, engage different effector systems (Figure 16.13).

One way in which the POA regulates temperature is to cause changes in physiological effector systems. These changes are often unconscious and regulated by the autonomic nervous system. For example, in response to cold internal body temperatures, cold-sensitive POA neurons in mammals activate effector neurons in the sympathetic nervous system that increase body heat. The sympathetic nervous system increases heat primarily by stimulating brown adipose tissue (BAT), fat cells that increase metabolic activity to release heat. Increasing sympathetic tone also constricts blood vessels so that warm blood does not lose heat to the external environment. In contrast, when body temperature becomes too high, warm-sensitive POA neurons decrease sympathetic tone, decreasing BAT thermogenesis and causing vasodilation of blood vessels to release excessive heat.

The POA also regulates temperature by causing changes in animal behavior. In response to cold internal body temperatures, cold-sensitive POA neurons cause an unpleasant cold sensation that motivates an animal to seek and conserve heat. Think about how uncomfortable it can be to feel cold—this aversive behavioral drive causes animals to relocate to warmer locations, such as places exposed to sunlight or other sources of heat. Animals can also change posture to decrease the exposed surface area of their bodies, thereby minimizing heat loss to the environment. Finally, animals engage in species-specific behaviors such as shivering, huddling with other individuals, or nest building to increase heat. In response to warmer temperatures, warm-sensitive POA neurons similarly cause an unpleasant warm sensation that motivates animals to cool down by seeking cooler, shady environments. Many animals change their postures to expose their skin to the outside air and release heat to the environment. Some species also engage in licking their bodies, panting, or sweating.

Investigating allostasis of body temperature during illness

During viral or bacterial infection, mammals exhibit a temporary increase in core body temperature (a fever) to try to destroy the foreign pathogens. This period of allostasis can last hours or days depending on the severity of the infection. Do the same neurons that play a role in temperature homeostasis also increase body temperature during illness?

A recent study (Osterhout et al., 2022) identified neurons active during infection. To cause an infection, mice were injected with a compound called lipopolysaccharide (LPS) that mimics a bacterial infection (Figure 16.14) (see Chapter 17 Neuroimmunology) caused an increase in body temperature, while ablating these neurons greatly reduced body temperature during infection. Therefore, these VMPO neurons are thought to be specialized to detect infection and are sufficient and necessary to generate fever by projecting to the POA neurons that normally increase body temperature.

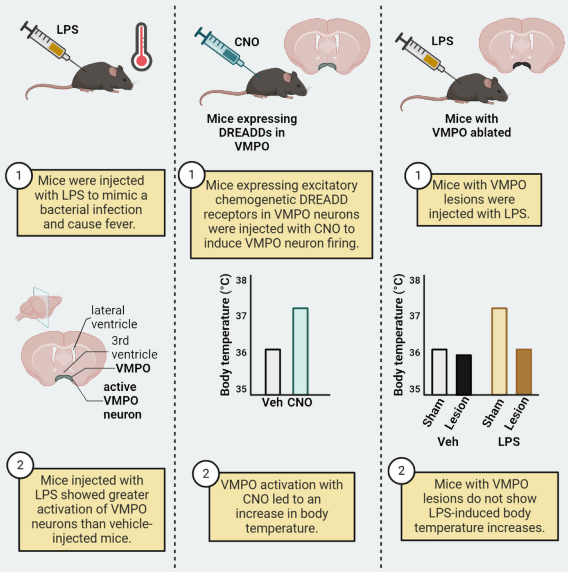

Figure 16.14 VMPO activity regulates body temperature

Interestingly, other areas of the brain have been discovered that also become activated during infection, such as a population of neurons in the brainstem (Ilanges et al., 2022). How different populations of neurons throughout the brain coordinate allostasis in response to illness is an active area of investigation and may lead to insights to help patients with a severe response to infection.

3.1.16: Neural Control of Feeding Behavior

Learning Objectives

By the end of this section, you should be able to

- 16.4.1 Describe the reasons why animals need to maintain homeostasis for calories and energy balance.
- 16.4.2 Describe the neural components of homeostatic systems that regulate hunger and satiety.

People typically celebrate major milestones (e.g., birthdays, promotions) or holidays (e.g., Thanksgiving, Independence Day), with a large, delicious meal. Think about the last time you gathered with friends or family for such an event. In the morning and early afternoon, you might only have had a light breakfast or lunch in anticipation of all the good food to come. By the time dinner starts, you are hungry and can't wait to eat. This hunger is palpable—your stomach might gurgle and feel "empty," and you think about food more and more. Perhaps you even start to feel "hangry"—emotionally upset because of your growing appetite. Once you finally start eating, your hunger dissipates, and you enjoy the meal. However, in the moments to come, another interesting process starts to occur—you eat so much that, not only are you satiated, you start to feel full. In fact, on holidays like Thanksgiving, people typically overeat to the point that they feel uncomfortably full and can't eat another bite.

This process of transitioning from a hungry state to a full state presents an interesting neurobiological question. At one moment in time, food is rewarding, and you are highly motivated to eat. But then, just 20-30 minutes later over the course of a meal, food no longer seems rewarding to consume—in fact, it becomes aversive. When you feel full, you wouldn't consume even the most delicious dish. How does the nervous system change the rewarding and aversive properties of food? How does the brain ensure that you consume enough food but not too much such that it overwhelms the digestive system?

Eating food is ultimately about maintaining an optimal caloric intake. All animals need to consume calories for energy and nutrition—and the only way to acquire calories is to seek food. Therefore, energy homeostasis requires that an animal's nervous system sense its caloric need and produce an appropriate motivational state to consume food, what we call being hungry or full. If we don't consume sufficient calories, we might become undernourished and lose weight to an unhealthy degree. In contrast, if we consume too much food, we store excess calories as body fat that could cause further health problems. Fortunately, our energy homeostasis systems work so well that the average person doesn't fluctuate in body weight more than 1-2 pounds over the course of a year. Like all homeostatic processes, various populations of cells serve as sensors, control centers, and effectors for driving and halting food intake to maintain energy homeostasis.

Hormonal and neuronal sensors of caloric intake

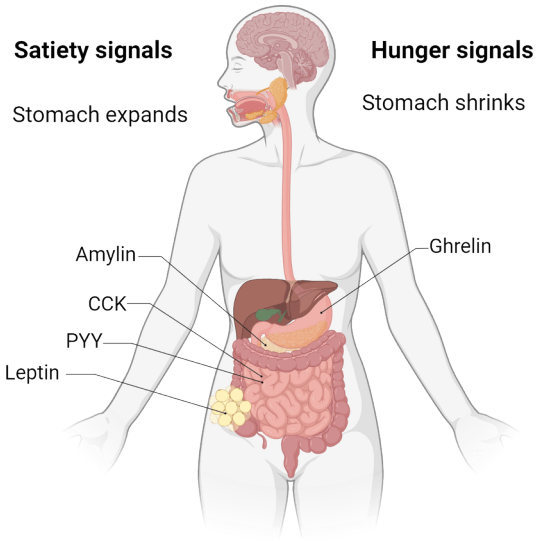

Figure 16.15 Hormonal indication of food intake

The nervous system measures caloric need using neural and hormonal mechanisms (Figure 16.15). The initial ingestion of food is sensed by the degree to which the stomach expands. The stomach is composed of elastic smooth muscle fibers that can stretch upon the ingestion of foods and liquids. Sensory fibers from the vagus nerve (the 10th cranial nerve) surrounding the stomach increase activity the more the stomach is stretched (Figure 16.16). Therefore, relatively high activity in these fibers indicate that the stomach is becoming more full, while relatively low activity in these fibers indicate that the stomach is empty. The amount of activity in these neurons indicates the degree to which an animal should feel full. (This is why drinking a large amount of water can temporarily make you feel full—the stomach is stretched in response to the water even though there are no calories). (See Studying the effect of digestive organ stretch on neural activity.)

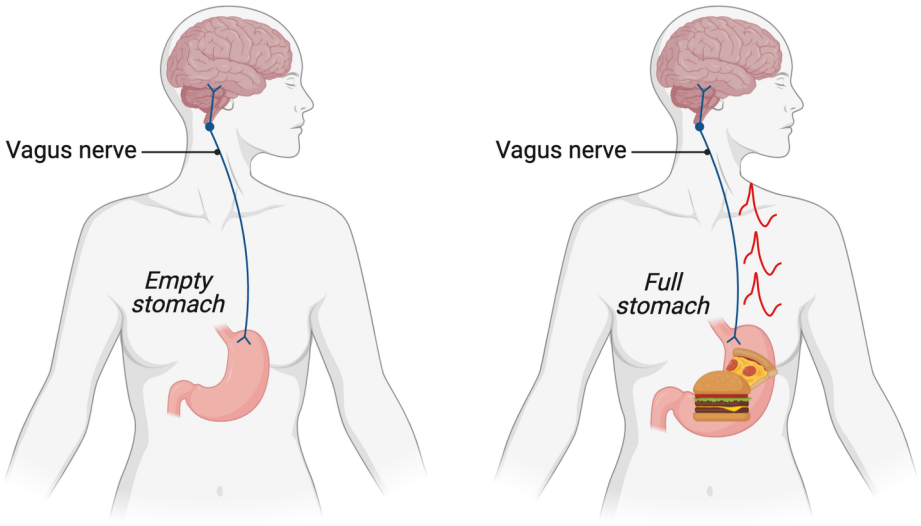

Figure 16.16 Stomach fullness as a satiety signal Stretch of the stomach muscles causes sensory fibers of the vagus nerve to fire.

Caloric need is also sensed by cells throughout the digestive tract that release a variety of hormones to indicate that an animal has recently ingested food. Many of these hormones are anorexigenic, meaning that they ultimately cause a reduction in feeding. For example, in response to food passing from the stomach into the gut, specialized cells in the pancreas release amylin. Cells in the intestines release cholecystokinin (CCK) and peptide YY (PYY). Levels of these hormones correlate with the amount of food recently consumed—they are relatively low just before a meal and relatively high during and just after a meal (Figure 16.17). The presence of these hormones in the bloodstream indicate that an animal has just consumed a meal and ultimately cause an animal

to feel satiated. In contrast, prior to a meal, cells in the stomach release the orexigenic hormone ghrelin (Figure 16.17). Elevated ghrelin levels indicate an absence of food and cause an animal to feel hungry.

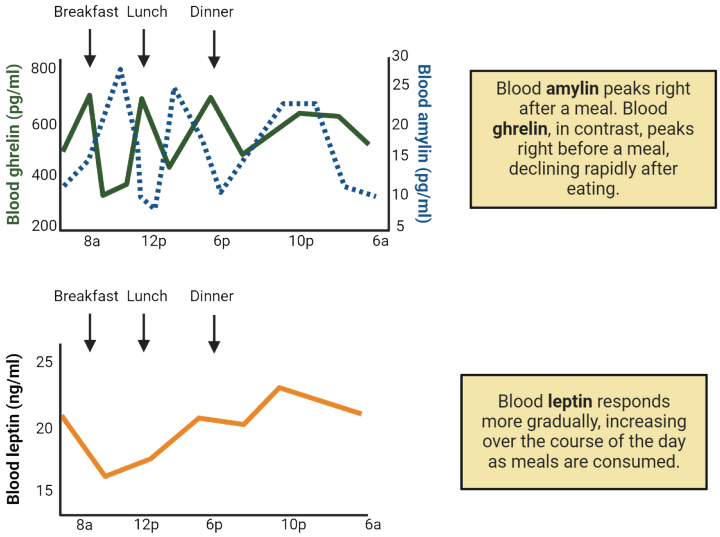

Figure 16.17 Variation in blood hormones after a meal Ghrelin and leptin data based on findings of: Cummings DE, Purnell JQ, Frayo RS, Schmidova K, Wisse BE, Weigle DS. A preprandial rise in plasma ghrelin levels suggests a role in meal initiation in humans. Diabetes. 2001 Aug;50(8):1714-9. doi: 10.2337/diabetes.50.8.1714. PMID: 11473029. Amylin data based on: Kruger DF, Gatcomb PM, Owen SK. Clinical Implications of Amylin and Amylin Deficiency. The Diabetes Educator. 1999;25(3):389-397. doi:10.1177/014572179902500310

Food intake is also regulated in a more long-term manner through the release of the hormone leptin (Figure 16.17). Leptin is released by adipocytes in white adipose tissue (WAT) in proportion to their size. Therefore, an animal with relatively low body fat will not release as much leptin as compared to levels if the same animal gains weight and accumulates more body fat. The larger the fat mass, the more leptin is released, which ultimately causes an animal to feel less hungry.

Therefore, if you have not eaten recently and are just about to start a meal, your stomach is likely to be in a contracted state, your blood concentration of ghrelin is relatively high, and your blood concentration of amylin, CCK, and PYY is relatively low. As you eat a meal, your stomach expands, ghrelin levels decrease, and concentration of amylin, CCK, and PYY increase. These signals are ultimately integrated within the brain.

Neuroscience in the Lab

Studying the effect of digestive organ stretch on neural activity

When you eat a meal, your stomach expands, holding and mixing the ingested food with enzymes and acids for 2-4 hours before slowly releasing it into the intestines. This stretch of the stomach is sensed by specialized nerve endings from the vagus nerve that transmit information to the brain about an increase in stomach volume. In fact, vagal nerve endings also sense stretch of the intestines as digested food passes through.

In the lab, it is possible to study the effects of stomach and intestinal stretch on neural activity by artificially inflating the stomach or intestines of an anesthetized laboratory animal with a small balloon (Figure 16.18). A sterile latex balloon is inserted into the stomach or intestines and inflated to a precise volume via a small catheter. Scientists can then inflate or deflate the balloon while simultaneously measuring neural activity in peripheral or central neuron populations.

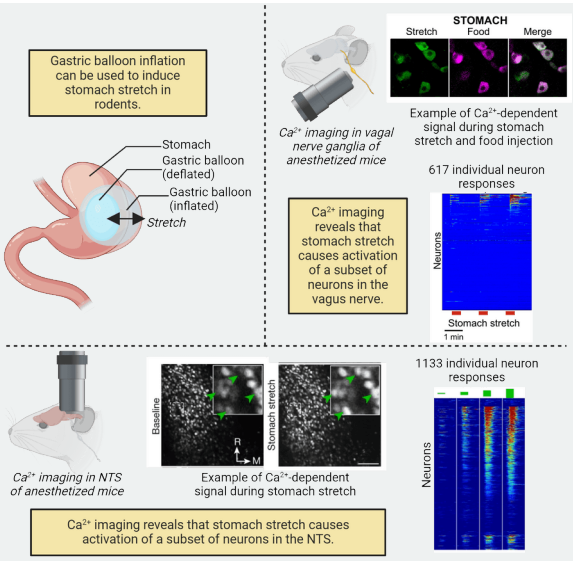

Figure 16.18 Neural activation by stomach stretch Vagus nerve Ca^{2+} imaging data reprinted from: Williams EK, Chang RB, Strochlic DE, Umans BD, Lowell BB, Liberles SD. Sensory Neurons that Detect Stretch and Nutrients in the Digestive System. Cell. 2016 Jun 30;166(1):209-21. doi: 10.1016/j.cell.2016.05.011. Epub 2016 May 26. PMID: 27238020; PMCID: PMC4930427. (C) 2016 with permission from Elsevier. NTS Ca2+ imaging data from: Ran, C., Boettcher, J.C., Kaye, J.A. et al. A brainstem map for visceral sensations. Nature 609, 320–326 (2022). https://doi.org/10.1038/s41586-022-05139-5 CC BY 4.0

Using this technique, recent studies have identified the exact neural populations that sense stomach and intestinal stretch using calcium imaging (see Methods: In Vivo Calcium Imaging). For example, a recent experiment (Williams et al., 2016) increased stomach or intestinal volume while measuring neural activity in different populations of vagus nerve sensory neurons (Figure 16.18). A small subset of vagus nerve neurons that express a distinct genetic marker, *Glp1r*, were found to innervate the stomach and intestines. Consistently, these neurons increased neural activity during artificial inflation of the stomach and intestines. Interestingly, other populations that expressed other genetic markers were found to innervate other peripheral organs.

Glp1r-expressing vagus neurons synapse onto neurons in the nucleus tractus solitarius (NTS). Another experiment (Ran et al., 2022) measured activity in the NTS during stomach and intestinal stretch, finding that NTS neurons are topographically organized based on the region being stretched. NTS neurons that increase activity in response to stomach stretch are located more dorsolaterally, while NTS neurons that increase activity in response to intestinal stretch are located more medially.

Taken together, these studies identified a genetically-defined anatomical pathway from the digestive tract to the brain that signals stomach and intestinal volume within the NTS. Future research will identify how this increase in volume along the digestive tract ultimately causes satiety and the perception of feeling full.

Central integration and regulation of food intake

Neural and hormonal signals from the digestive tract and adipose tissue are integrated in the central nervous system. Although there are multiple parts of the brain that regulate food intake, the two areas that seem to directly detect neural and hormonal signals from the periphery are the hypothalamus and brainstem.

The hypothalamus has several groups of neurons located along circumventricular organs, areas where the blood brain barrier is relatively diminished such that hormones and other substances can easily pass from the blood to the extracellular environment (Figure 16.19). These regions include the organ vasculosum of the lateral terminalis (OVLT), the median eminence, the neurohypophysis in the pituitary, the subfornical organ (SFO), the pineal gland, and the subcommissural organ. These brain regions play roles in multiple homeostatic processes.

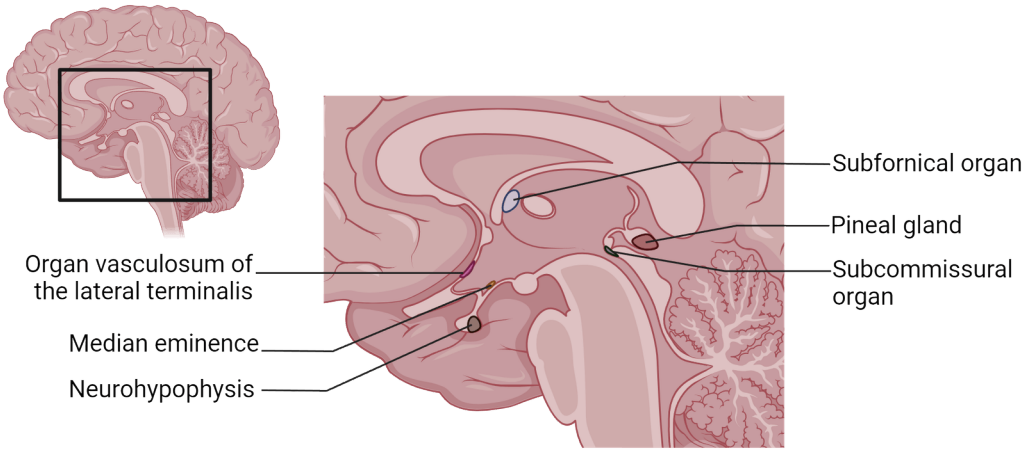

Figure 16.19 Circumventricular organs

In the case of caloric regulation, neurons in a region of the hypothalamus called the arcuate nucleus, which sits adjacent to the median eminence, have receptors for hormones that regulate feeding. The arcuate nucleus can be subdivided into two antagonistic populations of neurons: those that express the neuropeptide agouti-related peptide (AgRP) and those that express pro-opiomelanocortin (POMC) (Figure 16.20).

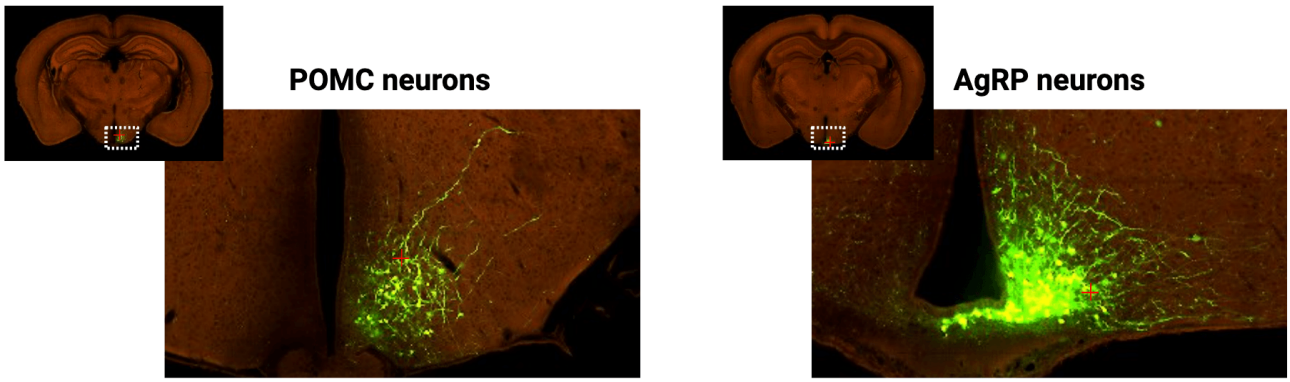

Figure 16.20 Acruate nucleus neuron tracing Green fluorescent tracers reveal POMC and AgRP cell bodies and axons. Image credit: POMC-Cre anterograde tracing. AgRP-IRES-Cre anterograde tracing. Allen Brain Atlas.

AgRP neurons increase activity in response to orexigenic hormones, such as ghrelin, and are inhibited by anorexigenic hormones. In contrast, POMC neurons increase activity in response to anorexigenic hormones and are inhibited by orexigenic hormones (Figure 16.21). Therefore, AgRP and POMC neurons are like two sides of a balance beam—the relative activity within AgRP and POMC neurons correspond with the homeostatic feeding state of an animal, with AgRP neurons preferentially activated the longer an animal goes without feeding, and POMC neurons activated when an animal consumes a meal (see feature box on studying the regulation of food intake by the hypothalamus).

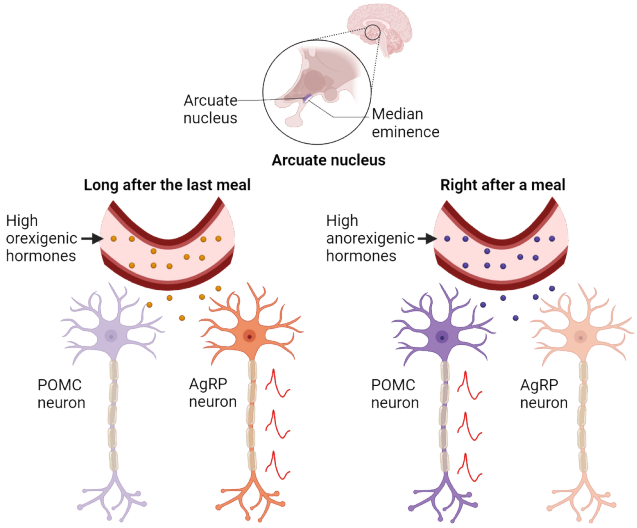

Figure 16.21 Hunger signaling in the brain

AgRP and POMC neurons therefore serve as control centers that integrate neural and hormonal information from the body about feeding. They also integrate information from other sources—for example, sensory information from visual, olfactory, and even auditory stimuli that can inform animals of feeding opportunities. AgRP and POMC neurons, in turn, affect several downstream populations of neurons that ultimately control hunger and satiety (Figure 16.22). Some downstream areas directly generate the emotional states of being hungry or full. Some downstream areas inhibit competing behaviors such as pain, itch, sex, and sleep to ensure that animals prioritize food seeking depending on homeostatic need.

Flowchart of central regulation of caloric balance. Caloric need -

Figure 16.22 Central regulation of food intake by the hypothalamus

Feeding is also directly regulated by neurons in the brainstem (Figure 16.23). These neurons seem to function in satiety and the feeling of being unpleasantly full after a meal. For example, when the stomach becomes relatively full and enlarged, neurons from the vagus nerve transmit this information to a population of neurons in the brainstem called the nucleus tractus solitarius (NTS). Increased stomach stretch causes increased NTS neural activity (see feature box on studying the effect of digestive organ stretch on neural activity). These neurons also have receptors for several anorexigenic hormones, including amylin, CCK, and PYY. The NTS sends axonal projections to other areas of the brain, especially parts of the limbic system (such as the amygdala) that seem to mediate feelings of satiety and the uncomfortable aspects of feeling full.

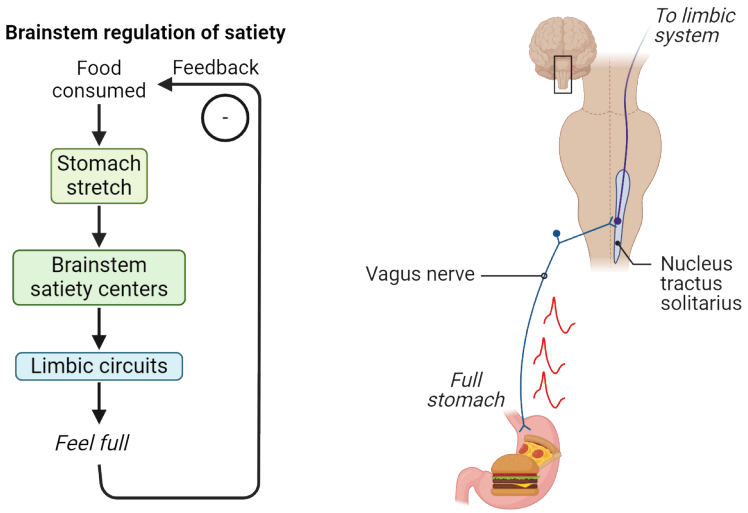

Figure 16.23 Central regulation of food intake by the brainstem

Dysfunction of hypothalamic and brainstem populations, as well as their upstream and downstream connections, can lead to food intake disorders including obesity and eating disorders (see next section).

Neuroscience in the Lab

Studying the regulation of food intake by the hypothalamus

How do neuroscientists study the neurobiology of homeostasis, such as the neural regulation of feeding behavior? Many food intake studies are performed in human subjects. However, these studies are limited by the fact that it is impossible to study specific cell types in a living person. To study and perform experiments to elucidate the neural basis of feeding, many neuroscientists turn to rodent models, especially mice. Because mice have homologous brain structures as humans, it is possible to perform experiments that are impossible in humans.

For example, in recent years, most of our understanding of the role of AgRP and POMC neurons has come from studies in mice. Using techniques like optogenetics (see Methods: Optogenetics) and chemogenetics (see Methods: Chemogenetics), it has been possible to artificially stimulate each individual population of neurons and observe behavior (Figure 16.24). For example, stimulating AgRP neurons using optogenetic activation of channelrhodopsin-2 causes a rapid behavioral response in animals in which animals consume much more food than normal (Aponte et al., 2011). In contrast, stimulating POMC neurons causes a reduction in feeding.

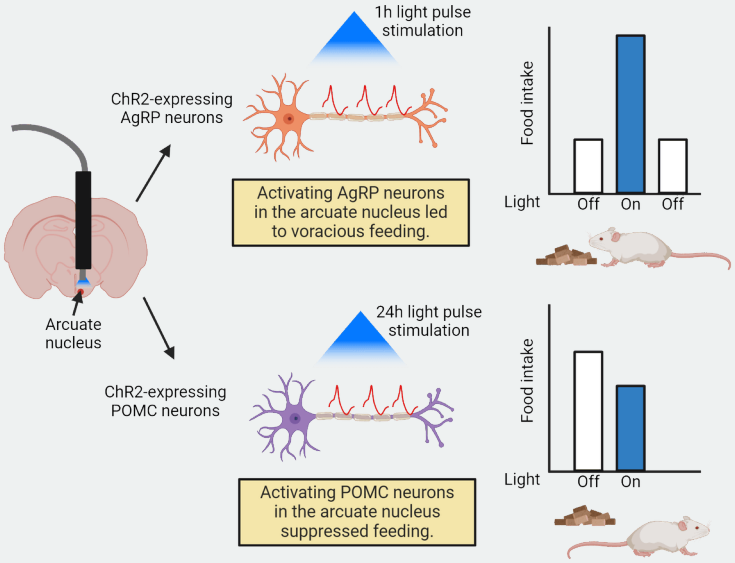

Figure 16.24 Optogenetic activation of AgRP and POMC neurons Based on data from: Aponte, Y., Atasoy, D. & Sternson, S. AGRP neurons are sufficient to orchestrate feeding behavior rapidly and without training. Nat Neurosci 14, 351–355 (2011). https://doi.org/10.1038/nn.2739

By expressing a fluorescent reporter molecule in AgRP or POMC neurons, it is possible to visualize where each of the axons travel throughout the brain. Current research is aimed at identifying the role of each downstream projection to more fully dissect how AgRP and POMC neurons orchestrate a behavioral state of hunger or satiety.

Food intake disorders

Dysregulation of the hormones and neurons that regulate food intake can cause severe problems in body weight regulation leading to obesity or various eating disorders. Because modern day society is very different from natural conditions faced by animals in the wild, humans encounter environmental stimuli (a surplus of highly palatable and calorically-dense food, extreme societal pressure to maintain a certain body weight, etc.) that contribute to food intake disorders that are often difficult to reproduce in animal models of disease.

Obesity is a complex and multifactorial disorder characterized by an excessive accumulation of body fat. The neurobiology of obesity is complex, with many potential underlying causes. Obesity is ultimately caused by consuming too many calories relative

to metabolic activity and caloric expenditure.

Why don't homeostatic systems prevent obesity? Consuming high calorie foods and gaining body weight likely causes dysregulation of the hormones and neurons that regulate food intake in the hypothalamus. For example, individuals with obesity often exhibit a state of leptin resistance, in which neurons in the hypothalamus downregulate leptin receptors and become insensitive to the satiety hormone. This leptin resistance results in increased appetite and decreased energy expenditure. Additionally, chronic overconsumption of high-calorie, high-fat foods can cause changes in the reward pathways of the brain, resulting in a decrease in the perceived pleasure of healthier, lower calorie foods.

Like obesity, eating disorders are complex psychiatric conditions characterized by altered eating behavior. These disorders often manifest with excessive and unrealistic body image perception. For example, anorexia nervosa is a disorder in which an unwarranted fear of gaining weight causes an individual to engage in too much fasting or exercising such that they manifest an abnormally low body weight. Bulimia nervosa is characterized by bouts of overeating followed by self-induced vomiting or extreme exercise to avoid absorbing calories.

Because eating disorders are intertwined with body image perception, these disorders do not seem to be caused by dysfunction of the neural systems and circuits that maintain caloric homeostasis. Indeed, individuals with food disorders are often very hungry and intentionally suppress the homeostatic motivation to consume food to correct for low body weights. Therefore, brain regions implicated in the pathophysiology of eating disorders seem to be located in areas that regulate cognition and perception, such as the cerebral cortex. The insular cortex regulates the conscious perception of taste, hunger, and satiety, and likely contributes to the etiology of eating disorders. Additionally, the prefrontal cortex is involved in executive functions such as decision making and impulse control. Neurons in the prefrontal cortex likely suppress homeostatic signals from the hypothalamus and brainstem to cause dysregulated food intake.

3.1.17: Neural Control of Drinking Behavior

Learning Objectives

By the end of this section, you should be able to

- 16.5.1 Describe the reasons why animals need to maintain homeostasis for water.
- 16.5.2 Describe the neural components of homeostatic systems that regulate water balance and drinking behavior.

Consider how interesting (or uninteresting) water is as a stimulus. Colorless, odorless, tasteless... By definition, water is about as neutral a stimulus as one can imagine. Most of the time, we don't think of water as rewarding. We often walk past drinking fountains and water coolers without feeling like we are missing a valuable opportunity. However, when we don't have enough water in our bodies, drinking water becomes *highly* rewarding. The feeling of being thirsty is very unpleasant and the longer we go without water, the more extraordinary lengths we will go to take a drink.

Mammals are composed mostly of water. Over half of a human's body weight is water, with approximately 65% located within the body cells, 28% in the extracellular fluid, and 7% in the blood. Maintaining an appropriate amount of water in our cells and surrounding fluids is critical for maintaining the structural integrity of cells and for providing an aqueous environment for the solutes (nutrients, ions, and biomolecules) that make life possible.

Water enters and leaves cells by the process of osmosis—the diffusion of water across a membrane from regions of low solute concentration to regions of high solute concentration (Figure 16.25). The unit of measurement of solute concentration within a solution is osmolarity, the number of moles of solute per liter of solution. Mammalian cells have an osmolarity of approximately 300 mOsm/L. If cells are surrounded by a solution of equal osmolarity, the environment is said to be isotonic, and there is no net water flow in or out of the cell. However, if the cell is surrounded by a solution that has a higher solute concentration, the environment is hypertonic. In these conditions, water will flow from inside the cell to the extracellular fluid, causing the cell to shrink. In contrast, if the cell is surrounded by a solution that has a lower solute concentration, the environment is hypotonic, and there is net movement of water from outside the cell to the cytoplasm. This state can cause the cell to swell up and even burst. Therefore, osmotic homeostasis systems must ensure that the blood and extracellular solutions are stably maintained at 300 mOsm/L.

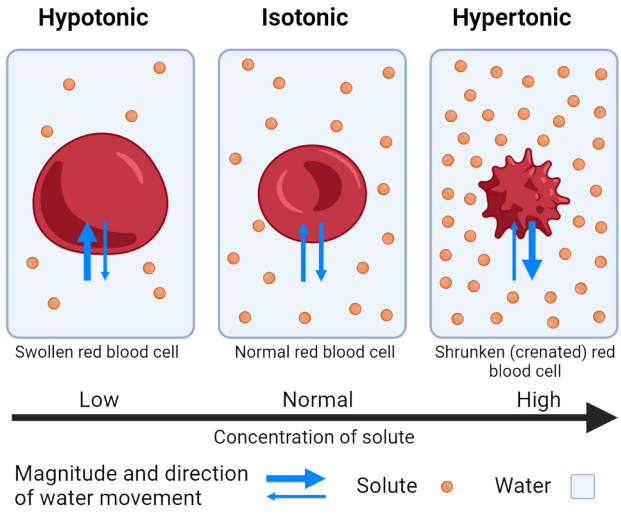

Figure 16.25 Osmolarity and tonicity

To maintain osmotic homeostasis, animals must measure the osmolarity of the blood and ensure that the amount of water lost over time is equal to the amount of water gained over time. Our bodies constantly lose water over time due to evaporation and the need to urinate metabolic waste products. Although animals can generate some water molecules on their own via the process of

cellular respiration, most mammals obtain water primarily by ingesting liquids. When the osmolarity of the blood becomes too low, homeostatic systems motivate us to excrete more water in the urine (having to pee!). When the osmolarity of the blood becomes too high, homeostatic systems motivate us to consume water—a process we describe as being thirsty.

Osmotic homeostasis systems

Mammals sense blood osmolarity within a brain structure called the subfornical organ (SFO) (Figure 16.26). Some SFO neurons increase action potential frequency when the blood becomes hypertonic, while others increase neural activity when the blood becomes hypotonic. These two populations of neurons within the SFO project to other hypothalamic populations including the organ vasculosum of the lateral terminalis (OVLT). Together, the SFO and OVLT control the neural response to osmotic change.

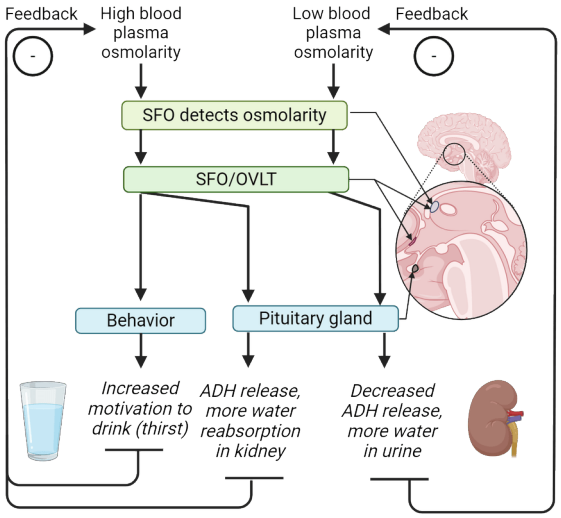

Figure 16.26 Neural regulation of water intake

For example, if you ingest food that is high in solutes (such as a handful of salty crackers), the solutes become absorbed by the bloodstream and can increase the hypertonicity of blood. Likewise, if you have not consumed water in a relatively long time (multiple hours), the blood also risks becoming hypertonic. In response to hypertonic conditions, the SFO and OVLT activate effector systems to increase the amount of water within the blood (Figure 16.26). One method of increasing water is to motivate an animal to drink by creating the sensation of thirst—an unpleasant condition in which the tongue dries and the act of swallowing liquids becomes highly rewarding. Thirst is a complex motivational state mediated by multiple downstream areas, including regions of the cerebral cortex and limbic areas. How neurons in these structures collectively coordinate the aversive feeling of being thirsty is an active area of investigation.

In addition to causing changes in behavior, the SFO and OVLT can cause a physiological response that results in less water loss in the urine (Figure 16.26). In response to hypertonic states, the SFO and OVLT cause an increase in the release of antidiuretic hormone (ADH) from the pituitary gland. This hormone primarily acts on cells within the kidney to release less water into the urine. This regulation of urine water content is why the color of urine can change depending on hydration state—the more water you drink, the less ADH is released from the pituitary, and the clearer your urine will become! Dysregulation of the ADH system (for example, mutations in the gene that encodes ADH or the ADH receptors in the kidney) disrupt osmotic homeostasis by causing abnormal water loss and urine formation by the kidneys. This disorder, called diabetes insipidus, can cause severe dehydration and constant thirst if untreated.

Interestingly, regulation of osmotic balance has a feed-forward mechanism, in which a homeostatic response occurs before there is actually a change in the system (see feature box on Studying feed-forward mechanisms in thirst). For example, if you feel thirsty and drink a large glass of water, sensors on the tongue detect the ingestion of water and cause a change in SFO neural activity before the water is actually absorbed into the bloodstream from the digestive tract. This mechanism allows you to feel satiated immediately when taking a large drink of water—otherwise, you would have to wait several minutes to feel the effect. In this way, homeostasis can be maintained faster than normal digestive processes would otherwise allow.

Neuroscience in the Lab

Studying feed-forward mechanisms in thirst

Neuroscientists have studied the effect of environmental stimuli on activity in SFO neurons using fiber photometry, a form of calcium imaging. SFO neurons can be made to express a transgene, GCaMP, that fluoresces proportionally to Ca^{2+} release inside the cell. This Ca^{2+} signal is a reflection of neural activity (see Methods: In Vivo Calcium Imaging). An optical fiber is placed directly above SFO neurons to measure changes in SFO activity in freely moving, behaving mice (Figure 16.27).

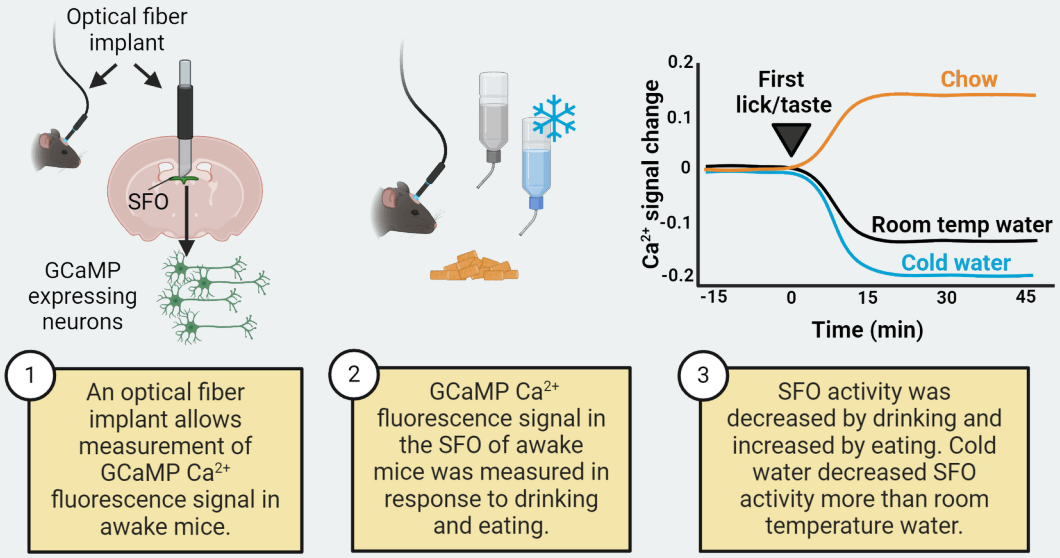

Figure 16.27 SFO activity is regulated by ingestion of food and water

A recent study (Zimmerman et al., 2016) showed that SFO neurons increase or decrease activity immediately when mice are allowed to ingest certain substances, much faster than digestive processes. For example, in thirsty mice, when SFO activity is already relatively high, SFO activity decreases immediately when mice are allowed to drink water. In fact, SFO activity decreases even more if the water is cold. This result might explain why drinking cold water is so much more satiating when we are thirsty compared with water served at room temperature. In contrast, SFO activity increases immediately when mice consume solid chow, likely a mechanism to anticipate the need for water before the food is actually absorbed by the digestive track into the bloodstream. Taken together, these feed-forward mechanisms allow an animal to minimize changes to homeostasis and avoid large deviations from a set point during ingestion of food and liquids during a meal.

View this Interactive Content online

Animals maintain a stable internal environment through the process of homeostasis. Life-sustaining factors, such as oxygen, temperature, food, and water, are maintained at optimal set-points for each organism. Animals maintain set-points via negative feedback mechanisms, in which a sensor detects a deviation from a set-point, a control system processes information from one or more sensors, and an effector system produces a response that counteracts the change. Many homeostatic systems throughout the body are regulated by the nervous system. The challenge for neuroscientists interested in studying the neurobiology of homeostasis is to understand the specific sensors, control centers, and effectors that regulate each life-sustaining factor.

16.2 Neural Control of Blood Oxygenation Levels

Homeostasis for blood oxygenation levels is regulated by the medullary respiratory control center (MRCC) and medullary cardiac control center (MCCC) in the brainstem. These populations of neurons sense changes in low blood oxygenation levels indirectly by sensing the pH of the blood. In response to higher acidity of the blood (lower pH), these neuronal populations increase respiratory rate and heart rate, respectively, to correct for deficiencies in blood oxygenation and to ensure delivery of oxygen to cells throughout the body.

16.3 Neural Control of Core Body Temperature

Regulation of core body temperature is important for survival to ensure that cells and organ systems are neither too hot nor too cold. Temperature can be sensed throughout the skin via thermosensitive ion channels, expressed in neurons that ultimately inform the brain about changes in body temperature throughout the body. Core body temperature is also sensed directly in the preoptic area (POA) of the hypothalamus. The POA serves as both a sensory and control center that employs several physiological and behavioral effector mechanisms to regulate homeostasis of body temperature. If too cold, an animal might increase sympathetic nervous system activity to increase metabolism and constrict blood vessels while simultaneously altering behavior to seek warmth. If too warm, an animal might decrease sympathetic tone, engage in behaviors such as panting or sweating, and seek cooler environments.

16.4 Neural Control of Feeding Behavior

Energy homeostasis ensures that animals consume enough calories for their daily metabolic needs without overwhelming their digestive systems with too much food. Feeding behavior is regulated by hormonal and neuronal systems in the peripheral and central nervous systems. A variety of hormones released by the digestive track including amylin, CCK, and PYY, as well as hormones released by fat cells, such as leptin, inform the brain about the course of a meal and energy reserves. Additionally, stomach volume is sensed by the vagus nerve. Various populations of neurons in the brain ultimately regulate feelings of hunger and satiety. Just before a meal, AgRP neurons initiate a behavioral state of feeling hungry and an animal is motivated to seek food. During and after a meal, POMC neurons and brainstem satiety centers, like the NTS, progressively cause a behavioral state of feeling full. Taken together, the neural populations that regulate food intake cause motivation to seek food such that an animal consumes enough calories throughout the day but not so much that it continuously overeats. Dysfunction of energy homeostatic

systems can cause an imbalance that leads to obesity or malnourishment.

16.5 Neural Control of Drinking Behavior

Homeostasis for water ensures that our cells and organ systems maintain a precise osmotic balance. Neurons in the SFO and OVLT sense a change in plasma osmolarity in adjacent blood vessels. If the plasma osmloarity becomes too hypertonic, the SFO and OVLT excite downstream neural populations that cause feelings of thirst and the motivation to drink. The SFO and OVLT also causes an increase in the release of antidiuretic hormone from the pituitary gland, causing the kidney to release less water into the urine.

3.1.21: Multiple Choice

16.1 Principles of Homeostasis

1.
How might set points for specific factors change over a 24-hour circadian period?

a. They always remain constant throughout the day and night
b. They typically decrease during the day and increase at night
c. They may fluctuate slightly depending on the factor and the organism
d. They vary based on environmental conditions

2 .
What is the purpose of negative feedback mechanisms in homeostasis?

a. To amplify deviations from set points
b. To reduce the need for optimal values of a life-sustaining factor
c. To counteract deviations and restore optimal set point values
d. To maintain physiological conditions outside a normal range

3.
Sometimes drivers pass by a highway patrol system that automatically measures their speed and displays how fast they are driving. If driving over the speed limit, most drivers will slow down. This can be considered an example of:

a. A negative feedback loop
b. Allostasis
c. Homeostasis
d. An autonomic response

4 .
Many laptop computers now have systems that automatically increase the brightness of the screen if the outside environment is well lit and that decrease the brightness of the screen if the outside environment becomes dim. This system can be considered an example of:

a. Allostasis
b. A bidirectional homeostatic system
c. An effector system
d. A control center

5.
During an immediate threat to survival, what does allostasis allow an organism to do?

a. Maintain internal physiological conditions within the normal range
b. Increase the speed by which control and effector systems counteract deviations from a set point
c. Persevere against short-term challenges by temporarily adjusting set points
d. Ignore environmental challenges for a brief period

6 .
_____ allows animals to maintain a stable internal environment.

a. Homeostasis
b. Allostasis
c. Adaptation
d. Positive feedback

7.

The neuroendocrine system regulates homeostasis by releasing _____ that affect target organs throughout the brain and body.

a. neurotrophic factors
b. cytokines
c. small molecule neurotransmitters
d. hormones

16.2 Neural Control of Blood Oxygenation Levels

8 .
How does the medullary respiratory control center (MRCC) indirectly sense blood oxygenation levels?

a. By measuring the concentration of carbon dioxide
b. By directly sensing oxygen in the lungs
c. By detecting changes in heart rate
d. By measuring the pH (acidity) of the blood

9.
How does the medullary cardiovascular control center (MCCC) affect heart rate?

a. It has no effect on heart rate
b. It increases heart rate
c. It decreases heart rate
d. It either increases or decreases heart rate depending on blood oxygenation levels

10 .
What would be the effect of administering isoproterenol, a drug that mimics the effects of norepinephrine, on the heart?

a. Heart rate increases
b. Heart rate decreases
c. No effect on heart rate
d. Parasympathetic activity decreases

16.3 Neural Control of Core Body Temperature

11.
What is the primary source of heat for endothermic animals?

a. Metabolism
b. The environment
c. Sunlight
d. Thermal vents

12 .
What is the role of the sympathetic nervous system in thermoregulation?

a. Decrease body heat
b. Induce panting
c. Stimulate sweating
d. Increase body heat

16.4 Neural Control of Feeding Behavior

13.
The release of the hormone _____ is inversely proportional to the stretch of the stomach.

a. ghrelin
b. CCK
c. amylin

d. leptin

14 .
If the _____ nerve is severed, an animal would not receive information about stomach stretch from nerve endings surrounding the stomach.

a. phrenic
b. vagus
c. glossopharyngeal
d. hypoglossal

15.
Artificial stimulation of the OVLT would cause an increase in the release of _____ from the pituitary gland.

a. POMC
b. AgRP
c. ADH
d. PYY

16 .
What is the main effect of leptin on appetite?

a. Increases hunger
b. Decreases hunger
c. Has no effect on hunger
d. Induces cravings for specific foods

17.
Why might drinking a large volume of water make you feel temporarily full?

a. Water has a calming effect on the nervous system
b. Stomach expansion in response to water
c. Water causes the release of appetite suppressing hormones
d. Ingesting water activates NTS neurons in the brainstem

18 .
If the vagus nerve was severed, how could the brain continue to receive information about stomach volume?

a. The sympathetic nervous system
b. The parasympathetic nervous system
c. Levels of CCK in the bloodstream
d. Levels of ghrelin in the bloodstream

19.
Immediately after a meal

a. The activity of POMC neurons is high and you experience a feeling of hunger
b. The activity of POMC neurons is high and you experience a feeling of fullness
c. The activity of AgRP neurons is high you experience a feeling of hunger
d. The activity of AgRP neurons is high you experience a feeling of fullness

16.5 Neural Control of Drinking Behavior

20 .
Dysregulation of the ADH system can lead to a disorder called _____, causing severe dehydration and thirst.

a. Diabetes insipidus
b. Hypoxia
c. Obesity

d. Diabetes mellitus

21.
Which neural population is involved in sensing blood osmolarity?

a. AgRP neurons
b. SFO neurons
c. POMC neurons
d. POA neurons

22 .
What is the feed-forward mechanism in the context of osmotic balance?

a. A response that occurs after water is absorbed into the bloodstream
b. A response that occurs independent of neural activity
c. A response that occurs before a change in blood osmolarity actually occurs
d. An osmotic response caused by external stimuli

23.
If blood plasma osmolarity is high all the following responses will occur, except:

a. Increased ADH release
b. Increased water reabsorption in the kidneys
c. Increased release of ghrelin
d. Increased motivation to drink

24 .
If a cell is surrounded by a solution with a greater osmolarity than the inside of the cell, then

a. Water will flow out of the cell
b. Water will flow into the cell
c. The cell will become swollen
d. The cell will have a normal shape

3.1.22: Fill in the Blank

16.1 Principles of Homeostasis

1.
Animals maintain homeostasis by maintaining internal values for life-sustaining factors at optimal _____.

16.2 Neural Control of Blood Oxygenation Levels

2 .
The medullary cardiovascular control center (MCCC) senses changes in blood oxygen levels indirectly by measuring the _____ of the blood.

16.3 Neural Control of Core Body Temperature

3.
The _____ area of the hypothalamus directly measures core body temperature.
4 .
Many mouthwashes contain menthol, a chemical compound that produces a cool sensation by activating _____ ion channels.

16.4 Neural Control of Feeding Behavior

5.
Neurons that express _____ increase their activity the longer an animal has gone without eating food.

16.5 Neural Control of Drinking Behavior

6 .
Water enters and leaves cells through the process of _____.

3.1.23: Consciousness

Learning Objectives

- Differentiate the main theories of consciousness.
- Describe the Default Mode Network including its associated brain structures and its role in varying levels of consciousness

Overview

What does it mean to be conscious? Clearly when someone has fainted, they are unconscious, and when they are sitting up and solving a math problem alongside you they are conscious. But consider this, when a child I was babysitting walked into my living room one night, but refused to answer me when I asked her if everything was alright, it was my first experience with sleepwalking. Would you say she was conscious? Alternately, is there a difference between the level or kind of consciousness you experience while taking an exam, versus when you have eaten some marijuana brownies, versus when you are meditating? There are theories about whether consciousness varies on levels or types. There has also been much research looking at the brain underpinnings of these different states. So theories of consciousness as well as the Default Mode Network (brain parts involved in resting wakefulness) will be described below.

Theories of Consciousness

Conscious states can be thought of as global dimensions of consciousness that can modulate how we think, feel and behave (Bayne and Hohwy 2016; Bayne et al. 2016). For example, in the state of ordinary waking awareness, a wide variety of inputs can enter consciousness, and a wide variety of cognitive and behavioral capacities can be exercised. In other conscious states, however, both the range of conscious content and the range of cognitive and behavioral capacities may be curtailed. Conditions that are often associated with changes in conscious state include post-comatose disorders of consciousness (Bruno et al. 2011; Casarotto et al. 2016), sleep and drug-induced sedation (Sarasso et al. 2015), and certain pathologies of consciousness, such as epileptic absence seizures (Gloor 1986; Blumenfeld 2005; Bayne 2011). For example, Minimally Conscious State patients can track certain features of their environment (such as the presence of motion or the semantic content of simple instructions), but they lack the capacity to engage in complex forms of cognition or behavior, and they seem unable to entertain complex thoughts or ideas (Giacino et al. 2002).

The **Integrated Information Theory of Consciousness (IITC)** is one theory suggesting that consciousness can be explained in terms of levels (Tononi & Koch, 2015). However, this assumes that conscious states can be ordered along a single continuum. Indeed, using transcranial magnetic stimulation (TMS – as you learned about in chapter 2) and computerized compression of the wave patterns that result, Casali et al (2013) figured out a way to objectively measure different states of consciousness including healthy subjects who are awake, dreaming, in NREM sleep, and those who are sedated, as well as in patients who had emerged from coma. But these are still not quite levels, and might indeed be thought of as qualitatively separate states of consciousness.

On the other hand, Bayne and Carter (2018) claim that consciousness ought to be construed in multidimensional terms, and that conscious states can differ from each other along multiple dimensions. For example, one of their central claims is that although the psychedelic state is distinct from the state of ordinary waking awareness, it is neither 'higher' nor 'lower' than the state of ordinary waking awareness.

The **Global Workspace Theory of Consciousness** (Dahaene et al., 2017) holds that changes in consciousness only involve 'vigilance' and 'wakefulness' where there is global availability of content. But this theory does not consider the multidimensional nature of consciousness.

Consider the state of consciousness elicited by psychedelic drugs. The psychedelic state involves a state that certainly differs from that associated with ordinary waking awareness, but there is no reason to think that individuals in the psychedelic state are more conscious (or, for that matter, less conscious) than individuals who are not in it. Why do psychedelics increase the vividness, complexity and possibly also the bandwidth of sensory experience? What explains the systematic effects that psychedelics have on the experience of unity across a wide range of domains (e.g. time, space and the self)? Addressing these questions have

helped researchers to identify the various dimensions that structure consciousness. Additionally, as presented in the chapter 6 on drugs, since much is known about the neurochemical effects of psychedelics, using this knowledge in both animal models and human imaging might provide a window into understanding the neural basis of consciousness.

Default Mode Network

Raichle et al coined the term, **Default Mode Network (DMN)** in 2001 to describe how the brain is constantly active even when not doing anything actively (See Figure 3.1.23.1). The regions in this network exhibit decreased activation when engaging in goal-oriented or attention-demanding tasks, and therefore facilitate a "default" functional state within the brain. (Raichle et al., 2001; Figure 3.1.23.1).

The brain is constantly active even when it is not engaged in a task. In the restful yet awake state, the default mode network is primarily activated. It used to also be called the task negative network – meaning that it was deactivated when we are engaged in a particular task. The main parts in this network include the medial prefrontal cortex, posterior cingulate cortex/precuneus and angular gyrus

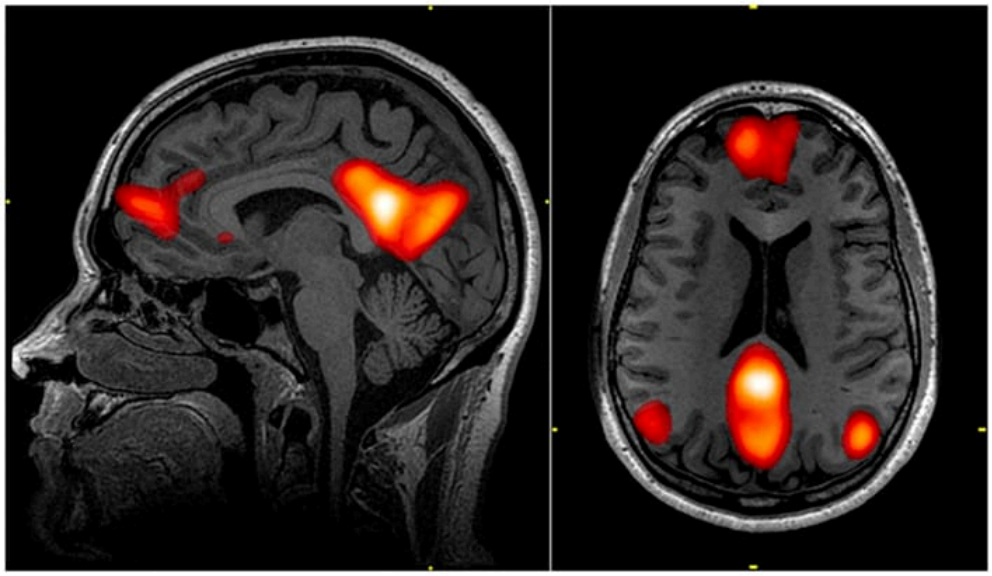

Figure 3.1.23.1: FMRI of Default Mode Network from Functional MRI in the investigation of blast-related traumatic brain injury by Graner, Oakes, French and Riedy in the Public Domain.

This network is active when one is in a state of wakeful rest, for example when one is daydreaming, relaxing, or meditating.

DMN activation is modulated in different types of consciousness changes. Table 3.1.23.1 summarizes studies showing these connections.

Table 3.1.23.1: Different studies have shown the ways in which the Default Mode Network (DMN) is affected by psychological events.

Consciousness change	Effect on DMN	Research credit
Acupuncture	DMN connectivity reduced in pain response	Huang et al, 2012
Meditation	Structural changes in areas of precuneus	Fox et al, 2014
Resting wakefulness	Increase in DMN	Picchioni et al, 2013
Sleep deprivation	Decrease in connectivity	McKenna & Eyler, 2012
Use of psychedelics	reduced blood flow to precuneus and medial prefrontal cortex	Carhart-Ellis et al, 2012
Deep brain stimulation	used to rebalance the restful brain structures	Kringelbach et al, 2011
Psychotherapy	helps stabilize the DMN in PTSD sufferers	Sripada et al, 2012

Consciousness change	Effect on DMN	Research credit
Attention training techniques	help increase connectivity in DMN	Kowalski et al, 2020
Antidepressant use	improves abnormalities in DMN in PTSD sufferers	Akiki et al, 2017
Physical activity and exercise	alters DMN	Shao et al, 2019; Muraskin et al, 2016; Voss et al, 2019

Summary

There has been a lot of research into what consciousness means philosophically and how that ties in with brain activity. Clearly, when one is asleep there is a difference in the awareness of stimuli, thought and function behaviorally. Biological psychologists have attempted to establish whether the differences in consciousness experienced while awake, asleep, under the influence of different drugs, while meditating, and in comatose states are qualitative or quantitative differences. Images of the brain in these different conditions have helped scientists come up with theories - and arguments - for each of these positions

3.1.24: What is Sleep?

Learning Objectives

1. Evaluate the overall complex nature of sleep, rather than simply the absence of wakefulness.
2. Demonstrate a general understanding of the biological nature of sleep.
3. Evaluate the importance of sleep, its functions and the negative ramifications of sleep deprivation.

Overview

When you are asleep are you unconscious? Why do all animals appear to need sleep, some at great expense and danger? Is it true that we "need" sleep every night, or are we just wasting time (about a third of our lives if we follow the 8 hours a day recommendation)? Really all we are doing is laying down and turning off the lights, right? And our brain just shuts off for that time, right?

The nature of sleep as a biological process that is generated by the brain will be discussed in this chapter. In this section, some ideas about how these discoveries came about are contrasted against people's general belief that sleep is just something that happens when one is not doing anything else.

What is Sleep?

Sleep is a complex biological process. While you are sleeping, you may appear unconscious (though there is certainly a difference between being asleep and having fainted), but your brain and body functions are still active. They are doing a number of important jobs that help you stay healthy and function at your best. So when you don't get enough quality sleep, it does more than just make you feel tired. It can affect your physical and mental health, thinking, and daily functioning.

Sleep is an important part of your daily routine—you spend about one-third of your time doing it. Quality sleep – and getting enough of it at the right times -- is as essential to survival as food and water.

Everyone needs sleep, but its full biological purpose remains a mystery. Sleep affects almost every type of tissue and system in the body – from the brain, heart, and lungs to metabolism, immune function, mood, and disease resistance. Research shows that a chronic lack of sleep, or getting poor quality sleep, increases the risk of disorders including high blood pressure, cardiovascular disease, diabetes, depression, and obesity.

Sleep is important to a number of brain functions, including how nerve cells (neurons) communicate with each other. In fact, your brain and body stay remarkably active while you sleep. Recent findings suggest that sleep plays a housekeeping role that removes toxins in your brain that build up while you are awake (Xie et al, 2013).

Without sleep you can't form or maintain the pathways in your brain that let you learn and create new memories, and it's harder to concentrate and respond quickly.

Sleep is a complex and dynamic process that affects how you function in ways scientists are now beginning to understand.

Functions of sleep

Memory consolidation

Another idea about why we sleep is that sleeping reinforces learning and memory, while at the same time, helping us to forget or to clear stores of unneeded memories. During the course of a day we are inundated with experiences, some of which should be remembered while others need not be. Perhaps sleep aids in rearranging all of the experiences and thoughts from the day so that those that are important are stored and those that are not are discarded. People who get plenty of deep NREM sleep in the first half of the night and REM sleep in the second half improve their ability to perform spatial tasks. This suggests that the full night's

sleep plays a role in learning—not just one kind of sleep or the other.

Other research has also shown that activity in the hippocampus during REM sleep supports the idea that dreams serve a memory consolidation function. Further the activity of the inferior parietal lobule, a part of the cortex that conveys experiences to memory, decreases during REM sleep, which probably helps to explain why we have so much trouble in remembering our dreams. There is also a lot of activity noted in the limbic regions – particularly the amygdala, probably in relation to the emotional quality of dreams that we report.

Research with rats, cats, songbirds, and humans have shown that multiple stages in sleep increase memory consolidation. Rasch and Born (2013) reviewed the multiple genetic, neurological, and chemical bases by which memory function is affected during sleep.

Studies show that a good night's sleep improves learning. Whether you're learning math, how to play the piano, how to perfect your golf swing, or how to drive a car, sleep helps enhance your learning and problem-solving skills. Sleep also helps you pay attention, make decisions, and be creative.

Energy Conservation

This theory states that we sleep to conserve energy and is based on the fact that the metabolic rate is lower during sleep. The theory predicts that total sleep time and NREM sleep time will be proportional to the amount of energy expended during wakefulness. Support for this theory is derived from several lines of evidence. For example, NREM and REM sleep states are found only in **endothermic** animals (that is, those that expend energy to maintain body temperature). Species with greater total sleep times generally have higher core body temperatures and higher metabolic rates. Consider also that NREM sleep time and total sleep time decrease in humans, with age, as do body and brain metabolism. In addition, infectious diseases tend to make us feel sleepy. This may be because molecules called **cytokines**, which regulate the function of the immune system, are powerful sleep inducers. It may be that sleep allows the body to conserve energy and other resources, which the immune system may then use to fight the infection.

Brain Development

This proposed function of sleep is related to REM sleep, which occurs for prolonged periods during fetal and infant development. This sleep state may be involved in the formation of brain synapses.

Children and teens who are sleep deficient may have problems getting along with others. They may feel angry and impulsive, have mood swings, feel sad or depressed, or lack motivation. They also may have problems paying attention, and they may get lower grades and feel stressed.

Discharge of emotions

Perhaps dreaming during REM sleep provides a safe discharge of emotions. As protection to ourselves and to a bed partner, the muscular paralysis that occurs during REM sleep does not allow us to act out what we are dreaming. Additionally, activity in brain regions that control emotions, decision making, and social interactions is reduced during sleep. Perhaps this provides relief from the stresses that occur during wakefulness and helps maintain optimal performance when awake.

Sleep Deprivation and Deficiency

Why Is Sleep Important?

Whichever theory is most effective, it is clear that sleep plays a vital role in good health and well-being throughout your life. Getting enough quality sleep at the right times can help protect your mental health, physical health, quality of life, and safety.

The way you feel while you're awake depends in part on what happens while you're sleeping. During sleep, your body is working to support healthy brain function and maintain your physical health. In children and teens, sleep also helps support growth and development.

The damage from sleep deficiency can occur in an instant (such as a car crash), or it can harm you over time. For example,

ongoing sleep deficiency can raise your risk for some chronic health problems. It also can affect how well you think, react, work, learn, and get along with others.

Healthy Brain Function and Emotional Well-Being

As seen above, sleep helps your brain work properly. While you're sleeping, your brain is preparing for the next day. It's forming new pathways to help you learn and remember information.

Studies also show that sleep deficiency alters activity in some parts of the brain. If you're sleep deficient, you may have trouble making decisions, solving problems, controlling your emotions and behavior, and coping with change. Sleep deficiency also has been linked to depression, suicide, and risk-taking behavior.

Physical Health

Sleep plays an important role in your physical health. For example, sleep is involved in healing and repair of your heart and blood vessels. Ongoing sleep deficiency is linked to an increased risk of heart disease, kidney disease, high blood pressure, diabetes, and stroke.

- Sleep deficiency also increases the risk of obesity. For example, one study of teenagers showed that with each hour of sleep lost, the odds of becoming obese went up. Sleep deficiency increases the risk of obesity in other age groups as well.
- Sleep helps maintain a healthy balance of the hormones that make you feel hungry (ghrelin) or full (leptin). When you don't get enough sleep, your level of ghrelin goes up and your level of leptin goes down. This makes you feel hungrier than when you're well-rested.
- Sleep also affects how your body reacts to insulin, the hormone that controls your blood glucose (sugar) level. Sleep deficiency results in a higher than normal blood sugar level, which may increase your risk for diabetes.
- Sleep also supports healthy growth and development. Deep sleep triggers the body to release the hormone that promotes normal growth in children and teens. This hormone also boosts muscle mass and helps repair cells and tissues in children, teens, and adults. Sleep also plays a role in puberty and fertility.
- Your immune system relies on sleep to stay healthy. This system defends your body against foreign or harmful substances. Ongoing sleep deficiency can change the way in which your immune system responds. For example, if you're sleep deficient, you may have trouble fighting common infections.

Daytime Performance and Safety

Getting enough quality sleep at the right times helps you function well throughout the day. People who are sleep deficient are less productive at work and school. They take longer to finish tasks, have a slower reaction time, and make more mistakes. After several nights of losing sleep—even a loss of just 1–2 hours per night—your ability to function suffers as if you haven't slept at all for a day or two.

Lack of sleep also may lead to microsleep. Microsleep refers to brief moments of sleep that occur when you're normally awake. You can't control microsleep, and you might not be aware of it. For example, have you ever driven somewhere and then not remembered part of the trip? If so, you may have experienced microsleep. Even if you're not driving, microsleep can affect how you function. If you're listening to a lecture, for example, you might miss some of the information or feel like you don't understand the point. In reality, though, you may have slept through part of the lecture and not been aware of it.

Who Is at Risk for Sleep Deprivation and Deficiency?

Sleep deficiency, which includes sleep deprivation, affects people of all ages, races, and ethnicities.

Sleep deficiency can cause problems with learning, focusing, and reacting. You may have trouble making decisions, solving problems, remembering things, controlling your emotions and behavior, and coping with change. You may take longer to finish tasks, have a slower reaction time, and make more mistakes.

The signs and symptoms of sleep deficiency may differ between children and adults. Children who are sleep deficient might be overly active and have problems paying attention. They also might misbehave, and their school performance can suffer.

Sleep-deficient children may feel angry and impulsive, have mood swings, feel sad or depressed, or lack motivation.

You may not notice how sleep deficiency affects your daily routine. A common myth is that people can learn to get by on little sleep with no negative effects. However, research shows that getting enough quality sleep at the right times is vital for mental health, physical health, quality of life, and safety.

Summary

It is clear that sleep is a complex biological process that all humans, indeed all animals, engage in. Several brain regions are involved in sleep and wakefulness processes, and sleep serves complex functions that continue to be researched. The seemingly simple idea that we put on our pajamas, close our eyes and nod off to sleep involves far more complexity than appears on the surface.

3.1.25: Stages of Sleep

Learning Objectives

1. Explain the different stages of sleep.
2. Describe the nature of REM sleep, its biological underpinnings and possible functions.

Overview

While watching someone sleep might appear as if they are seemingly unconscious with eyes closed for an extended period of time, in fact brain wave recordings show that the brain is cycling through several different stages as an individual sleeps. These stages each have distinct characteristics of brain activity and conscious experience and are divided into two main types known as Rapid Eye Movement (REM) and Non-REM. This section will explore these characteristics and some of the peculiar and unexpected features of REM sleep, in particular.

The different stages of sleep

From a behavioral standpoint, sleep is defined by four criteria:

1. reduced motor activity
2. diminished responses to external stimuli
3. stereotyped posture (in humans, lying down with eyes closed)
4. relatively ready reversibility.

These criteria distinguish sleep from hibernation and unconscious states, such as coma.

Sleep is a highly organized sequence of events that follows a regular, cyclic program each night. Polysomnograms - literally "many sleep measures" - are used to measure different body functions in a sleep lab (See Figure to see where electrodes are placed for each of the measurements). Thus, the EEG (electroencephalogram) is the technique used to measure sleep most readily and often (as discussed in chapter 2). For the EEG, electrodes are placed on the head and the brain's electrical activity is amplified and recorded). EMG (electromyograph that measures muscle tension), and EOG (electrooculogram that measures eye movement) patterns also change in predictable ways several times during a single sleep period.

NREM sleep is divided into four stages according to the **amplitude** and **frequency** of brain wave activity. In general, the EEG pattern of NREM sleep is slower, often more regular, and usually of higher voltage than that of wakefulness. As sleep gets deeper, the brain waves get slower and have greater amplitude. NREM Stage 1 is very light sleep; NREM Stage 2 has special brain waves called **sleep spindles** and **K complexes**; NREM Stages 3 and 4 show increasingly more high-voltage slow waves. In NREM Stage 4, it is extremely hard to be awakened by external stimuli. The muscle activity of NREM sleep is low, but the muscles retain their ability to function. Eye movements normally do not occur during NREM sleep, except for very slow eye movements, usually at the beginning. With the exception of brain activity, the body's general physiology during these stages is fairly similar to the wake state.

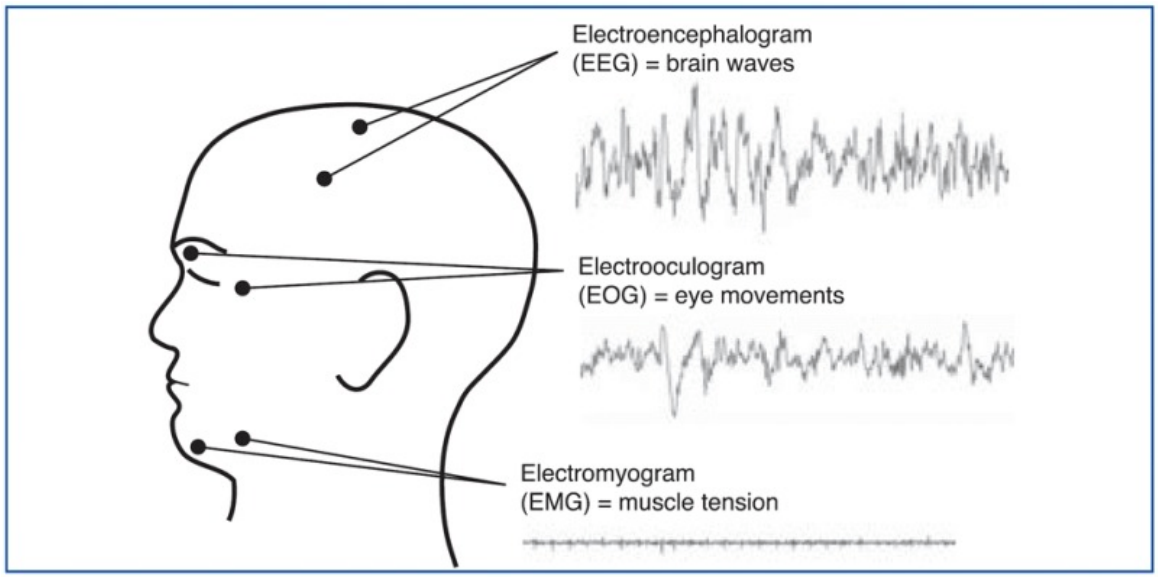

Figure 3.1.25.1: Placement of electrodes to determine EEG, EOG, and EMG. (NIH in the public domain)

From the time you fall asleep to the time you reach the deepest non-REM sleep, about 1½ hours later, the amplitude of these waves increases continuously, while their frequency diminishes correspondingly. Compared with wakefulness and with REM (rapid eye movement) sleep, non-REM sleep is characterized by an electroencephalogram (EEG) in which the waves have a greater amplitude and a lower frequency.

Hypnograms were developed to summarize the voluminous chart recordings of electrical activities (EEG, EOG, and EMG) collected during a night's sleep. Hypnograms provide a simple way to display information originally collected on many feet of chart paper or stored as a large file on a computer. The figure illustrates a hypnogram. (Of course, it is important to keep in mind that individuals' hypnograms might be much less uniform than this relative "ideal" presented here.)

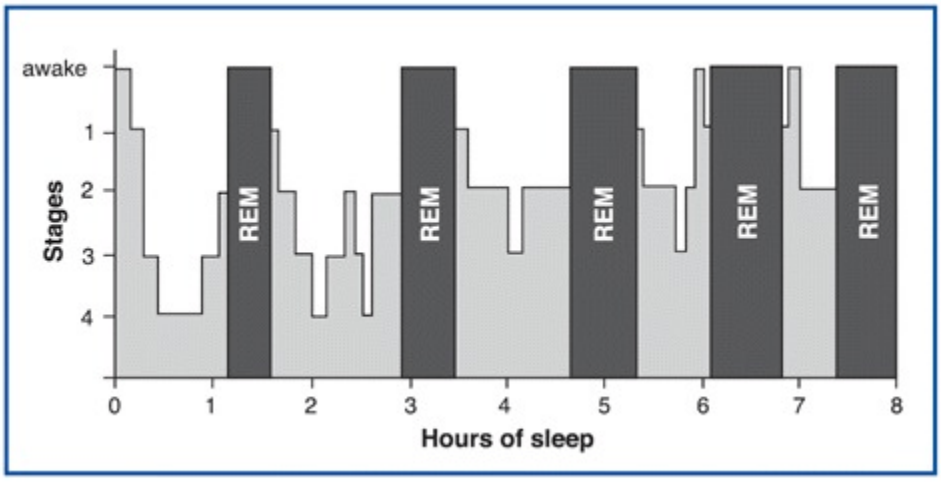

Figure 3.1.25.2: A typical hypnogram from a young, healthy adult. Light-gray areas represent non–rapid eye movement (NREM) sleep (NIH in the public domain)

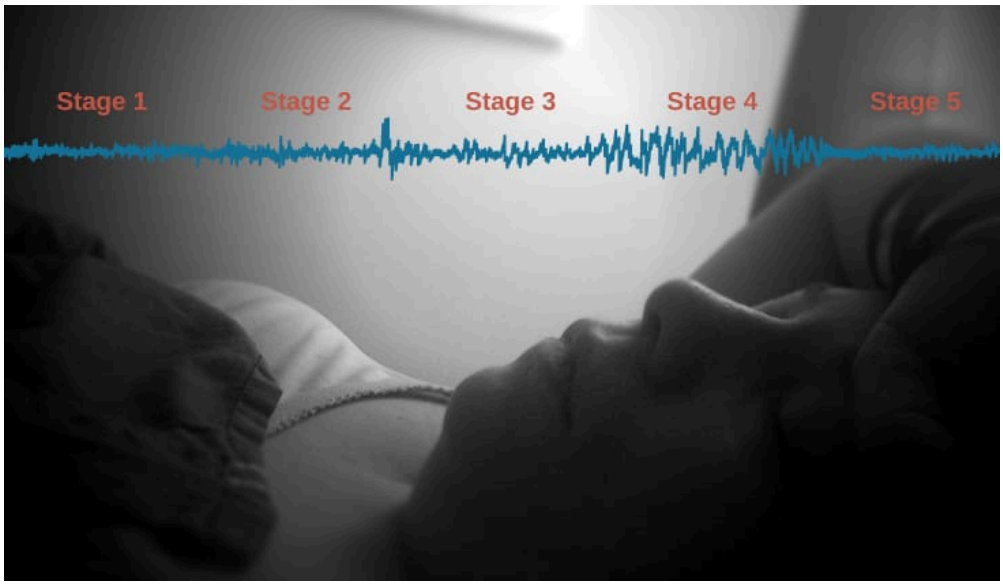
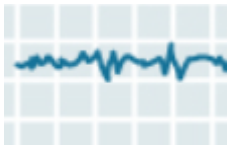
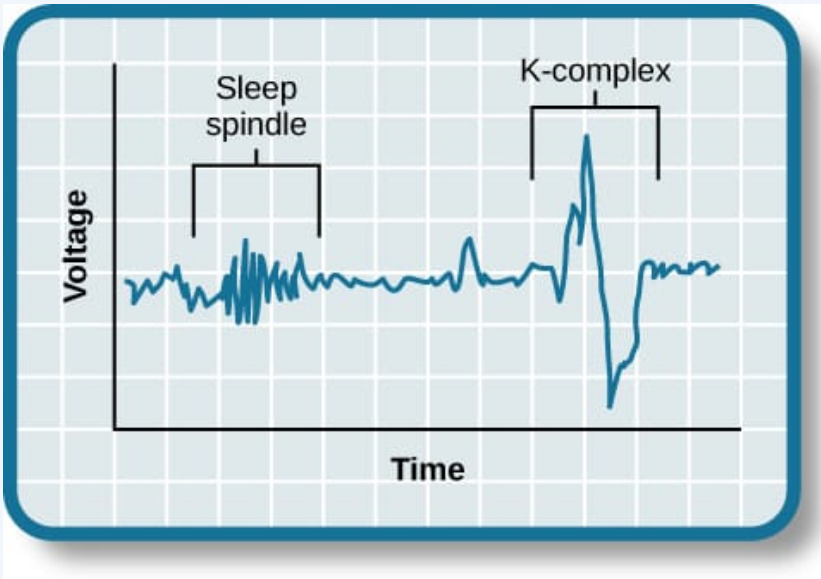
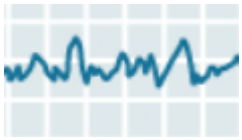
We can make several observations about the hypnogram in this figure. First, the periods of NREM and REM sleep alternate during the night. Second, the deepest stages of NREM sleep occur in the first part of the night. Third, the episodes of REM sleep are longer as the night progresses. This hypnogram also indicates two periods during the night when the individual awakened (at about six and seven hours into the night).









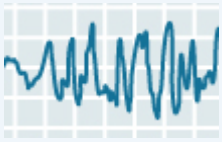


Figure 3.1.25.3: Note the amplitude and frequency of the wave patterns during different stages of sleep (Stage 5 indicates REM sleep). (CC BY 4.0; Lumen Learning)

The four types of brain waves (shown in Figure 3.1.25.3, and others discussed below, are important criteria that have been used to define four distinct stages of non-REM (NREM) sleep. Obviously, falling into a deeper and deeper sleep as the night progresses is actually a gradual, continuous process, but these four stages still provide a convenient means of describing the relative depth of NREM sleep.

Table 11.3.1 Stages of sleep

Stage	EEG	Description
Stage 1		Stage 1 non-REM sleep begins when you first lie down and close your eyes. After a few sudden, sharp muscle contractions in the legs, the muscles relax. Then, as you continue falling asleep, the rapid beta waves of wakefulness are replaced by the slower alpha waves of someone who is relaxed with their eyes closed. Soon, the even slower theta waves begin to emerge. Though your reactions to stimuli from the outside world diminish, Stage 1 is still the phase of sleep from which it is easiest to wake someone up. In experiments where people are awakened from Stage 1 sleep and asked about their state of consciousness, they usually report that they had just fallen asleep or had been in the process of doing so. They also often report having had stray thoughts and short dreams. Each period of Stage 1 sleep generally lasts 3 to 12 minutes,

Stage	EEG	Description
Stage 2		Stage 2 non-REM sleep is a stage of light sleep in which the frequency of the EEG trace decreases further while its amplitude increases. The theta waves characteristic of Stage 2 sleep are interrupted by occasional series of high-frequency waves known as sleep spindles. These bursts of activity have a frequency of 8 to 14 Hz and an amplitude of 50 to 150 µV. Sleep spindles generally last 1 to 2 seconds. They are generated by interactions between thalamic and cortical neurons. During Stage 2 sleep, the EEG trace may also show a fast, high-amplitude wave form called a K-complex. The K-complex seems to be associated with brief awakenings, often in response to external stimuli. People in Stage 2 sleep are unlikely to react to a light or a noise, unless it is extremely bright or loud. It is still possible to awaken them, even if they then report that they were really sleeping during the 10 to 20 minutes that this stage lasts during the earliest of the night's sleep cycles. But because people go through Stage 2 sleep several times during the cycles in a night, this is the stage in which adults spend the greatest proportion of their sleep–nearly 50% of the total time that they sleep each night.

Stage	EEG	Description
Stage 3		Stage 3 non-REM sleep marks the passage from moderately to truly deep sleep. Delta waves appear and soon account for nearly half of the waves in the EEG trace. Sleep spindles and K-complexes still occur, but less often than in Stage 2. The greater activity observed in the electro-oculogram (EOG) trace during stages 3 and 4 reflects the greater amplitude of EEG activity in the prefrontal areas, rather than movements of the eyes. Stage 3 lasts about 10 minutes during the first sleep cycle of the night but accounts for only about 7% of a total night's sleep. During Stage 3, the muscles still have some tonus, and sleepers show very little response to external stimuli unless they are very strong or have a special personal meaning (for example, when someone calls your name, or when a baby cries within earshot of its mother).
Stage 4		Stage 4 non-REM sleep is the deepest, the one in which we sleep the most soundly. The EEG trace is dominated by delta waves, and overall neuronal activity is at its lowest. The brain's temperature is also at its lowest, and breathing, heart rate, and blood pressure are all reduced under the influence of the parasympathetic nervous system. In adults, Stage 4 lasts about 35 to 40 minutes during the first sleep cycle of the night; it accounts for 15 to 20% of total sleep time in young adults. The muscles still have their tonus, and some movements of the arms, legs, and trunk are possible. This is the stage of sleep that accomplishes most of the body's repair work and from which it is most difficult to wake someone up. This is also the stage of sleep in which children may have episodes of somnambulism (sleepwalking) and night terrors.

REM/NREM Sleep Chemicals and Brainstem Structures

In addition to maintaining wakefulness, several of the nuclei of the two pathways from the brainstem and the pons to the cortex use acetylcholine and glutamate as neurotransmitters and are partly responsible for the cortical activation that occurs during REM sleep.

The midbrain reticular formation projects massively into the thalamic nuclei, which in turn influence the entire cortex. The role of this formation is to desynchronize the cortex in the broad sense, thus facilitating not only wakefulness but REM sleep as well. Formerly known as the ascending activating reticular system, it is now regarded simply as part of the wakefulness network.

Brain structures involved in REM

Rapid eye movement (REM) sleep is a distinct, homeostatically controlled brain state characterized by an activated electroencephalogram (EEG) in combination with paralysis of skeletal muscles and is associated with vivid dreaming.

In 1953, Aserinsky and Kleitman first reported the existence of rapid eye movement (REM) sleep in humans as a periodically recurring brain state marked by a low amplitude electroencephalogram (EEG) and rapid eye movements (Aserinsky and Kleitman, 1953). Soon afterward, Kleitman and Dement found that the EEG during REM sleep resembles that during alert waking and showed that REM sleep coincides with periods of vivid dreaming (Dement and Kleitman, 1957). Two years later, Jouvet discovered in cats that the activated EEG during REM sleep is associated with a complete paralysis of skeletal muscles, reflected in a flat electromyogram (EMG), and therefore coined the term paradoxical sleep (Jouvet and Michel, 1959). Besides these defining properties in EEG and EMG, REM sleep is characterized by further striking neurophysiological and behavioral features, including high-amplitude theta oscillations in the hippocampus, muscle twitches, autonomic and respiratory activation, an elevated arousal threshold and bursts of large waves in the local field potential (LFP), called PGO-waves (P= pons, G= (lateral) geniculate nucleus, O= occipital cortex), that originate in the pons and propagate to the lateral geniculate nucleus, occipital cortex, and other brain areas (Datta, 1997; Karashima et al., 2010).

The fact that the prefrontal cortex is relatively silent in REM falls in line with the fact that our dream content is often bizarre, illogical and socially inappropriate. Also the anterior cingulate gyrus which plays a role in attention and motivation is quite involved in REM sleep. And it appears that certain nuclei in the pons help trigger REM.

The amygdala is one of the parts of the brain that is most active during REM sleep, but this state is actually generated deep in the brainstem. However, the set of cortical and limbic structures involved in REM sleep do not just passively submit to orders issued by the brainstem. On the contrary, the particular kind of dream images associated with REM sleep are the result of a dynamic interaction between certain key structures in the brainstem and the rest of the brain (See Figure 3.1.25.4).

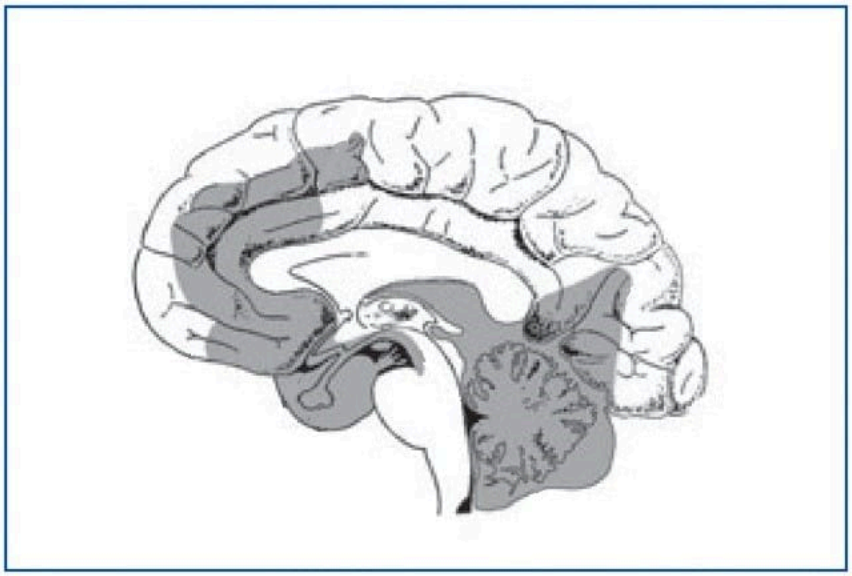

Figure 3.1.25.4: Areas of brain active during REM sleep and dreaming. (Adapted from NIH in the public domain)

REM and dreams

It was shown by 1950s that the cortex is as active in REM as when someone is awake – which is one reason why REM is also called paradoxical sleep.

In humans, sleep is punctuated by REM (rapid eye movement) sleep about every 90 min (Ohayon et al., 2004). This is when most dreaming occurs (Hobson, 2009). Although some forms of dreaming can occur during non-REM sleep, such dreams are quite different from REM dreams; non-REM dreams usually are related to plans or thoughts, and they lack the visual vividness and hallucinatory and delusory components of REM dreams (Roffwarg et al., 1962; Nielsen, 2000). Rapid eye movement during sleep is thought to be associated with visual experience of dreaming (Andrillon et al., 2015).

It was also found using MRIs that while the primary visual cortex was relatively silent in REM (clearly their eyes are closed and therefore they aren't seeing anything), the secondary visual areas of the cortex, that interpret and analyze visual information, are relatively active in REM state. This is consistent with the fact that when we are awakened from REM sleep we often report highly elaborate visual dream scenes.

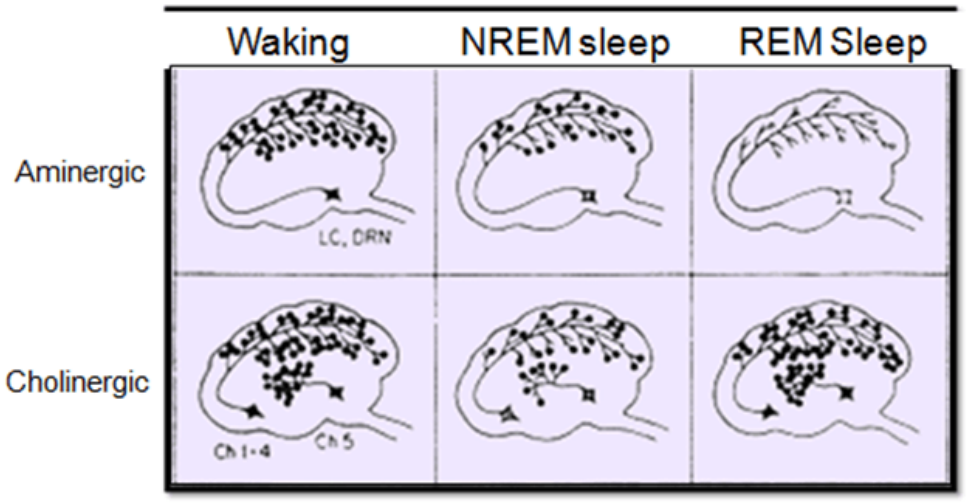

Figure 3.1.25.5: The numbers of black dots are proportional to the activity of the aminergic and cholinergic systems during the various stages of wakefulness and sleep. REM sleep (paradoxical sleep) characteristics by Dr. Mohammad Torabi Nami and Dr. Khsoro Sadeghniaat. Licensed CC BY 3.0 via Webmed Central

Neurochemical bases of REM

REM is a combination of increase in cholinergic (acetylcholine) activity (in pontine tegmentum/pons and midbrain) and decrease in aminergic (monoamines - serotonin and norepinephrine) activity (in dorsal raphe nucleus and locus coeruleus).

That a sudden elevation in the activity of the cholinergic neurons of the pons is necessary for the onset of REM sleep may seem somewhat strange, because the brain's acetylcholine systems are known for their role in wakefulness. How then can this system associated with wakefulness be activated during one of the phases of sleep? The answer probably lies in the simultaneous reduction in the activity of two other nuclei that produce other wakefulness neurotransmitters, a reduction that is just as necessary for REM sleep as the increase in cholinergic activity. The two nuclei in question are the dorsal raphe nucleus, a group of serotonergic neurons, and the locus coeruleus, a group of noradrenergic neurons, and both of them are located in the rostral portion of the pons.

REM sleep cannot begin unless all activity in these two main aminergic systems of the brainstem ceases (See Figure 3.1.25.5 for some of the comparisons of neurochemical activation) . The serotonergic and noradrenergic neurons in these systems are referred to as REM-off neurons because of their inactivity during REM sleep, and they can be said to act as a sort of permissive system for REM sleep, in the sense that REM sleep becomes possible only when their activity has ceased. The shutdown of these neurons might, for example, help to suppress consciousness during REM sleep. Also, the periods of REM sleep end when these aminergic neurons become active again.

The rapid eye movements - that REM gets named for - come from originating signals in the pontine reticular formation sending signals to the midbrain and which coordinate the duration and direction of eye movements.

Musculature in REM

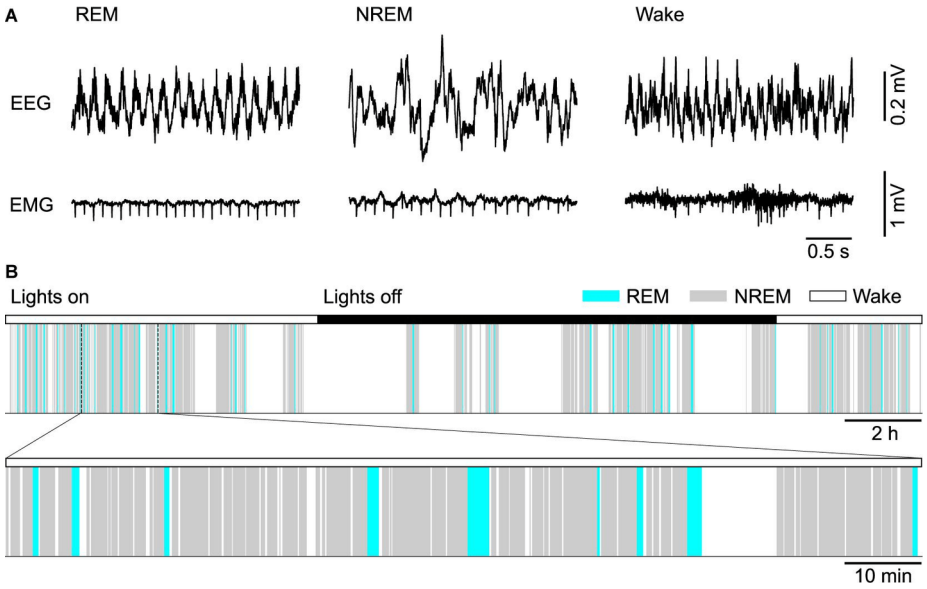

Figure 3.1.25.6: Sleep in mice. **(A)** Example electroencephalogram (EEG) and electromyogram (EMG) recordings from a mouse during REM sleep, NREM sleep and wakefulness (Wake). **(B)** Top, color-coded brain state (hypnogram) for a continuous 24 h recording from a mouse during dark and light cycles. Bottom, a 2 h segment of the hypnogram shown at an expanded scale. (Neural and Homeostatic Regulation of REM sleep by Park and Weber, CC-BY)

One of the most singular characteristics of REM sleep—the paralysis of the large muscles of the body that it causes —also is explained by phenomena that occur in certain parts of the brainstem. Intense neural activity of REM sleep excites majority of neurons in the cortex including those in the primary motor cortex. These generate organized sequences of activities that represent commands for bodily movements. But they never reach motor neurons of arms and legs (only the respiratory muscles, those of eye and middle ear actually respond to those commands). See Figure 3.1.25.6 for the coordination of EEG and EMG in the 24-hour hypnogram of a mouse. Increase of cholinergic activity in the pons will, ultimately, inhibit motor neurons in the spinal cord.

When you are awake, your brain's wakefulness circuits exert controls that prevent you from displaying the forms of brain activity that characterize REM sleep. But in the human fetus, these controls are not yet in place, which may explain why, during the last few months of gestation, the fetus spends such a large proportion of its sleeping time (about 80%) in REM sleep.

PGO Waves - (Pons - geniculate - occipital cortex)

PGO waves are among the various phasic events that occur during REM sleep, along with the rapid eye movements and changes in breathing and heart rates. PGO waves can be generated in the absence of REM sleep by stimulation of the pons with acetylcholine. As shown in figure3.1.25.7, the pons send signals to the thalamus which in turn signal the occipital cortex.

REM sleep is triggered by a specialized set of neurons in the pons (Hobson et al., 1975). Increased activity in this neuronal population has two consequences. First, elaborate neural circuitry keeps the body immobile during REM sleep by paralyzing major muscle groups (Chase, 2008). The muscle shut-down allows the brain to simulate a visual experience without moving the body at the same time. Second, we experience vision when waves of activity travel from the pons to the lateral geniculate nucleus and then to the occipital cortex (these are known as ponto-geniculo-occipital waves or PGO waves) (Gott et al., 2017). When the spikes of activity arrive at the occipital pole, we feel as though we are seeing even though our eyes are closed (Nir and Tononi, 2010). The visual cortical activity is presumably why dreams are pictorial and filmic instead of conceptual or abstract.

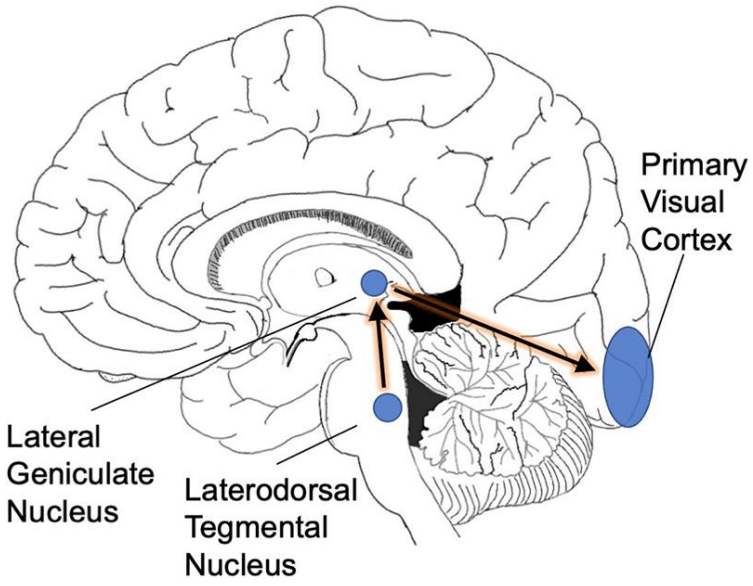

Figure 3.1.25.7: PGO waves. During REM sleep, waves of activity move from the brainstem into the occipital cortex. (PGO waves in The Defensive Activation Theory: REM Sleep as a Mechanism to Prevent the Takeover of the Visual Cortex by David Eagleman and Don Vaughn licensed CC-BY 4.0)

Summary

In an 8 hour typical night's sleep we move through distinct stages of sleep, several times through the night. We go from relative wakefulness to the deepest stages of sleep, cycle back out and into REM multiple times. Each of these stages correspond with different EEG wave patterns as well as the involvement of different regions of the brain and neurochemicals. The nature of REM sleep is paradoxical in a number of ways, and it seems to be different from the other stages in terms of quality and quantity.

3.1.26: The Brain and Sleep

Learning Objectives

1. Describe the role of the pons, medulla, hypothalamus (SCN), thalamus, basal forebrain and pineal gland in the initiation and maintenance of sleep.
2. Analyze the role of different neurochemicals, particularly the inhibitory neurotransmitter GABA and the sleep hormone melatonin in sleep initiation and maintenance.
3. Contrast the role of other neurochemicals like excitatory neurotransmitters glutamate and norepinephrine in wakefulness and sleep.

Overview

In general, there are several regions of the brain that work in concert to increase wakefulness and arousal, or to cause us to fall asleep or stay asleep. The primary excitatory neurotransmitters like glutamate and acetylcholine and the primary inhibitory neurotransmitter GABA play a role in these processes.

During the Spanish flu of 1918 some patients went into coma and some were sleepless before they died. Von Economo did autopsies and found different types of lesions. He concluded that the posterior hypothalamus/upper part of midbrain might be a wakefulness center, and the preoptic area of anterior hypothalamus might be a sleep center. These areas are illustrated in Figure 3.1.26.1. Later countless autopsies suggest that when one goes into a coma, their brainstem has suffered damage.

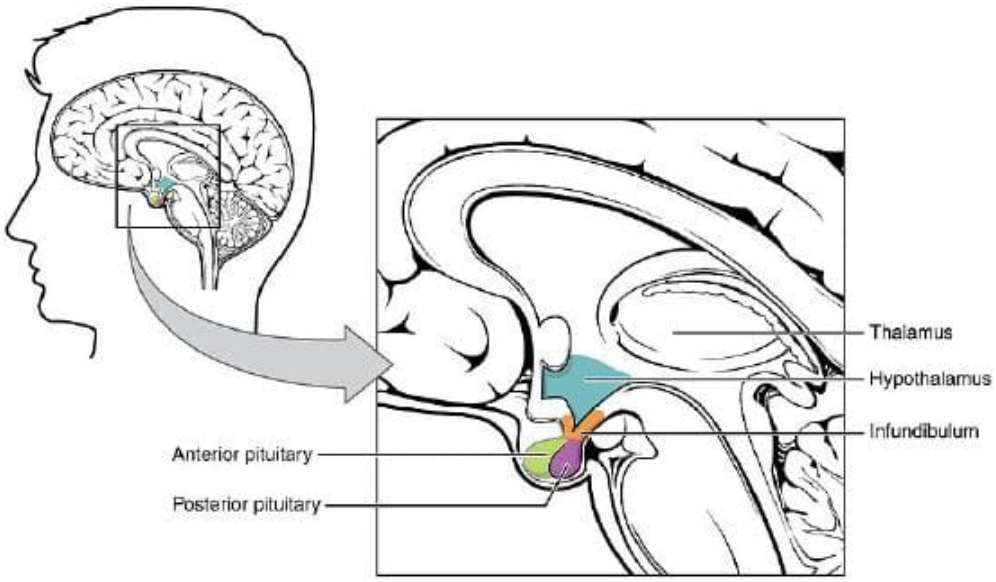

Figure 3.1.26.1: This sagittal section of the brain shows where the anterior and posterior pituitary, hypothalams and thalamus are located and their relations to each other in the inset - the thalamus is above the hypothalamus and the latter is above the pituitary glands. (CC BY 3.0; OpenStax College via Wikimedia Commons)

Sleep is not a state of neural silence

Work by Moruzzi and Magoun (1949) also suggested that when the reticular formation of cats was destroyed, comas were triggered, and stimulating this part led to awakening from normal sleep. Also, since this part receives incoming messages via sensory pathways, they developed the concept of “ascending activating reticular system” or the prime contender for “wakefulness center.”

But these initial experiments had several issues. Since neurotoxic substances that were used to destroy the neurons/cell bodies

of the posterior hypothalamus and reticular formation kept the axons that originated elsewhere intact, the wakefulness function that was diminished initially, quickly returned to normal.

Most importantly, these studies also showed that sleep is not a passive process, in which being deprived of sensory input causes sleep. Many people believe that sleep is something that happens in the absence of anything else like when someone is bored. For example, medical students attending a lecture in a subject that does not totally interest them will fall off to sleep. However, it is important to keep in mind that that is **not** actually what is happening. If a group of seven year old children who had had enough sleep the previous nights were sitting in the same lecture, they would not fall asleep but rather be bouncing off the walls!

In subsequent studies, application of electrical stimuli to the thalamus of cats when they were awake caused them to fall asleep. This indicates that sleep involves interactions between the thalamus and cortex. Also, when it was discovered that sleep and wakefulness cycles were not disrupted by sensory activation and that during REM there is intense activity in the cortex, the idea of sleep as passivity was further discredited.

There are two major neural circuits in the brainstem that operate in opposition to and alternation with each other. One of these circuits stimulates wakefulness, the other stimulates sleep, and their interaction is regulated by the body's internal clock (SCN).

Some large areas of the cortex are thus under the control of these networks of small groups of neurons that are located in the **brainstem** and that form complex circuits, not single "sleep centers" or "wakefulness centers." Wakefulness, which is indispensable for survival, is thus ensured by a whole network of redundant structures.

Forebrain regions involved in sleep

In the Figure 3.1.26.1 you can see the hypothalamus where the specific area of the brain, the suprachiasmatic nucleus (SCN- which is involved in the body's daily/circadian rhythm regulation) is located.

Anterior hypothalamus/SCN

SCN

The SCN is considered "body's internal clock." It will be discussed in a later section in more detail. The SCN is a bilateral structure located in the anterior part of the hypothalamus. It is the central pacemaker of the circadian timing system and regulates most circadian rhythms in the body (Hastings et al, 2018). The SCN receives signals from many different places. The major one is the retinohypothalamic tract originating from photosensitive (light-sensitive) ganglion cells of the retina. The SCN sends signals to structures such as the pineal gland, producing melatonin during the night for induction of sleep. Disruptions in the SCN circadian system have been found to correlate with various mood disorders and sleep disorders.

Preoptic area

The anterior hypothalamus also plays a fundamental role in the process of falling asleep. This structure, and in particular its preoptic area, appears to be sensitive to the serotonin released during waking periods. Apparently, when serotonin stimulates this preoptic area of the anterior hypothalamus, its GABAergic (GABA producing) neurons in turn inhibit the posterior hypothalamus, thus encouraging sleep. Damage to these GABAergic neurons is known to cause insomnia, whereas stimulating them causes experimental subjects to fall asleep rapidly.

Sleep-wakefulness switch

In vitro experiments have indicated that the wake-promoting neurotransmitters serotonin, norepinephrine, and acetylcholine inhibit identified preoptic GABA neurons (Gallopin et al., 2000); therefore, mutually inhibitory interactions between the sleep-promoting preoptic region and the arousal-related hypothalamic and midbrain structures may provide a substrate for a "sleep–wakefulness switch" (McGinty and Szymusiak, 2000; Saper et al., 2001). Thus, activation of preoptic sleep-promoting cells could lead to sleep onset by inhibiting arousal structures; in turn, activation of arousal hypothalamic and midbrain structures could suppress activity by preoptic NREM sleep-promoting cells as well as REM-promoting neurons (Reinoso-Suárez et al., 2010) and facilitate the switch to wakefulness.

Posterior hypothalamus

Stimulating the posterior hypothalamus produces a state of wakefulness comparable to that induced by stimulating the reticular formation in the brainstem. The activity of the posterior hypothalamus diminishes naturally during sleep, when it releases less histamine, a molecule that it uses as a neurotransmitter. The antihistamines that people take for allergy symptoms are known to cause some sleepiness, by reducing the activity of histamine.

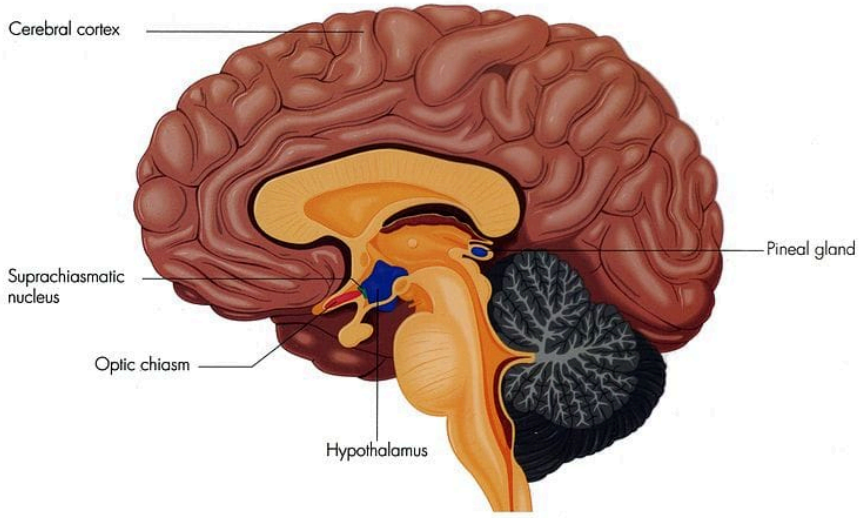

Figure 3.1.26.2: Sagittal view of the brain - note the hypothalamus shown in blue, located below the thalamus, and just above the pituitary gland (CC BY-SA 3.0; 黃雨伞 via Wikimedia Commons)

Thalamus

The thalamus contains neurons that send projections throughout the cortex. The activation of these thalamocortical neurons causes them to release excitatory amino acids such as aspartate and glutamate, thus contributing to excitation of the cortex and to wakefulness. During wakefulness, these neurons generate single action potentials at regular intervals. However, as the individual falls asleep these neurons begin firing in bursts instead, thus causing the cortex to display the synchronized EEG pattern that is typical of sleep (see section * for sleep stages).

Basal forebrain

The system of the basal forebrain is composed of neurons that synthesize acetylcholine and/or GABA. On their own, these neurons account for 70% of the cholinergic innervation of the cortex (where the cortex is activated by acetylcholine), while also sending projections to the thalamic nuclei. Stimulating these neurons causes wakefulness, but destroying them with neurotoxic substances causes wakefulness to decline for only a very short time.

In the situations just described, the cortical activation that causes wakefulness results from the direct stimulation of the cortical neurons by the various components of the wakefulness network. But these cortical neurons can also be activated in another way: by the inhibition of those neurons that naturally inhibit cortical activity. And that is exactly what the GABAergic neurons located in the posterior hypothalamus and the basal forebrain do: they inhibit other, cortical GABAergic neurons.

This executive network for wakefulness is itself activated by other systems arising in the brainstem.

It is thus all of these wakefulness signals that stop reaching the cortex at the onset of non-REM sleep. They are interrupted at the thalamus, which serves as a true gatekeeper to the cortex and is greatly influenced by the diffuse neuromodulatory systems of the brainstem. The complexity of these interactions in NREM sleep is illustrated in the diagram of the cat brain below (See Figure 3.1.26.2). This diagram illustrates a complex set of connections between cortical, subcortical, and brainstem structures that mediate various aspects of REM and NREM sleep. The figure is complicated, and the details are not important for our purpose here. It is included to illustrate the complexity of the connections between different brain sub-structures and signals being sent

in order to maintain the individual's movement through the different stages of sleep throughout the night.

[A legend indicates that the thalamus–cerebral cortex complex or unit is darker to emphasize that these structures are necessary for the behavioral and bioelectric signs that characterize NREM sleep. AC, anterior commissure; CC, corpus callosum; DCN, deep cerebellar nuclei; Fo, fornix; G7, genu of the facial nerve; IC, inferior colliculus; IO, inferior olive; LV, lateral ventricle; MRF; midbrain reticular formation; MT, medullary tegmentum; OCh, optic chiasm; PGS, periaqueductal gray substance; RPC, caudal pontine reticular nucleus; RPO, oral pontine reticular nucleus; SC, superior colliculus; SC and PN, spinal cord and peripheral nerves; SN, solitary nucleus; TB, trapezoid body.]

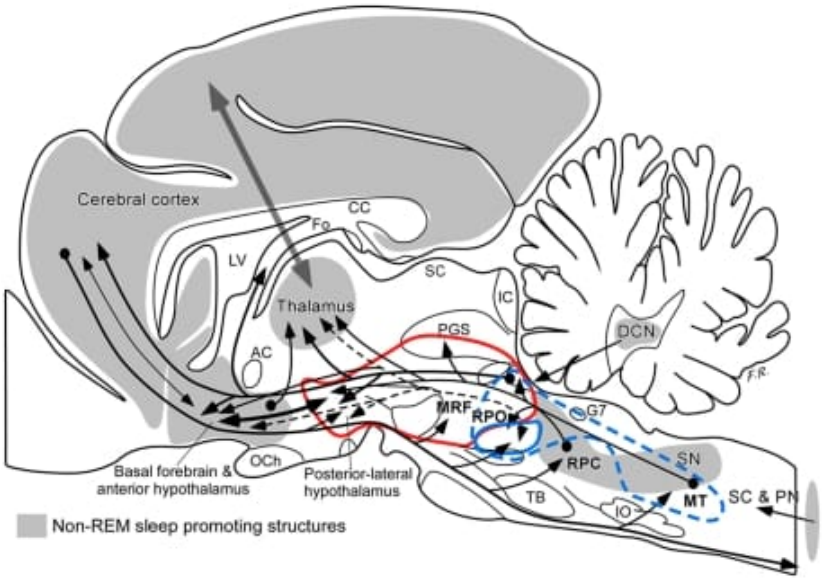

Figure 3.1.26.3: Schematic representation of the encephalic NREM sleep-promoting structures. Modified from Reinoso-Suárez et al. (2011). (Functional anatomy of non-REM sleep by Isabel De Andres, Miguel Garzón, and FernandoReinoso-Suárez via ResearchGate licensed CC-BY 4.0)

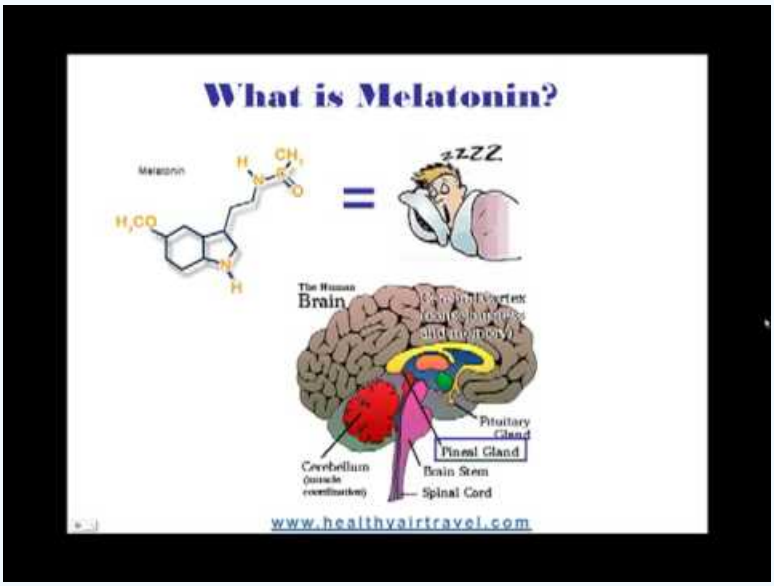
The rhythmic activity pattern established by the thalamocortical neurons that disconnects the cortex from internal and external signals at the onset of non-REM sleep. In contrast, during the REM phases of sleep, the thalamus probably continues to pass at least some of these signals on to the cortex, at least in some fragmentary, filtered, or distorted form.

The regulation of wakefulness is essential for survival and involves several different redundant structures in the brain. None of these structures, taken in isolation, is indispensable for activation of the cortex. But three of these brain structures that send projections to the cortex are sufficient to maintain the desynchronized EEG pattern that is characteristic of wakefulness. These structures are the 1. posterior hypothalamus, 2. the (intralaminar nuclei of the) thalamus and 3. the basal forebrain. Together they are often referred to as the “executive network”.



Pineal Gland

Inferior and somewhat posterior to the thalamus is the **pineal gland**, a tiny endocrine gland whose functions are not entirely clear. The **pinealocyte** cells that make up the pineal gland are known to produce and secrete the amine hormone **melatonin**, which is derived from serotonin.

The secretion of melatonin varies according to the level of light received from the environment. When photons of light stimulate the retinas of the eyes, a nerve impulse is sent to the SCN. From the SCN, the nerve signal is carried to the spinal cord and eventually to the pineal gland, where the production of melatonin is inhibited. As a result, blood levels of melatonin fall, promoting wakefulness. In contrast, as light levels decline—such as during the evening—melatonin production increases, boosting blood levels and causing drowsiness. The pineal gland and melatonin are discussed in more detail in section *

[reveal-answer q="598458"]Show Answer[/reveal-answer]
[hidden-answer a="598458"]Turning on the lights.[/hidden-answer]

The secretion of melatonin may influence the body's circadian rhythms (discussed in section *), the dark-light fluctuations that affect not only sleepiness and wakefulness, but also appetite and body temperature. Interestingly, children have higher melatonin levels than adults, which may prevent the release of gonadotropins from the anterior pituitary, thereby inhibiting the onset of puberty. Finally, an antioxidant role of melatonin is the subject of current research.

Jet lag occurs when a person travels across several time zones and feels sleepy during the day or wakeful at night. Traveling across multiple time zones significantly disturbs the light-dark cycle regulated by melatonin. It can take up to several days for melatonin synthesis to adjust to the light-dark patterns in the new environment, resulting in jet lag. Some air travelers take melatonin supplements to induce sleep.

Hindbrain regions involved in sleep

There are several "lower regions" of the brainstem that seem to be involved in sleep regulation according to early and current research.

Pons

The brainstem region known as the pons is critical for initiating REM sleep. During REM sleep, the pons sends signals to the visual nuclei of the thalamus and to the cerebral cortex (this region is responsible for most of our thought processes). The pons also sends signals to the spinal cord, causing the temporary paralysis that is characteristic of REM sleep. This is what happens in the experience of temporary sleep paralysis that many people might have experienced. Since the pons is effectively still "asleep" while the cortex is "awake," people experience the terrifying inability to move their body while they are completely conscious!

Also, the structures like the anterior hypothalamus play an important role in the onset of sleep.

Medulla and RAS

The reticular activating system (RAS) plays an important role in conscious awareness. According to Iwanczuk and Guzniczak (2015), "The ascending reticular activating system (ARAS) is responsible for a sustained wakefulness state. It receives information from sensory receptors of various modalities, ... [and those pathways] reach the thalamus directly or indirectly... The reticular activating system begins in the dorsal part of the posterior midbrain and anterior pons, continues into the diencephalon, and then divides into two parts reaching the thalamus and hypothalamus, which then project into the cerebral cortex."

The solitary tract nucleus region in the dorsal medulla is thought to provide a link between visceral activities such as respiratory, cardiovascular and gastrointestinal functions, and the sleep–wakefulness states. The solitary tract nucleus does not directly project to the cerebral cortex (Saper, 1995), although it does project to several brainstem, thalamic, and hypothalamic areas that innervate the cortex and can mediate EEG and sleep responses, such as the lateral hypothalamus, and nuclei of the midline thalamus.

Summary

The main brain regions working together to produce sleep and wakefulness have been discussed here. The neurons of the RAS play a role in arousal and sleep to some degree. The "executive network" seems to play an important role in regulating the responsiveness of the cortex to outside stimulation. The anterior hypothalamus and pineal regulate and fine tune many of these functions as well.

3.1.27: Theories of Sleep

Learning Objectives

- Evaluate the functions of sleep in relation to the biological mechanisms underlying it and affected by it.
- Describe the circadian nature of sleep.
- Describe the homeostatic or recuperative theory of sleep, and other theories of why we sleep.

Overview

When you ask most people why they think they sleep – the answer is "so I can rest" or "because I am tired from the activities of the day." However, the animals that work the hardest do not sleep the longest and even after pulling an all-nighter we don't sleep for the entire following day to make up for the lack of sleep. There are two theories of sleep that work in conjunction to explain why we sleep – recuperative and circadian.

Research indicates that for someone to be able to fall asleep, two bodily processes must be properly synchronized. The first is the **circadian rhythm**, which has a 24-hour period and is governed by your body's biological clock. The circadian rhythm controls the cyclical secretion of several hormones, including melatonin, that are involved in sleep. The second process is the **recuperative function** illustrated by the accumulation of hypnogenic substances in your body for 16 hours every day. These substances induce a desire to sleep that does not go away until you in fact get some sleep.

Thus you can fall asleep only when two conditions have been met: your body's biological clock must have brought it into a hormonal balance conducive to sleep, and it must have been a good while since you last slept, so that your levels of hypnogenic (sleep-producing) substances have built up sufficiently. The following section describes these two theories in greater detail, as well as other functions of sleep.

Sleep Regulation and Circadian Rhythms: A Two-Process Model

Sleep is a dynamic process that adjusts to the body's needs every day. What time you fall asleep, how long you sleep, and how well you sleep all result from the combined effects of two forces: the homeostatic debt and the phase of your circadian rhythm. Individuals of course differ as to what time they go to bed and how much sleep they need to function well, but on the whole, the characteristics of sleep can be regarded as the result of complex interactions between two processes.

The first of these processes is called homeostatic debt (see below) or recuperative theory, which increases as a function of how long you have been awake and decreases as you sleep. The process is somewhat like the sand accumulating in one end of an hourglass and having to be emptied into the other after a certain time. See Figure 3.1.27.1 for a graph of how the pressure to sleep increases as a function of time spent awake, and then decreases as we sleep.

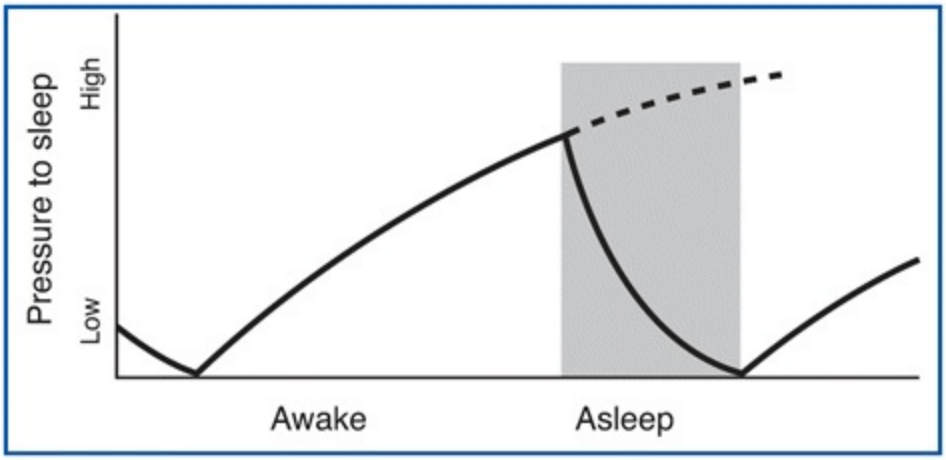

Figure 3.1.27.1: Homeostatic regulation of sleep: the pressure to sleep grows stronger across the day as one stays awake and then dissipates when one sleeps at night (shaded area). Sleep pressure increases (dashed line) as one stays awake longer into the normal sleeping hours. (NIH in the public domain)

The second process that greatly influences the onset, duration, and quality of your sleep is the phase of your circadian rhythm. This phase is governed by your biological clock, whose rhythm is endogenous but is reset regularly by daylight. This clock therefore produces a cycle lasting about 24 hours during which the optimal times for falling asleep, dreaming, waking up, and doing work occur over the course of each day. The external cues or zeitgebers (German for "time-givers") - of which sunlight is the most important - entrain your endogenous (internal) body clock to fall in line with the earth's day.

Endogenous sleep rhythms can be depicted graphically. The figure shows a day-by-day representation of one individual's sleep/wake cycle. The black lines indicate periods of sleep, and the gray lines indicate periods of wakefulness. The upper portion of the figure (days 1 through 9) represents this individual's normal sleep/wake cycle. Under these conditions, the individual is exposed to regularly timed exposure to alternating daylight and darkness, which has entrained this person's sleep/wake cycling to a period of 24 hours.

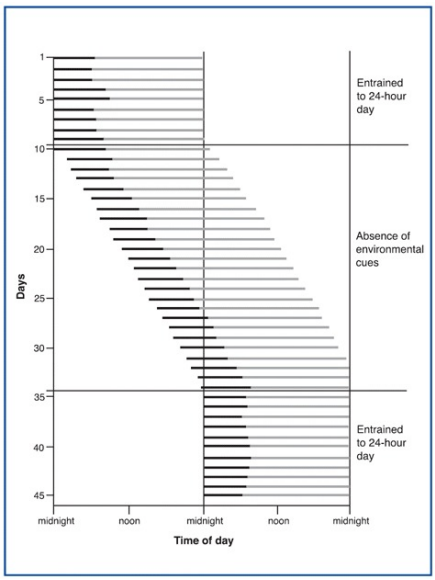

Figure 3.1.27.2: Entrainment of the biological clock. Black bars=sleep, gray bars=awake. (NIH in the public domain)

Thus your entire sleep-wake cycle operates as if your circadian oscillator made falling asleep easier at certain times of day, making you appreciably sleepier from 1:00 PM to 4:00 PM, and even sleepier from 2:00 AM to 5:00 AM. These patterns are confirmed by the statistics on workplace and highway accidents.

This two-process model - homeostatic and circadian - for regulating sleep can be diagrammed as a double pendulum.

Under normal circumstances, your periods of activity and rest are in phase with the alternation of day and night—your “circadian”

pendulum and your “homeostatic” pendulum are in synch, you sleep well when you fall asleep, and you function well when you wake up.

But when this relationship is disturbed and the two pendulums are no longer in phase, then the quality both of your sleep and of your performance when awake deteriorate significantly. The peaks of activity for several circadian markers occur at inconvenient times in the sleep-wake cycle, which is the source of the problems caused by jet lag and by working night shifts.

In other words, the longer you stay awake, the greater the pressure you will feel to go to sleep. This process of homeostatic debt, or sleep debt, also explains why, if you stay up all night, then the next night, not only will you sleep longer, but your percentage of deep sleep will be higher.

Molecules that build up and make you sleep – Adenosine and Melatonin

As each day draws to a close, you feel the need to lie down and go to sleep. The onset of sleep, which seems like such a simple phenomenon from a behavioral perspective, is actually quite complex from a molecular one.

Adenosine and homeostasis/recuperation

It was in the early 1980s that scientists first discovered the chemical mechanism by which drinking coffee helps people to stay awake: caffeine, the psychoactive substance in coffee, prevents adenosine from binding to certain neurons in the brain. Both the caffeine in coffee and the theophylline in tea are examples of such adenosine antagonists and are well known for their stimulant effects.

Once this discovery was made, adenosine became a subject of interest for more and more neurobiologists who were doing sleep research. Numerous animal experiments eventually confirmed that adenosine definitely plays a role in the sleep/wake cycle. Some of the experimental findings that led to this conclusion: a) blocking the effects of adenosine made animals more alert; b) injecting animals with an adenosine agonist (enhancer) caused them to fall asleep; c) in certain parts of the brain, the concentration of adenosine normally increases naturally during the day and decreases at night, but if animals are forced to stay awake at night, this concentration keeps increasing.

These experiments thus showed that adenosine, along with other chemicals such as serotonin and melatonin, is one of the molecules whose concentration in the brain influences the onset of sleep.

Adenosine is produced by the degradation of adenosine triphosphate (ATP), the molecule that serves as the “energy currency” for the body’s various cellular functions. The amount of adenosine produced in the brain thus reflects the activity level of its neurons and glial cells. The brain’s intense activity during periods of wakefulness consumes large amounts of ATP and hence causes adenosine to accumulate.

Glycogen=ATP reserves or energy currency of the brain

Brain uses energy --> ATP degrades into adenosine

More brain energy used = more adenosine accumulates

More adenosine levels --> non-REM sleep triggered

Non-REM sleep = less active brain --> recovery/rebuild glycogen stores

The accumulation of adenosine during waking periods is thus associated with the depletion of the ATP reserves stored as glycogen in the brain. The increased adenosine levels trigger non-REM sleep, during which the brain is less active, thus placing it in a recovery phase that is absolutely essential—among other things, to let it rebuild its stores of glycogen.

But how exactly does adenosine exert this influence? During periods of wakefulness, neuronal activity increases the concentration of adenosine, which has an inhibitory effect on a great many neurons. Among these are the neurons of the hormonal systems that are the most active when we are awake: the norepinephrine, acetylcholine, and serotonin systems. Experiments have shown, for example, that when the levels of adenosine in the basal forebrain are raised artificially, the neurons in this structure that project axons throughout the cortex produce less acetylcholine. As a result, cortical activity slows, and the individual falls asleep.

The synchronized brain activity characteristic of non-REM sleep can then become established. But once non-REM sleep has continued for a while, the adenosine levels begin to decline. The systems responsible for wakefulness can then start becoming more active, causing the individual to awaken and the cycle to begin all over again. Thus we see that the sleep/wake cycle involves a highly efficient negative feedback loop.

Circadian rhythms

There are two important structures for the circadian cycle that could be considered our biological clocks.

The suprachiasmatic nuclei and the pineal gland and melatonin

Most human bodily functions and behaviors are not “steady-state”. Instead, they fluctuate in 24-hour cycles, such as the sleeping and waking cycle and the cycles for body temperature, hunger, and the secretion of various hormones. The central clock that regulates all of these circadian cycles is located in two tiny structures in the brain, at the base of the left and right hypothalamus. Each of these structures is no larger than a pencil tip and contains several tens of thousands of neurons. These structures are called the suprachiasmatic nuclei (as mentioned earlier in section *) because they are located just above the optic chiasma, where the left and right optic nerves cross paths.

This strategic position enables the suprachiasmatic nuclei to receive projections from the optic nerve from special retinal ganglion cells that tell them about the intensity of the ambient light entering the eyes. The neurons of these nuclei use this information to resynchronize themselves with daylight every day, because like any clock, the human biological clock is not perfect and does need to be reset periodically. One interesting thing about the retinohypothalamic path is that it is separate from those for vision such that even blind people (and blind mole rats, a species that is otherwise blind) receive information from light to reset their biological clocks.

Despite this need to resynchronize with an external cue, it has been shown that the suprachiasmatic nuclei do in fact constitute a biological clock with its own independent rhythm. First, many experiments have shown that the fluctuations of the human circadian cycle persist even when individuals are cut off from the light of day. Second, in experiments where the suprachiasmatic nuclei were destroyed in animals such as hamsters, their cyclical behaviors, such as their sleep/wake cycles, become completely disorganized. And when suprachiasmatic nuclei were then transplanted from hamster fetuses into these animals, their biological rhythms returned, but with the properties of the donors.

These findings indicate that the mammalian biological clock mechanism is in fact not only endogenous, but also of genetic origin. Scientists have now even determined that these rhythms are the result of the cyclical activity of certain genes.

The circuit of light entering the eye, the signal going to the SCN and to the pineal gland is shown in the figure 3.1.27.4. Melanopsin in retinal ganglion cells in the eye respond to light (natural or artificially) and transmit signals to the SCN. Then light-induced activation of the SCN prevents the pineal gland from producing melatonin and; conversely, melatonin production and secretion is increased during the dark period.

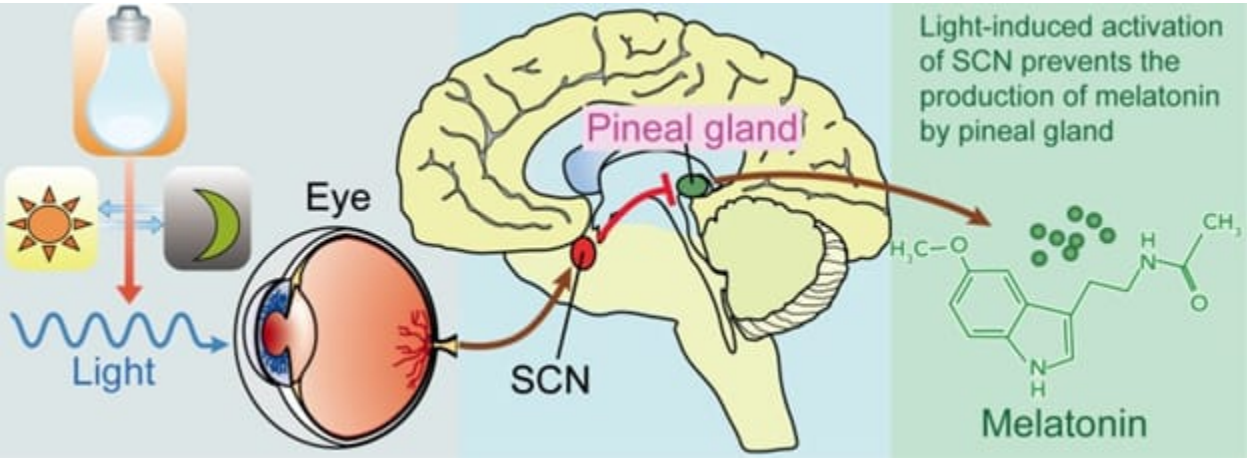

Figure 3.1.27.3: Light, suprachiasmatic nuclei (SCN), and the pineal/melatonin circuit. (Zhiqiang Ma, Yang Yang, Chongxi Fan, Jing Han, Dongjin Wang, Shouyin Di, Wei Hu, Dong Liu, Xiaofei Li, Russel J. Reiter, and Xiaolong Yan, CC BY 4.0 <https://creativecommons.org/licenses/by/4.0>, via Wikimedia Commons)

Pineal gland

Using these cyclical rhythms, the suprachiasmatic nuclei send signals along their output pathways–for example, to the pineal gland–to regulate the cycles of a number of physiological and behavioral functions. In birds, reptiles, and fish, this small gland located at the top of the brain is sensitive to light and co-ordinates some cyclical phenomena on its own. In mammals, however, though the pineal gland (mentioned earlier in section 12.2) does retain its ability to produce secretions cyclically (specifically, the hormone melatonin, at night), it does not constitute a clock on its own; instead, its cyclical synthesis of melatonin is controlled by timing signals that it receives from the SCN.

Each day, the pineal gland begins to produce melatonin (sometimes called the “sleep hormone”) as night falls. As the level of melatonin in the blood rises, body temperature falls slightly, and the individual feels sleepier and sleepier. The melatonin level remains high for just about 12 hours, then starts falling again in the early morning, as daylight (via the SCN) inhibits this gland’s activity.

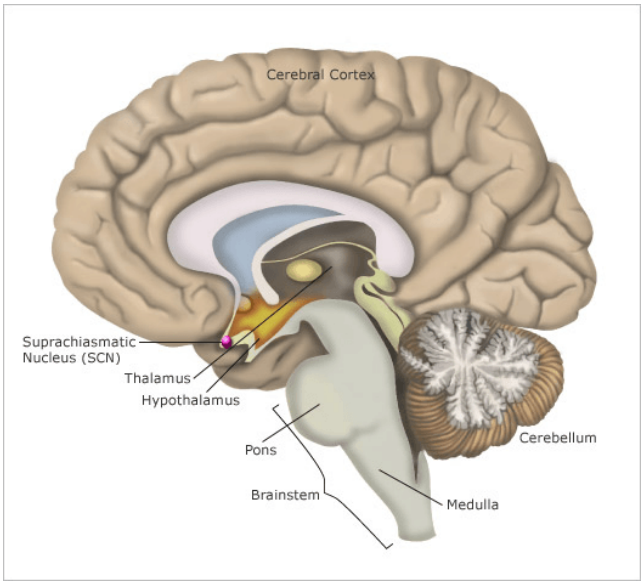

Figure \({3{.}1{.}27{.}\eatSpaces{4\): The SCN in the anterior part of the hypothalamus is indicated along with the brainstem - pons and medulla - below (Sagittal image of brain licensed CC BY-SA)

The main neurotransmitter regulating the activity of the pineal gland is norepinephrine. When norepinephrine binds to its receptors, it triggers a cascade of second messengers, including cyclic AMP. This cyclic AMP contributes to the synthesis of melatonin. This melatonin is released into the bloodstream, through which it reaches every organ in the body. That is how it participates in the modulation of the circuits of the brainstem that ultimately control the sleep-wake cycle.

Output of SCN

The output pathways from each SCN (see Figure Extra close brace or missing open brace for another picture of its location) consist of axons that innervate mainly the hypothalamus and nearby structures. Some of these axons also project to other parts of the forebrain, while others project to the midbrain.

Scientists do not yet know the details of how the central biological clock in the SCN regulates so many different human cyclical behaviors. But they do know that it uses the pineal gland to do so, and they have shown that destroying the SCN's output pathways also destroys the body’s circadian rhythms. Because GABA is the essential neurotransmitter for almost all of the SCN's neurons, one would expect an inhibitory effect on the neurons that they innervate. In addition to sending out messages along these axonal pathways, the SCN's neurons seem to secrete a neuropeptide called vasopressin in a cyclical pattern.

Yet another figure 3.1.27.5 shows the relative location of the different structures involved in the regulation of the circadian rhythms.

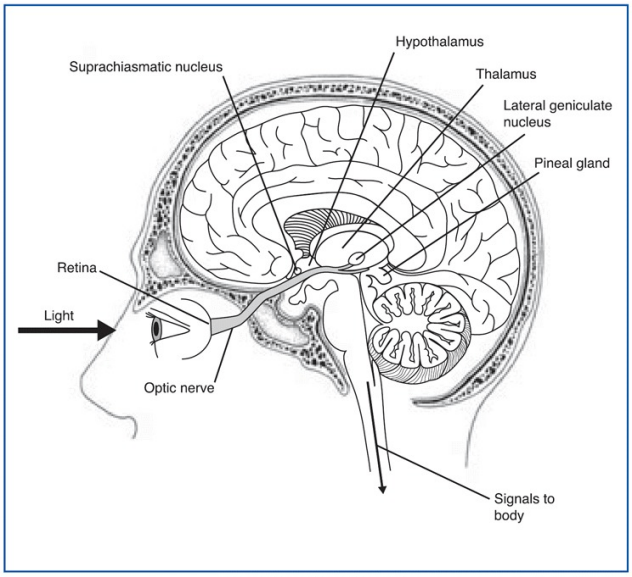

Figure 3.1.27.5: The biological clock is located in the SCN of the brain (NIH in the public domain)

Scientists have now discovered that the neurotransmitter GABA excites the cells of the dorsal SCN but inhibits those of the ventral SCN. These opposing effects might influence the differing reaction times of these two sub-regions when someone travels across several time zones. This discovery thus opens new insights into the mechanisms behind the disturbing symptoms of jet lag.

Scientists removed neurons from the suprachiasmatic nuclei of rats and isolating these cells in a culture medium in vitro and found that feedback loops inside each of the cells discharge at frequencies varying in cycles lasting about 24 hours. But unlike suprachiasmatic nucleus cells in the brain, which synchronize their activity with the day/night cycle, suprachiasmatic nucleus cells in vitro do not. Like any other clock, the human body's biological clock needs to be reset periodically. For that to happen, every cell in this clock must resynchronize itself daily with external cues that tell it when the day begins and ends. These external cues, also known as Zeitgebers (German for "time givers"), include the ambient temperature, the consumption of meals, ambient noise, and the body's activity level. But the strongest of these cues is undoubtedly the overall intensity of the ambient light.

Resetting the body's internal clocks - Zeitgebers

Light-sensitive ganglion cells

Thanks to various tagging methods, scientists now know that a certain sub-population of the ganglion cells in the human retina contain a photosensitive pigment and project their axons directly into the suprachiasmatic nuclei as well as into other brain structures that are concerned with the intensity of ambient light.

These light-sensitive ganglion cells have large receptive fields, because of their long, widely dispersed dendrites. In these cells, accurate reception of information on shape, orientation, and movement is sacrificed to general sensitivity. These cells clearly constitute another light-sensitive system that runs parallel to the visual system but is dedicated to detecting light intensity rather than to forming images.

Molecular clockwork

Many human functions, such as alertness, body temperature, and the secretion of certain hormones, work better if they are adjusted according to whether it is day or night. As you might therefore expect, a mechanism has evolved within the human body to co-ordinate its major functions with the time of day.

The human biological clock is extremely regular, though not exactly 24 hours: it is accurate to within 1%. But just like a watch that is never absolutely accurate on its own and needs to be reset occasionally, this biological clock needs a mechanism to prevent tiny errors from accumulating in each cell. Also, it needs to synchronize itself with external signs that tell it when each new day begins. The growing intensity of the natural light is the first sign of daybreak, and special photopigments in the retina detect this change in light intensity and transmit this information to the human biological clock.

In Figure 3.1.27.7, the levels of organization of information and operation of the circadian systems are shown. Circadian systems need to be considered in relation to three differing levels of organization of information and operation. First is the way in which the physical environment communicates (or 'Inputs') key information, particularly related to differentiation of night from day, to the internal 'master' clock (located in the brain's suprachiasmatic nucleus (SCN)). Second are the 'Intrinsic' brain factors, consisting of the master clock and its linked regulatory systems (notably secretion of melatonin from the pineal gland). These contribute to sleep onset, sleep architecture, sleep-wake cycles and other central nervous system (CNS)-dependent behavioral changes. Third is the way in which the circadian system coordinates all other hormonal, metabolic, immune, thermoregulatory, autonomic nervous and other physiological processes to optimize the relationships between behavior and body functions (that is, the 'Outputs').

At the cellular level, almost all individual cells and, hence, organ systems have their own intrinsic clocks. As these cellular (for example, fibroblasts, fat cells, muscles) and organ-based (for example, liver, pancreas, gut) clocks run to intrinsically different period lengths, the differing physiological systems need to be aligned in coherent patterns. Fundamentally, the master circadian clock permits the organism to align key behavioral and intrinsic physiological rhythms optimally to the external 24-hour light–dark cycle.

In the figure, the black arrows from eye (and sunlight), genes, and environment/daily patterns (eating/sleeping/exercising) to the SCN indicate input received by the master clock. The red arrows from the raphe nuclei and pineal gland (via melatonin) to the SCN, and from the SCN to the pituitary indicate intra-CNS modulation of the signals. The blue arrows from melatonin to sleep regulation signals, from the SCN to ANS activity and temperature regulation, and pituitary to hormone regulation (ACTH and TSH) indicate output from the brain controlling other organ systems in the body.

The table at the end illustrates how muscle, liver, fat and pancreas function changes depending on time of day or night. During the day, muscle uptake fatty acid, and increase glycolitic metabolism. For fats, there is lipogenesis and adiponectin production. In the liver, there is glycogen, cholesterol and bile acid synthesis. In the pancreas there is insulin secretion. At night, muscles engage in oxidative metabolism. Fats have lipid catabolism and leptin secretion. The liver engages in gluconeogenesis, glycogenolysis, and mitochondrial biogenesis. The pancreas secrete glucagon.

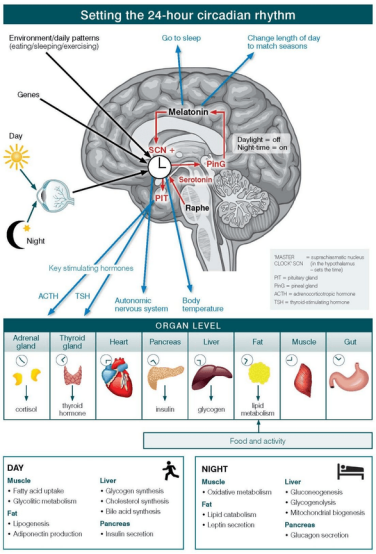

Figure 3.1.27.6: The master clock (SCN) receives input from external stimuli, connects with other brain regions (primarily the pineal gland), and regulates/moderates several organ systems and functions in the body. Other theories of why we sleep

As mentioned in section * there are many functions of sleep including memory consolidation, energy conservation, brain development and discharge of emotions. Further, the importance of sleep is apparent in the multiple negative ramifications of sleep deprivation.

Summary

Under normal circumstances, there are two main mechanisms by which our sleep is regulated - homeostatic or recuperative and circadian or rhythmic. Adenosine appears to be the main chemical underlying the homeostatic/recuperative functions of sleep. Indeed most of us are aware of how we feel tired after long periods of wakefulness. Melatonin and the free running rhythms of the SCN seem to underlie the circadian/rhythmic aspects of sleep. Jet lag, shift work, and the overall disruption of people's body clocks during the COVID pandemic provide testimony to how this theory is also an important basis of sleep. Certainly it is clear that humans need sleep for a variety of reasons and that when we are sleep deprived, there are many mental and physical health consequences.

3.1.28: Sleep Disorders

Learning Objectives

1. Describe the different kinds of sleep disorders.
2. Describe the causes of different sleep disorders.
3. Analyze different treatment options for sleep disorders.
4. Describe current research on the connection between sleep disorders and other physical health conditions.

Overview

Research has demonstrated that good sleep habits result in improved health and psychological functioning (Hyyppa & Kronholm, 1989). In fact poor sleep quality can result in severe psychiatric symptoms. Worldwide, approximately 30 percent of adults report difficulty initiating or maintaining sleep or experiencing poor sleep quality.

About 50 to 70 million Americans have sleep or wakefulness disorders. Sleep deficiency and untreated sleep disorders are associated with a growing number of health problems, including heart disease, high blood pressure, stroke, diabetes, obesity, and certain cancers. Sleep disorders can also be costly. Each year sleep disorders, sleep deprivation, and sleepiness add to the national health care bill. Undiagnosed sleep apnea alone is estimated to cost the US $150 billion annually. Additional costs to society for related health problems, lost worker productivity, and accidents make sleep disorders a serious public health concern.

In this section insomnia, circadian rhythm disorders, sleep apnea and narcolepsy are discussed.

Insomnia

Insomnia is a common sleep disorder. With insomnia, you may have trouble falling asleep, staying asleep, or getting good quality sleep. Chronic (long-term) insomnia occurs three or more nights a week, lasts more than three months, and cannot be fully explained by another health problem or a medicine.

Insomnia can affect your memory and concentration. Chronic insomnia raises your risk of high blood pressure, coronary heart disease, diabetes, and cancer.

In addition to finding out your medical history and having you keep a sleep diary, your doctor may have you take the following tests.

- **A sleep study** to look for other sleep problems, such as circadian rhythm disorders, sleep apnea, and narcolepsy.
- **Actigraphy** to measure how well you sleep. This requires you wear a small motion sensor three to 14 days.
- **Blood tests** to check for thyroid problems or other medical conditions that can affect sleep.

In the short term, insomnia can make it hard to concentrate or think clearly. You may feel irritable, sad, and unrested or have headaches. Insomnia raises your risk of falling, having a road accident, or missing work.

In addition, chronic insomnia can affect how well your brain, heart, and other parts of your body work. It can raise your risk of certain health problems or make existing problems worse. These conditions include:

- **Breathing problems** such as asthma
- **Heart problems** such as arrhythmia, heart failure, coronary heart disease, and high blood pressure
- **Mental health conditions** such as anxiety, depression, and thoughts of suicide. Insomnia can also make it difficult for you to stick to treatment for a substance use disorder.
- **Pain.** People who have chronic pain and insomnia may become more aware of and distressed by their pain.
- **Pregnancy complications** such as having more pain during labor, giving birth preterm, needing a cesarean section (C-section), and having a baby with low birth weight.
- **Problems with your immune system,** your body's natural defense against germs and sickness. These problems can lead

to inflammation in your body or make it harder to fight infections.
- **Problems with your metabolism.** Not getting enough sleep can change the levels of hormones that control hunger and how you break down food. This can raise the risk of overweight and obesity, metabolic syndrome, and diabetes.

Treatment

Doctors may recommend healthy lifestyle habits such as a regular sleep schedule, cognitive behavioral therapy for insomnia, and medicines to help manage the insomnia.

Medicines

Prescription medicines

Many prescription medicines are used to treat insomnia. Some are meant for short-term use while others are meant for longer-term use. Some insomnia medicines can be habit-forming and all of these medicines may cause dizziness, drowsiness, or worsening of depression or suicidal thoughts. All of the medicines listed below may also cause insomnia.

- **Benzodiazepines,** like Valium, and **Benzodiazepine receptors agonists,** such as zolpidem**,** zaleplon, and eszopiclone can be habit-forming and should be taken for only a few weeks. Benzodiazepines are GABA agonists. Remember, from chapter *, that GABA is one of the most common inhibitory neurotransmitters in the central nervous system. Hence Benzodiazepines (and Benzodiazepine receptor agonists) make it even less likely that neurons will fire. Additional side effects of Benzodiazepine receptor agonists may include anxiety. Rare side effects may include a severe allergic reaction or unintentionally doing activities while asleep such as walking, eating, or driving.
- **Melatonin receptor agonists,** such as ramelteon. Rare side effects may include doing activities while asleep such as walking, eating or driving or a severe allergic reaction.
- **Orexin receptor antagonists,** such as suvorexant. This medicine is not recommended for people who have narcolepsy. Rare side effects may include doing activities while asleep such as walking, eating, or driving or not being able to move or speak for several minutes while going to sleep or waking up.

Off-label medicines

In some special cases healthcare providers may prescribe medicines that are commonly used for other health conditions but are not yet approved by the FDA to treat insomnia. Some of these medicines may include antidepressants, antipsychotics, and anticonvulsants.

Some over-the-counter (OTC) products that contain antihistamines are sold as sleep aids. Although these products might make you sleepy, talk to your doctor before taking them. Antihistamines can be unsafe for some people. Also, these products may not be the best treatment for your insomnia. Your doctor can advise you whether these products will help you.

Melatonin supplements are lab-made versions of the sleep hormone melatonin. Many people take melatonin supplements to improve their sleep. However, research has not proven that melatonin is an effective treatment for insomnia. Talk to your doctor before using these supplements. Dietary supplements can be beneficial to your health, but they can also have health risks.

The U.S. Food and Drug Administration regulates dietary supplements under a different set of regulations than those covering "conventional" foods and medicines. It does not have the authority to review dietary supplement products for safety and effectiveness before they are marketed.

Side effects of melatonin may include daytime sleepiness, headaches, upset stomach, and worsening depression. It can also affect your body's control of blood pressure, causing high or low blood pressure.

Other treatments

Your doctor may recommend that you use light therapy to set and maintain your sleep-wake cycle. With this treatment, you plan time each day to sit in front of a light box, which produces bright light similar to sunlight.

Sleep apnea

Sleep apnea is a common condition in the United States. It can occur when the upper airway becomes blocked repeatedly during sleep, reducing or completely stopping airflow. This is known as obstructive sleep apnea. If the brain does not send the signals needed to breathe, the condition may be called central sleep apnea.

Healthcare providers use sleep studies to diagnose sleep apnea. They record the number of episodes of slow or stopped breathing and the number of central sleep apnea events detected in an hour. They also determine whether oxygen levels in the blood are lower during these events.

Sleep studies can be done in a special center or at home. Studies at a sleep center can detect apnea events, detect low or high levels of activity in muscles that control breathing, monitor blood oxygen levels, brain and heart activity during sleep.

Other medical conditions that can cause sleep apnea are diagnosed in the following manner:

- Blood tests to check the levels of certain hormones and to rule out endocrine disorders that could be contributing to sleep apnea. Thyroid hormone can rule out hypothyroidism. Growth hormone tests can rule out acromegaly. Total testosterone and dehydroepiandrosterone sulphate (DHEAS) tests can help rule out polycystic ovary syndrome (PCOS).
- Pelvic ultrasound to examine the ovaries and detect cysts. This can rule out PCOS.

Doctors may want to know whether there is use of medicines, such as opioids, that could be affecting sleep or causing breathing symptoms of sleep apnea. Doctors may also want to know whether the patient has traveled recently to altitudes greater than 6,000 feet, because these low-oxygen environments can cause symptoms of sleep apnea for a few weeks after traveling.

Undiagnosed or untreated sleep apnea can lead to serious complications such as heart attack, glaucoma, diabetes, cancer, and cognitive and behavioral disorders.

Breathing devices such as continuous positive air pressure (CPAP) machines and lifestyle changes are common sleep apnea treatments.

Narcolepsy

Narcolepsy is a chronic neurological disorder that affects the brain's ability to control sleep-wake cycles. People with narcolepsy may feel rested after waking, but then feel very sleepy throughout much of the day. Many individuals with narcolepsy also experience uneven and interrupted sleep that can involve waking up frequently during the night.

Symptoms

Narcolepsy is a lifelong problem, but it does not usually worsen as the person ages. Symptoms can partially improve over time, but they will never disappear completely. The most typical symptoms are excessive daytime sleepiness, cataplexy, sleep paralysis, and hallucinations. Though all have excessive daytime sleepiness, only 10 to 25 percent of affected individuals will experience all of the other symptoms during the course of their illness.

- **Excessive daytime sleepiness (EDS).** All individuals with narcolepsy have EDS, and it is often the most obvious symptom. EDS is characterized by persistent sleepiness, regardless of how much sleep an individual gets at night. However, sleepiness in narcolepsy is more like a "sleep attack", where an overwhelming sense of sleepiness comes on quickly.
- **Cataplexy**. This sudden loss of muscle tone while a person is awake leads to weakness and a loss of voluntary muscle control. It is often triggered by sudden, strong emotions such as laughter, fear, anger, stress, or excitement. Some people may only have one or two attacks in a lifetime, while others may experience many attacks a day. Attacks may be mild and involve only a momentary sense of minor weakness in a limited number of muscles, such as a slight drooping of the eyelids. The most severe attacks result in a total body collapse during which individuals are unable to move, speak, or keep their eyes open. But even during the most severe episodes, people remain fully conscious, a characteristic that distinguishes cataplexy from fainting or seizure disorders. The loss of muscle tone during cataplexy resembles paralysis of muscle activity that naturally occurs during REM sleep.

- **Sleep paralysis**. The temporary inability to move or speak while falling asleep or waking up usually lasts only a few seconds or minutes and is similar to REM-induced inhibitions of voluntary muscle activity. Sleep paralysis resembles cataplexy except

it occurs at the edges of sleep.
- **Hallucinations**. Very vivid and sometimes frightening images can accompany sleep paralysis and usually occur when people are falling asleep or waking up. Most often the content is primarily visual, but any of the other senses can be involved.

Additional symptoms of narcolepsy include:

- **Fragmented sleep and insomnia**. While individuals with narcolepsy are very sleepy during the day, they usually also experience difficulties staying asleep at night. Sleep may be disrupted by insomnia, vivid dreaming, sleep apnea, acting out while dreaming, and periodic leg movements.
- **Automatic behaviors**. Individuals with narcolepsy may experience temporary sleep episodes that can be very brief, lasting no more than seconds at a time. A person falls asleep during an activity (e.g., eating, talking) and automatically continues the activity for a few seconds or minutes without conscious awareness of what they are doing. This happens most often while people are engaged in habitual activities such as typing or driving. They cannot recall their actions, and their performance is almost always impaired.

In a normal sleep cycle, a person enters rapid eye movement (REM) sleep after about 60 to 90 minutes. Dreams occur during REM sleep, and the brain keeps muscles limp during this sleep stage, which prevents people from acting out their dreams. People with narcolepsy frequently enter REM sleep rapidly, within 15 minutes of falling asleep. Also, the muscle weakness or dream activity of REM sleep can occur during wakefulness or be absent during sleep. This helps explain some symptoms of narcolepsy. Narcolepsy affects both males and females equally. Symptoms often start in childhood, adolescence, or young adulthood (ages 7 to 25), but can occur at any time in life. It is estimated that anywhere from 135,000 to 200,000 people in the United States have narcolepsy. However, since this condition often goes undiagnosed, the number may be higher. Since people with narcolepsy are often misdiagnosed with other conditions, such as psychiatric disorders or emotional problems, it can take years for someone to get the proper diagnosis.

Individuals may be asked by their doctor to keep a sleep journal noting the times of sleep and symptoms over a one- to two-week period. Although none of the major symptoms are exclusive to narcolepsy, cataplexy is the most specific symptom and occurs in almost no other diseases.

A physical exam can rule out or identify other neurological conditions that may be causing the symptoms. Two specialized tests, which can be performed in a sleep disorders clinic, are required to establish a diagnosis of narcolepsy:

- **Polysomnogram (PSG or sleep study)**. The PSG is an overnight recording of brain and muscle activity, breathing, and eye movements. A PSG can help reveal whether REM sleep occurs early in the sleep cycle and if an individual's symptoms result from another condition such as sleep apnea.
- **Multiple sleep latency test (MSLT).** The MSLT assesses daytime sleepiness by measuring how quickly a person falls asleep and whether they enter REM sleep. On the day after the PSG, an individual is asked to take five short naps separated by two hours over the course of a day. If an individual falls asleep in less than 8 minutes on average over the five naps, this indicates excessive daytime sleepiness. However, individuals with narcolepsy also have REM sleep start abnormally quickly. If REM sleep happens within 15 minutes at least two times out of the five naps and the sleep study the night before, this is likely an abnormality caused by narcolepsy.

  Occasionally, it may be helpful to measure the level of hypocretin in the fluid that surrounds the brain and spinal cord. To perform this test, a doctor will withdraw a sample of the cerebrospinal fluid using a lumbar puncture (also called a spinal tap) and measure the level of hypocretin-1. In the absence of other serious medical conditions, low hypocretin-1 levels almost certainly indicate type 1 narcolepsy.

Causes

Narcolepsy may have several causes. Nearly all people with narcolepsy who have cataplexy have extremely low levels of the naturally occurring chemical hypocretin, which promotes wakefulness and regulates REM sleep. Hypocretin levels are usually normal in people who have narcolepsy without cataplexy.

Although the cause of narcolepsy is not completely understood, current research suggests that narcolepsy may be the result of a combination of factors working together to cause a lack of hypocretin. These factors include:

- **Autoimmune disorders**. When cataplexy is present, the cause is most often the loss of brain cells that produce hypocretin. Although the reason for this cell loss is unknown, it appears to be linked to abnormalities in the immune system.
- **Family history**. Up to 10 percent of individuals diagnosed with narcolepsy with cataplexy report having a close relative with

similar symptoms.
- **Brain injuries**. Rarely, narcolepsy results from traumatic injury to parts of the brain that regulate wakefulness and REM sleep or from tumors and other diseases in the same regions.

Treatment

Early recognition and diagnosis of narcolepsy could be significant for certain treatment possibilities. Although under debate, autoimmunity is believed to be responsible for the hypocretin neuron loss. Some case reports and uncontrolled small studies suggest that immunomodulatory treatment, such as intravenous immunoglobulin, is able to ameliorate narcolepsy symptoms and influence hypocretin status (see Giannoccaro, 2020 for an overview). Based on the assumption that immunomodulatory treatment could prevent neuronal death, it should be administered as close to disease onset as possible. However, the presence of cataplexy already indicates the loss of the majority of hypocretinergic cells. Recognition of narcolepsy even before cataplexy onset is therefore crucial in order to modify the course of the pathological process. The emerging evidence of T-cell activation in the blood and CSF of narcolepsy type 1 patients in a very early stage of the disease might become useful in early recognition as well as timing of immunomodulatory treatment.

Although there is no cure for narcolepsy, some of the symptoms can be treated with medicines and lifestyle changes. When cataplexy is present, the loss of hypocretin is believed to be irreversible and lifelong. Excessive daytime sleepiness and cataplexy can be controlled in most individuals with medications.

Medications

- **Modafinil**. The initial line of treatment is usually a central nervous system stimulant such as modafinil, which is less addictive and has fewer side effects than older stimulants.
- **Amphetamine-like stimulants**. In cases where modafinil is not effective, doctors may prescribe amphetamine-like stimulants such as methylphenidate to alleviate EDS. The potential for side effects and abuse is higher so monitoring is necessary.
- **Antidepressants**. Two classes of antidepressant drugs have proven effective in controlling cataplexy in many individuals: tricyclics (including imipramine, desipramine, clomipramine, and protriptyline) and selective serotonin and noradrenergic reuptake inhibitors (including venlafaxine, fluoxetine, and atomoxetine).
- **Sodium oxybate**. Sodium oxybate (also known as gamma hydroxybutyrate or GHB) has been approved by the U.S. Food and Drug Administration to treat cataplexy and excessive daytime sleepiness in individuals with narcolepsy.

Lifestyle changes

Not everyone with narcolepsy can consistently maintain a fully normal state of alertness using currently available medications. Drug therapy should accompany various lifestyle changes such as taking short naps, maintaining a regular sleep schedule, avoiding caffeine, large meals and alcohol before bed, avoiding smoking, relaxing before bedtime, and exercising daily. Safety precautions while driving, operating heavy machinery and even walking down long flights of stairs are important.

Circadian Rhythm Disorders (Also known as Sleep-Wake Cycle Disorders)

Circadian rhythm disorders are problems that occur when your sleep-wake cycle is not properly aligned with your environment and interferes with your daily activities.

Your body tries to align your suprachiasmatic nuclei and endogenous sleep-wake cycle to cues from the environment, for example, when it gets light or dark outside, when you eat, and when you are physically active. When your sleep-wake cycle is out of sync with your environment, you may have difficulty sleeping, and the quality of your sleep may be poor. Disruptions of your sleep-wake cycle that interfere with daily activities may mean that you have a circadian rhythm disorder.

Disruptions in your sleep patterns can be temporary and caused by external factors such as your sleep habits, job, or travel. Jet lag and shift work are two major contemporary conditions that are a result of technology and our present social and economic realities. Or a circadian rhythm disorder can be long-term and caused by internal factors such as your age, your genes, or a medical condition. Symptoms may include extreme daytime sleepiness, insomnia, tiredness, decreased alertness, and problems with memory and decision-making.

To diagnose a circadian rhythm disorder, your doctor may ask about your sleep habits, suggest sleep tests, a diary to track when and how long you sleep, and test the levels of certain hormones in your blood or saliva. Your treatment plan will depend on the type and cause of your circadian rhythm disorder. Treatment may include light therapy, medicines to help you fall asleep or stay awake, or healthy lifestyle changes including steps to improve your sleep habits. If left untreated, circadian rhythm disorders may increase the risk of certain health problems or lead to workplace and road accidents.

There are many sleep-wake phase disorders which include Advanced sleep-wake phase disorder, Delayed sleep-wake phase disorder, Irregular sleep-wake rhythm disorder, and Non–24-hour sleep-wake rhythm disorder.

Circadian rhythm disorders cause problems with metabolism in shift workers. When shift work triggers a circadian rhythm disorder, it can disrupt your metabolism in a few ways. Normally, your biological clock helps control your hunger hormones. However, when you do not get enough good-quality sleep, your body makes less leptin, the hormone that tells your body when you are full, and more ghrelin, the hormone that tells your body you are hungry. You may respond by eating larger amounts of food than normal, as well as more fatty, sweet, and salty foods.

Improving health with current research

Learn about the following ways the NHLBI continues to translate current research into improved health for people who have circadian rhythm disorders. Research on this topic is part of the NHLBI's broader commitment to advancing sleep science and sleep disorders scientific discovery.

- NHLBI's National Center on Sleep Disorders Research (NCSDR). For 25 years, the NCSDR has led foundational research on sleep and circadian biology across the NIH and has worked with federal and private organizations to disseminate sleep health information. The NCSDR administers sleep and circadian research projects, training, and educational awareness programs, and serves as an NIH point of contact for federal agencies and public interest organizations. The Center also participates in research translation and dissemination of scientific sleep and circadian advances to healthcare professionals, public health officials, and the public.
- Advancing Circadian Rhythm Research. We have organized workshops to help direct future research into circadian rhythms and circadian rhythm disorders. These workshops have brought together experts in the fields of sleep and circadian rhythm research to identify pertinent areas of research into the role of circadian rhythms in the development and progression of several health conditions. Learn more about Developing Biomarker Arrays Predicting Sleep and Circadian-Coupled Risks to Health and Circadian-Coupled Cellular Function and Disease in Heart, Lung, and Blood.
- Investigating the Link between Circadian Rhythms and Lung Diseases. We have hosted workshops to address current gaps in our understanding of acute and chronic lung diseases. Our workshops have helped direct research to build upon preliminary discoveries showing that lung diseases such as asthma may be influenced by circadian rhythms. Learn more about The Circadian Clock's Influence on Lung Health.
- Research Conference on Sleep and the Health of Women. This 2018 conference focused on the importance of sleep for women's health. It showcased a decade of federally funded research advances in understanding the health risks, societal burden, and treatment options associated with sleep deficiency and sleep disorders in women. Topics discussed at this conference included the influence of sleep and circadian rhythms on alcohol consumption and cancer in women, and the social, environmental, and biological factors that affect sleep in women, including during pregnancy, postpartum, and menopause. Learn more from the Research Conference on Sleep and the Health of Women.
- Improving the Quality of Medical School Education on Sleep Disorders. As part of its efforts to ensure that research advances are utilized by healthcare providers, the NCSDR has supported the development of medical school curricula and durable educational materials on sleep disorders, including circadian rhythm disorders.
- Sleep Disorders Research Advisory Board (SDRAB). The NHLBI has administered this specialty program advisory panel since 1993. Board members, including medical professionals, federal partners, and members of the public, meet regularly to provide feedback to the NIH on sleep-related research needs and to discuss how to move sleep research forward. The SDRAB has supported advances to improve our understanding of circadian rhythms and circadian rhythm disorders. Visit the Sleep Disorders Research Advisory Board for more information.
- National Sleep Research Resource (NSRR). This resource was established by the NHLBI to provide biomedical researchers a large, well-characterized data collection from NIH-funded sleep research studies. These data can be used in new research studies to advance sleep research, including research into circadian rhythm disorders. Visit the National Sleep Research Resource external link for more information.

Learn more about how the NHLBI is contributing to knowledge about circadian rhythm disorders.

- Helping to improve the health and well-being of shift workers. Shift work is known to increase the risk of several medical conditions, including cardiovascular disease, diabetes, metabolic syndrome, and obesity. We have funded research to help understand how disruptions in the sleep-wake cycle can cause these conditions. We have also supported research that uses computer analysis to help understand shift work disorder.
- Identifying the genes that control circadian rhythms. We have supported research into discovering the genes that control our circadian clocks and how these genes help us align our circadian rhythms with the environment. In 2017, researchers supported by several NIH Institutes, including the NHLBI, won the Nobel Prize in physiology or medicine for discovering several genes that control circadian rhythms. View Wake-up call: 2017 Nobel Prize in Medicine awarded for studies of the body's internal clock for more information.

Summary of Disorders

Disorder	Causes	Symptoms	Treatments
Insomnia	Risk factors can include age, family history, environmental factors, stress and physical conditions.	Lying awake for a long time, sleeping for only short periods, waking up too early in the morning and/or having poor quality sleep.	Lifestyle changes can include - making bedroom sleep-friendly, going to sleep and waking up at same time everyday, avoiding caffeine, nicotine and alcohol, getting regular physical activity, avoiding daytime naps, eating meals on a regular schedule, limiting fluid intake close to bedtime, learning new ways to manage stress, and avoiding certain over-the-counter meds. Psycholotherapeutic treatments can include –cognitive therapy, relaxation or meditation therapy, sleep education, sleep restriction therapy, stimulus control therapy. Medical treatments can include – Benzodiazepines, Benzodiazepine receptor agonists, Melatonin receptor agonists, Orexin receptor agonists, sometimes antidepressants, antipsychotics and anticonvulsants are used, and Melatonin supplements

Sleep apnea	Obesity, large tonsils, endocrine disorders, neuromuscular conditions, heart or kidney failure, genetic syndromes, and premature birth	Reduced or absent breathing, known as apnea events, frequent loud snoring, gasping for air during sleep, excessive daytime sleepiness and fatigue, decreases in attention, vigilance, concentration, motor skills, and verbal and visuospatial memory, dry mouth or headaches when waking, sexual dysfunction or decreased libido, waking up often during the night to urinate	Healthy lifestyle changes include - Heart healthy eating, regular physical activity, aiming for healthy weight, healthy sleeping habits, and quitting smoking. Breathing devices such as continuous positive airway pressure (CPAP) machine. Oral devices including - Mandibular repositioning mouthpieces, tongue retaining devices Implants including those that detect breathing and nerve stimulator. Therapy for mouth and facial muscles called orofacial therapy. Surgical procedures including – Tonsillectomy, Maxillary/jaw advancement and tracheostomy
Narcolepsy		Unwillingly fall asleep in middle of driving, eating or talking, sudden muscle weakness (cataplexy), vivid dream-like images or hallucinations, total paralysis just before falling asleep or just after waking (sleep paralysis), excessive daytime sleepiness, fragmented sleep and insomnia, automatic behaviors	Medications including Modafinil, Amphetamine-like stimulants, Antidepressants and Sodium oxybate (also called GHB) Lifestyle changes including - taking short scheduled naps, maintaining regular sleep schedules, avoiding caffeine or alcohol before bed, avoiding smoking, exercising daily, avoiding large heavy meals right before bedtime, relaxing before bed and safety precautions particularly while driving.

Circadian rhythm or sleep wake cycle disorders	Genetic conditions, lifestyle issues like jet lag, environment or occupational factors, age, sex and other medical conditions like ASD and blindness	Consistent difficulty falling asleep, staying asleep, or both, excessive daytime sleepiness or sleepiness during shift work, fatigue and exhaustion, lethargy, decreased alertness and difficulty concentrating, impaired judgment and trouble controlling mood and emotions, aches and pains, including headaches, stomach problems, in people who have jet lag disorder	Healthy lifestyle changes, bright light therapy and melatonin

Summary

Since sleep is such a complex biological and psychological process, it should come as no surprise that there are many different kinds of disorders of sleep. These disorders have different symptoms, can be caused by a variety of different situational and biological issues, and can be treated in a variety of ways.

3.1.29: Maintaining Water Balance

Learning Objectives

- Discuss the importance of water balance.
- Explain the role of hormones in maintaining water balance.
- Describe the renin-angiotensin-aldoesterone system and how it impacts blood volume and pressure.

Overview

As with eating behavior, environmental factors also impact our intake of fluids. But while we have varied sources of energy and mechanisms for storing that energy, the need to drink is triggered by a disruption in water balance. What makes thirst and drinking more complicated is the fact that water imbalances can be created by either a loss of fluids or an increase in solutes that causes water to move out of calls. In other words, just as it appears that we monitor both short-term and long-term energy stores to trigger hunger, we also monitor two different water stores to determine a need to drink. We'll explore this in more detail following an overview of the biological controls of water balance and the brain mechanisms that trigger thirst.

Maintaining Water Balance - Physiological Mechanisms

Maintaining a proper water balance in the body is important to avoid dehydration or over-hydration. The water concentration of the body is monitored by osmoreceptors in the hypothalamus, which detect the concentration of electrolytes in the extracellular fluid. The concentration of electrolytes in the blood rises when there is water loss caused by excessive perspiration, inadequate water intake, or low blood volume due to blood loss. An increase in blood electrolyte levels results in a neuronal signal being sent from the osmoreceptors in hypothalamic nuclei.

The hypothalamus produces a polypeptide hormone known as antidiuretic hormone (ADH, also known as vasopressin), which is transported to and released from the posterior pituitary gland. The principal action of ADH is to regulate the amount of water excreted by the kidneys. As ADH causes direct water reabsorption from the kidney tubules, salts and wastes are concentrated in what will eventually be excreted as urine. The hypothalamus controls the mechanisms of ADH secretion, either by regulating blood volume or the concentration of water in the blood. Dehydration or physiological stress can cause an increase in solute concentration which leads to ADH secretion and the retention of water, causing an increase in blood pressure. ADH travels in the bloodstream to the kidneys. Once at the kidneys, ADH changes the kidneys to become more permeable to water by temporarily inserting water channels, aquaporins, into the kidney tubules. Water moves out of the kidney tubules through the aquaporins, reducing urine volume. The water is reabsorbed into the capillaries returning the blood's solute levels back toward normal. As the blood solute concentration decreases, a negative feedback mechanism reduces osmoreceptor activity in the hypothalamus, and ADH secretion is reduced. ADH release can be reduced by certain substances, including alcohol, which can cause increased urine production and dehydration.

Chronic underproduction of ADH or a mutation in the ADH receptor results in diabetes insipidus, a condition characterized by the rapid loss of water following intake. If the posterior pituitary does not release enough ADH, water cannot be retained by the kidneys and is lost as urine. This causes increased thirst, but water taken in is lost again and must be continually consumed. If the condition is not severe, dehydration may not occur, but severe cases can lead to electrolyte imbalances due to dehydration.

Another hormone responsible for maintaining electrolyte concentrations in extracellular fluids is aldosterone, a steroid hormone that is produced by the adrenal cortex. In contrast to ADH, which promotes the reabsorption of water to maintain proper water balance, aldosterone maintains proper water balance by enhancing sodium (Na^+) reabsorption and potassium (K^+) secretion from extracellular fluid of the cells in kidney tubules. Because it is produced in the cortex of the adrenal gland and affects the concentrations of minerals Na^+ and K^+, aldosterone is referred to as a mineralocorticoid, a corticosteroid that affects ion and water balance. Aldosterone release is stimulated by a decrease in blood sodium levels, blood volume, or blood pressure, or an increase in blood potassium levels. It also prevents the loss of Na^+ from sweat, saliva, and gastric juice. The reabsorption of Na^+ also results in the osmotic reabsorption of water, which alters blood volume and blood pressure.

Aldosterone production can be stimulated by low blood pressure, which triggers a sequence of chemical release, as illustrated in Figure 3.1.29.1. When blood pressure drops, the renin-angiotensin-aldosterone system (RAAS) is activated. Cells in the juxtaglomerular apparatus, which regulates the functions of the nephrons of the kidney, detect this and release renin. Renin, an enzyme, circulates in the blood and reacts with a plasma protein produced by the liver called angiotensinogen. When angiotensinogen is cleaved by renin, it produces angiotensin I, which is then converted into angiotensin II in the lungs. Angiotensin II functions as a hormone and then causes the release of the hormone aldosterone by the adrenal cortex, resulting in increased Na^+ reabsorption, water retention, and an increase in blood pressure. Angiotensin II in addition to being a potent vasoconstrictor also causes an increase in ADH and increased thirst, both of which help to raise blood pressure.

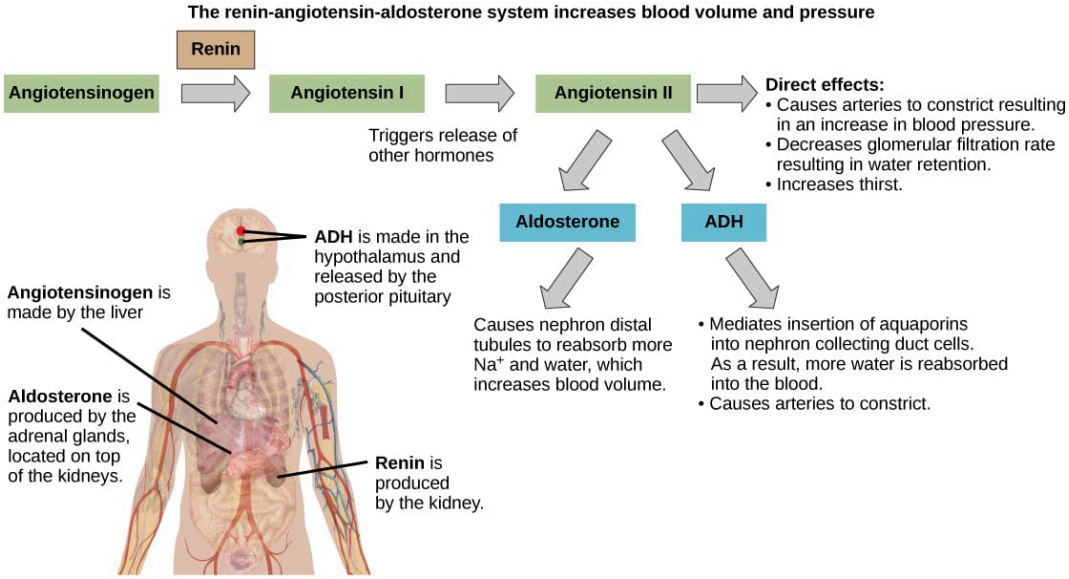

Figure 3.1.29.1: ADH and aldosterone increase blood pressure and volume. Angiotensin II stimulates release of these hormones. Angiotensin II, in turn, is formed when renin cleaves angiotensinogen. (credit: modification of work by Mikael Häggström).

Maintaining Water Balance - Triggering Thirst

When your body starts to run low on water, a number of changes take place: for one, the volume of your blood decreases, causing a change in blood pressure. Because the amount of salt and other minerals in your body is staying constant as the volume of liquids decreases, their relative concentration increases (the same number of particles in a smaller volume means that the particles are more concentrated). This concentration of particles in bodily fluids relative to the total amount of liquid needs to be kept in a narrow range to keep the cells in your body functioning properly. Your body also needs a steady supply of fluids to transport nutrients, eliminate waste, and lubricate and cushion joints. To some extent, the body can compensate for water depletion by altering heart rate and blood pressure and by modifying kidney function to retain more water. For you, though, the most noticeable indication that your body is running low on fluids is likely the feeling of thirst, as you increasingly feel like you need to drink some water.

So how does your body know that these responses are necessary, and how are they coordinated across so many different organ systems? Research indicates that a highly specialized part of the brain called the lamina terminalis is responsible for guiding many of these thirst responses (Figure 3.1.29.2). Brain cells within the lamina terminalis can sense when the body is running low on water and whether you've had anything to drink recently. When researchers manipulate this brain region, they can also drive animals to seek out or avoid water, regardless of how hydrated that animal might be.

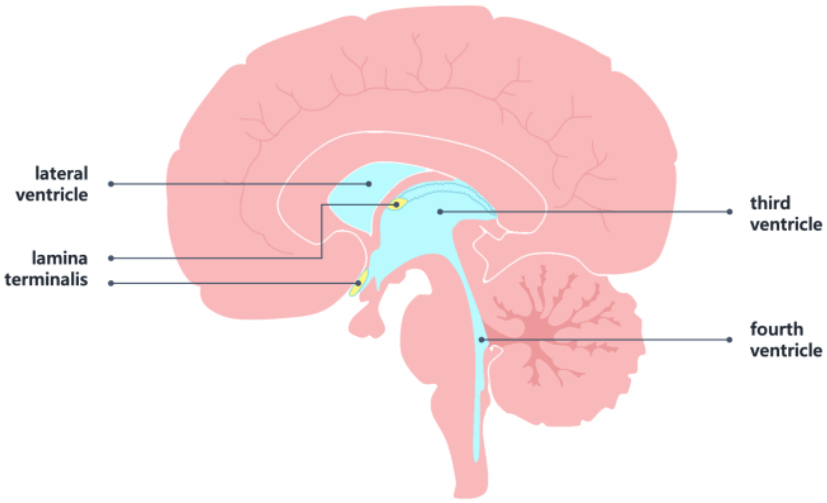

Figure 3.1.29.2: **Brain regions controlling thirst.** The lamina terminalis (yellow) is a series of interconnected brain structures that act as a central hub to control fluid levels in the body. Some cells in the lamina terminalis are adjacent to large, fluid-filled compartments in the brain, called ventricles (blue). When the body begins to run low on water, the composition of the body's fluids (including the fluid in the brain's ventricles) starts to change. The lamina terminalis neurons that border the ventricles can sense changes in the ventricular fluids, giving a snapshot of whether the body has enough water. These neurons also receive messages from other parts of the brain to give an even more complete picture of the body's water needs.

The lamina terminalis is located towards the front of the brain and occupies a prime location just below a fluid reservoir called the third ventricle. Unlike much of the rest of the brain, many cells in the lamina terminalis aren't guarded by a blood-brain barrier. This barrier prevents many circulating factors in the blood and other fluids from interacting with cells in the brain, offering the brain protection against potentially dangerous invaders like certain bacteria, viruses, and toxins. However, the blood-brain barrier also cuts the brain off from many circulating signals that might hold useful information about the body's overall status. Because certain cells in the lamina terminalis lie outside the blood-brain barrier, these cells can also interact with the fluid in the third ventricle to keep tabs on factors that indicate whether the body needs more or less water. In particular, these cells can monitor the fluid in the ventricle to determine its osmolality (the ratio of salt particles to a given amount of liquid) and the amount of sodium present.

When other parts of the brain detect information that's relevant to understanding the body's water needs, they frequently pass it along to the lamina terminalis, as well (Figure 3.1.29.2). In this way, the lamina terminalis also collects information about things like blood pressure, blood volume, and whether you've eaten recently (even before food can cause any change in circulating salt or water levels, your body tries to maintain a balance between these factors by encouraging you to drink water every time you eat). Information from the part of the brain that controls the circadian clock (the suprachiasmatic nucleus of the hypothalamus) also gets forwarded to the lamina terminalis, encouraging animals to drink more water before sleeping to avoid becoming dehydrated during long periods of sleep. Collectively, this information gives the lamina terminalis the resources needed to make a call about whether the body needs more or less water. In turn, cells in the lamina terminalis project to many other areas of the brain, sending out their verdict about current water needs. Although scientists are still trying to figure out exactly how information from the lamina terminalis affects other brain regions, it's clear that this output can influence an animal's motivation to seek out water, as well as physiological factors like kidney function and heart rate (Figure 3.1.29.3).

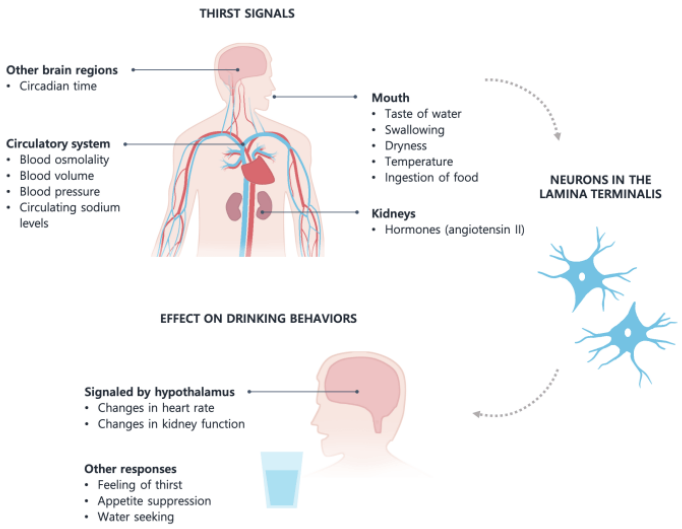

Figure 3.1.29.3: **Thirst signals and their effects.** Neurons in the lamina terminalis receive many different messages about the body's water needs. Thanks to their location next to ventricles in the brain, they can directly sense key indicators of water need like sodium levels and osmolality (the ratio of salt particles to a given amount of liquid). They also receive information about what time of day it is from another brain region, as well as cues from the mouth and kidneys. Neurons in the lamina terminalis can pool all of this information to determine whether the body needs more or less water. If it needs more, they can trigger feelings of thirst and appetite suppression. If it needs less, the brain will send signals telling you to stop drinking. The lamina terminalis also sends messages to a brain region called the hypothalamus. In turn, the hypothalamus can affect heart rate or urge the kidneys to retain more or less water.

What makes water so refreshing?

After a while standing outside in the hot sun, a cold drink of water tends to feel instantly refreshing. You might also find that drinking a very sugary beverage feels equally refreshing but leaves you feeling thirsty again later. In both cases, it takes tens of minutes for that drink to have any effect on attributes like osmolality or blood pressure, the body's main indicators of hydration status. Instead, the brain must rely on some other cue to tell you to stop drinking and give you that instant feeling of refreshment.

The Role of the Lamina Terminalis

Researchers have discovered that neurons in the lamina terminalis respond to the physical act of swallowing liquids, even before there are any changes in the amount of water in the blood. Researchers have identified a group of neurons in the lamina terminalis whose activity is required for drinking behaviors: when you artificially turn off the activity in these cells, mice no longer drink water, even when they are water deprived (Zimmerman et al., 2017). When the researchers recorded the activity of these cells as animals drank water, they found that the cellular activity decreased in lockstep with each sip of water, far before any physiological changes in blood pressure or solute concentration could have an effect. They also found that this change in activity only happened when the mice drank water, not when they drank a salt solution. This study suggests that our brains have a built-in mechanism to compare how much water we need with the amount of water we're currently drinking, telling us when we've had enough and leaving us feeling instantly hydrated. Still, scientists don't know exactly how the brain can tell water apart from other liquids, or why drinking some non-water beverages can leave you feeling instantly hydrated, as well.

The Role of Dopamine

Another group of researchers set out to tackle the problem of why we find drinking water so rewarding when we're thirsty (Augustine at al., 2019). Neuroscientists have long recognized the role of dopamine in determining what we find reinforcing. In order to look at the role that dopamine plays with respect to drinking behaviors, these researchers used a new kind of sensor that glows in the presence of dopamine. By putting this sensor into a mouse's brain, they were able to record dopamine levels in real time as the mouse went about its tasks (Figure 3.1.29.4.

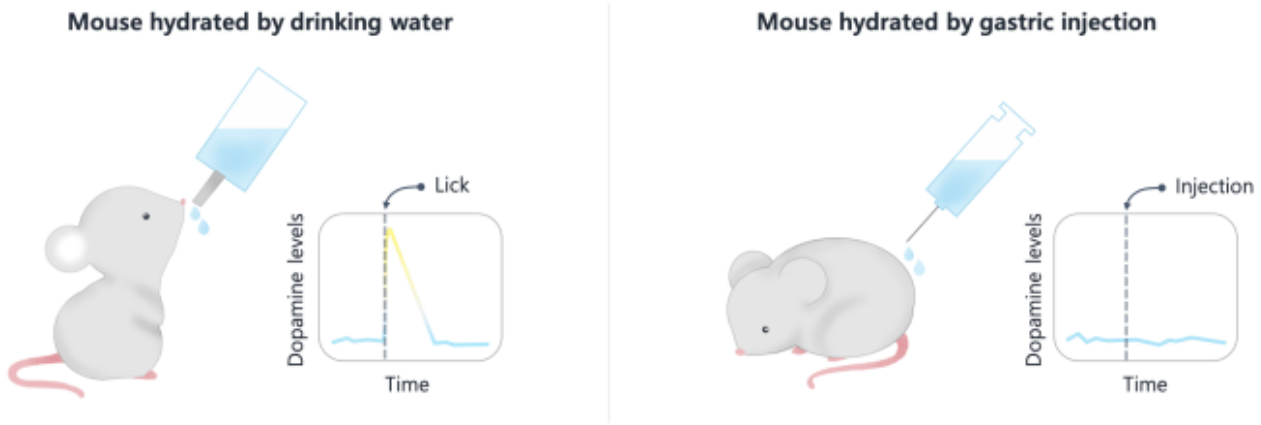

Figure 3.1.29.4: **Drinking water is rewarding.** Researchers in Yuki Oka's group at Caltech conducted a study to see why animals find water rewarding. By using a special kind of sensor that glows in the presence of the rewarding molecule dopamine, they could see what kinds of liquids caused dopamine release. They recorded large spikes of dopamine release when thirsty mice drank both water and salty saline solutions, indicating that mice found both of these liquids rewarding. When researchers injected water into thirsty mice, though, they found no changes in dopamine levels, even though the injected water would also hydrate the thirsty animals.

These researchers looked at dopamine levels after thirsty mice drank water and other liquids. They also recorded dopamine levels after they injected water directly into the gastrointestinal system; this procedure hydrated thirsty animals, but meant that the mice didn't actually drink any water. Oka's group found that thirsty mice had a large surge in dopamine levels after drinking either water or saline and that these dopamine changes happened even before drinking would have any effect on blood fluid levels. In contrast, the animals didn't release any dopamine after water was pumped into their gastric systems, suggesting that it's the act of drinking itself that's rewarding—not the feeling of being hydrated. This effect also starts to explain why drinking beverages other than water can be so satisfying, even when they leave you feeling thirsty later: the dopamine spike that comes from drinking liquids when animals are thirsty doesn't depend on what kind of liquid they're drinking, even though not all liquids are equally hydrating.

These two studies highlight the varying strategies the brain uses to monitor essential nutrients like water; because no single sensor can tally current water levels and predict future water needs, the brain relies on a variety of sensations and cues.

3.1.30: Triggering Drinking Behavior - Osmometric and Volumetric Thirst

Learning Objectives

1. Discuss the role of solutes in determining the movement of water in the body.
2. Distinguish between intracellular and extracellular fluid.
3. Compare and contrast osmometric and volumetric thirst.

Overview

When talking about thirst, we are talking not just about water in the body, but also the major solute (dissolved substance) we find in this water, salt or sodium chloride (NaCl). Regulating the body's water is necessarily impacted by the substances that are dissolved in that water. Thirst is a signal to the body that there has been a loss of fluid or, more specifically, that there is a fluid imbalance. About two-thirds of the body's water is intracellular, meaning within cells. The other third, the extracellular fluid, consists of interstitial fluid (the fluid bathing cells), cerebrospinal fluid (fluid in the ventricular system), and blood plasma (intravascular).

Because we effectively have two places where water is found (intracellular and extracellular), we have two systems for monitoring the body's fluid levels - and a variety of ways of inducing thirst, as well as different types of thirst. In addition, salt appetite is necessarily associated with one form of thirst as the need created by the fluid loss requires both salt and water to restore homeostasis. One system focuses on the levels of intracellular fluid and triggers osmometric thirst. The other monitors extracellular levels - more specifically, plasma or blood volume - and triggers volumetric thirst. Volumetric thirst is associated wth a neeed for both salt and water.

Intracellular Fluid Volume

Intracellular fluid volume is controlled by the concentration of solutes in the interstitial fluid (the fluid outside of cells). Under normal circumstances, the fluid outside and inside the cell is isotonic (the concentration of solutes is equal). If, however, the solute concentration is increased in the interstitial fluid (due to ingestion of solutes or loss of water), water will leave the cell by the process of osmosis. Osmosis is simply movement of water from an area of low solute concentration to an area of high concentration, water will move as needed to even out the solute concentration (Figure 3.1.30.1). If the interstitial fluid (the fluid outside of the cell) is hypertonic (if it has a higher solute concentration), water will leave the cell. If the interstitial fluid is hypotonic, water will enter the cell. Both conditions may be dangerous - disrupting normal neuronal function. When there is a difference between the solute concentration of the interstitial fluid and the intracellular fluid, the movement of water by osmosis causes changes in intracellular volume.

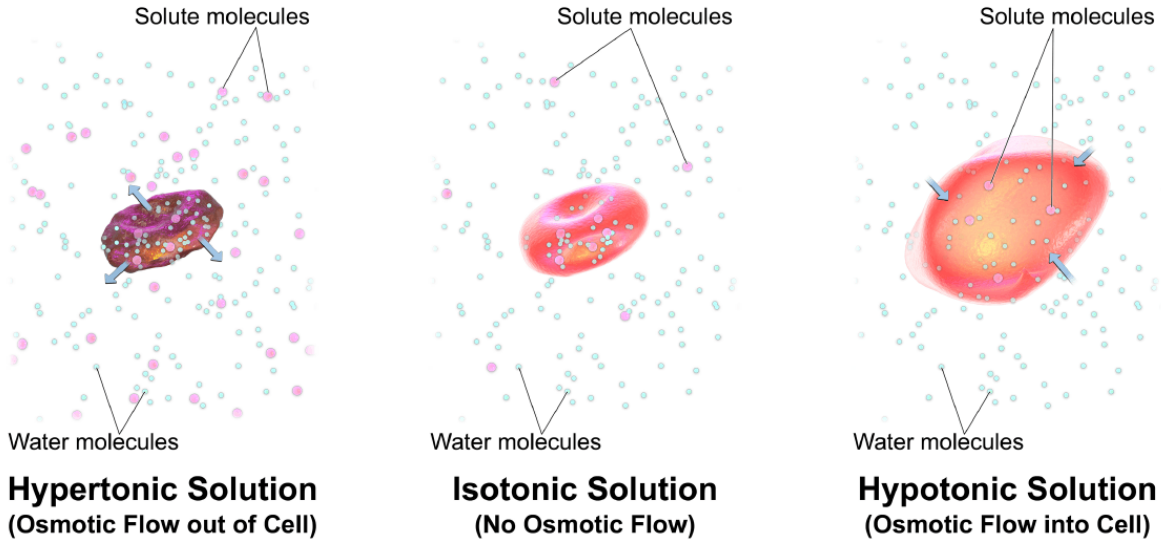

Figure 3.1.30.1: Water movement in hypertonic, isotonic and hypotonic solutions. (Images from Blausen.com staff (2014). "Medical gallery of Blausen Medical 2014". WikiJournal of Medicine 1 (2). DOI:10.15347/wjm/2014.010. ISSN 2002-4436., CC BY 3.0 <https://creativecommons.org/licenses/by/3.0>, via Wikimedia Commons)

Generally, there is no need to regulate the volume of the interstitial fluid, although we do regulate its tonicity (solute concentration) through its effects on the intracellular fluid volume. More specifically, we monitor the movement of water.

Plasma Volume (Extracellular)

The other important and closely regulated fluid compartment is the blood plasma. If there is a loss of plasma volume (hypovolemia), this can impair the functioning of the heart. If increased, there may be a dangerous increase in blood pressure. If hypovolemia is severe enough the heart can no longer pump effectively. The vascular system can correct for loss of volume, but only within a limited range.

Two Variables, Two Regulatory Mechanisms

In order to maintain optimal fluid balance, the two variables are monitored:

- Movement of water (intracellular)
- Plasma volume (extracellular)

As there are two variables being monitored, there will be two different regulatory mechanisms that underlie thirst. The monitoring of fluid levels is tied to the monitoring of sodium levels. There are two mechanisms for dealing with a need for fluid and salt or sodium - we see both physiological and behavioral mechanisms for dealing with a need for water and salt:

- Physiologically - At the kidney, the excretion (loss) of water and salt can be modified. And alterations in heart rate and blood pressure can also compensate for losses.
- Behaviorally - ingest water and salt

What is the role of the kidneys and how is kidney activity regulated? Typically, we ingest much more salt and water than we need and what we don't need is excreted. Blood is essentially filtered by the kidneys. The functional units of the kidneys, the nephrons, extract fluid from the blood and carry it (collect it into) the ureter. From the ureter, urine passes to the urinary bladder where urine is stored.

As discussed in the prior section, two hormones are involved in the excretion of sodium and water by the kidney - both hormonal signals increase retention:

- Aldosterone is secreted by the adrenal cortex.

- Vasopressin (Anti Diuretic Hormone or ADH) is secreted by the posterior pituitary, but produced by the hypothalamus. The two names by which this hormone is known reflect two aspects of its effects, "vasopressin" is a reference to its ability to cause contraction of blood vessels while ADH reflects its role in preventing excretion.

What happens without vasopressin? No water is retained. Without vasopressin, diabetes insipidus develops, leading to excessive water loss and increased thirst. Incidentally, the term diabetes insipidus literally means "a tasteless passing through". The urine is so dilute, it has little taste. It is, as you might expect, treated with vasopressin - in the form of a nasal spray. The diabetes you more commonly hear of (due to a lack of or insensitivity to insulin) is technically diabetes mellitus. Diabetes, again, means "passing through". Mellitus means "sweet" as the urine of the diabetic would be sweet with unused glucose.

Osmometric (Osmotic) Thirst - Detecting Water Movement Out of Cells

So, we can drink to replenish lost fluid and the kidney's function can conserve or allow fluids to be lost. As we have two variables that we are monitoring, we have two different types of thirst. Osmometric thirst derives its name from the word osmosis. Osmometric thirst is triggered by loss of volume from the intracellular fluid stores. This form of thirst is produced when the solute concentration or tonicity of the interstitial compartment (the fluid outside of the cell) is increased, causing water to move out of the cell. Detectors, osmoreceptors, detect the loss of water. Interestingly, it is more than just the change in the solute concentration that triggers this form of thirst. It is the actual effect of this change on the water in the intracellular fluid. If water does not move out of the cell, drinking will not increase. If the concentration of interstitial solutes is increased with something that passes into the cell - so the extracellular and intracellular solute concentrations remain isotonic and there's no net movement of water - drinking will not be triggered. In other words, it isn't just changes in the solute concentration that are detected, it is the loss of water from the intracellular compartment that matters. An increase in fluid intake is only seen when there is an increase in interstitial solute concentration that results in the movement of water out of cells. The movement of water out of cells (cellular dehydration) triggers osmometric thirst.

Where is this change detected? Where are the osmoreceptors? We can find hints of this by looking at the effects of various solutes on thirst.

If urea is injected, the extracellular solute concentration is increased. Urea does pass into cells, but it only crosses the blood brain barrier slowly. In other words, there's no movement of water in the cells of the body, but as you've increased the solute concentration outside of the brain, there will be a net movement of water out of the brain. Not surprisingly, even a slight and temporary decrease in the intracellular fluid concentration of the brain results in thirst. It also makes sense that osmoreceptors would be found in the brain as the brain needs to be protected from changes and it is the brain that triggers behavior. A simpler (and less disturbing) way of demonstrating this is by injecting hypertonic saline directly into the brain. Osmoreceptors can be classified as central or peripheral osmoreceptors based on their location. The central receptors are primarily present in the anterior hypothalamus, including the organum vasculosum laminae terminalis (OVLT) and the subfornical organ (SFO) (Danziger & Zeidel, 2015; Xu et al., 2000; Muhsin & Mount, 2016). These central receptor cells have respond to osmotic changes and they are sensitive to angiotensin II (abbreviated as AII; Bichet, 2012; Benarroch, 2011). Some SFO/OVLT neurons also receive signals from peripheral arterial baroreceptors. Thus, SFO/OVLT neurons sense plasma osmolality, volume, and pressure to control thirst. These cells depolarize due to increased Na+ concentration, cell shrinkage, angiotensin II or negative suction pressure, and discharge neuronal spikes, which later initiate the sensation of thirst or vasopressin release or both (Muhsin & Mount, 2016; Gizowski & Bourque, 2018).

One of the central receptor organs, SFO, has two distinct types of neurons with opposing actions. A glutamatergic population (SFO-GLUT) that promotes thirst and sodium intake, and a GABAergic population (SFO-GABA) that inhibits thirst (Zimmerman, Leib, & Knight, 2017). The proper agonistic and antagonistic functioning of these cells maintain the optimum level of hydration. As the SFO has access to the systemic blood, it has a markedly different ependymal surface with a flattened appearance, lacks normal cilia count, and has tight junctions between adjacent cells. These features help block the diffusion of substances across the SFO parenchyma into the third ventricle. This peculiar position of the SFO cells is suitable for sensing both plasma and CSF components (Hiyama & Noda, 2016).

OVLT, the other central receptor, is close to the median preoptic nucleus. The peripheral receptors which are present within the upper gastrointestinal tract and portal venous system also detect changes in solute concentration and blood volume via a specific type of receptor (Danziger & Zeidel, 2015; Xu et al., 2000; Muhsin & Mount, 2016; Xu et al., 2000). They act as a supplementary center for osmoregulation in addition to the central osmoreceptors (Muhsin & Mount, 2016).

Volumetric (Hypovolemic) Thirst - Detecting Blood Loss

Volumetric thirst is triggered when there is a loss of volume from the extracellular fluid stores. Volumetric thirst is triggered by a decrease in blood volume referred to as hypovolemia. Hypovolemia is usually accompanied by a drop in blood pressure (hypotension). Hypovolemia and hypotension then ultimately lead to the production of angiotensin II. As discussed in the last section, a cascade of events is triggered when the kidneys detect a decrease in blood pressure and release the enzyme renin. This activates the renin-angiotensin-aldosterone system. Angiotensinogen, produced by the liver, is acted on by renin to produce angiotensin I, which is then converted into angiotensin II. Angiotensin II functions as a hormone and then causes the release of the hormone aldosterone by the adrenal cortex, resulting in increased sodium reabsorption, water retention, and an increase in blood pressure.

But how do we produce volumetric thirst experimentally? Obviously, we could remove blood. But removing a large volume of blood creates other problems. A better method is to inject a colloid. A colloid is a large molecule that can't cross cell membranes. By placing a colloid under the skin or in the abdominal cavity, extracellular fluid will move out of tissues. As the interstitial fluid decreases, fluid from the plasma fills the vacancy. As a consequence of the resulting drop in blood volume, vasopressin is released and the subject drinks. Early studies using this procedure documented the presence of both thirst (Fitzsimons, 1961) and sodium appetite (Stricker & Wolf, 1966) as indicated by ingestion of both. Later work (Stricker, 1981) explored the effects of colloid treatment on both water and saline drinking in greater detail. Stricker's work explored the effects of various manipulations on thirst and sodium appetite, revealing that sodium appetite accompanies thirst when dietary sodium is controlled. In other words, earlier studies had found that there was a delay in sodium appetite that may be accounted for by the excess of sodium that had previously been ingested. The separate timelines associated with thirst and sodium appetite indicate separate systems for detecting the needs for water and sodium.

Following extracellular fluid loss - loss of plasma volume - there is a need for both salt and water. A rat will now drink the saline solution that it normally rejects. This indicates that there is a mechanism for monitoring the body's sodium concentration, so that needs are detected and then mechanisms are employed to satisfy them. Unlike osmometric thirst, volumetric thirst is accompanied by a salt appetite.

Angiotensin II, the 3rd "step" when the renin-angiotensin-aldosterone system is activated, travels through the blood stream and exerts multiple effects.

- Angiotensin II acts at the adrenal cortex to stimulate aldosterone secretion.
- Angiotensin II acts at the posterior pituitary to stimulate vasopressin (ADH) secretion.
- Angiotensin II acts at the muscles of the the small arteries to cause contraction (increasing blood pressure).
- Angiotensin II triggers drinking and salt ingestion.

Although angiotensin II is thought to produce thirst and act on other brain sites, it does not cross the blood-brain barrier. Thus, in order to cause thirst and other effects, angiotensin II must act at a part of the brain that lacks this barrier. This is characteristic of the circumventricular organs (organs surrounding the ventricles), which includes the organum vasculosum laminae terminalis (OVLT) and the subfornical organ (SFO) mentioned earlier. The subfornical organ (SFO) appears to be the site at which angiotensin II acts to cause volumetric thirst.

Evidence for the role of the SFO in water ingestion:

- Very low doses of angiotensin II at the SFO cause drinking.
- Angiotensin II-induced drinking is blocked by blocking angiotensin II receptors at the SFO.
- Electrical stimulation of the SFO produces drinking.

Furthermore, neurons in the SFO increase their activity in response to angiotensin II, even when neural connections are cut - demonstrating that the neurons are responding to the AII.

The SFO has outputs to several brain regions. And these connections mediate the endocrine, autonomic, and behavioral responses associated with thirst. It is involved in a number of the effects of AII. How do the SFO and angiotensin II work together to produce all the effects associated with angiotensin II?

- Secretion of aldosterone by the kidney is a direct response to AII at the kidney. The other effects of AII are initiated at the brain.
- Endocrine outputs of the SFO communicate with the hypothalamic regions controlling release of vasopressin.
- Autonomic outputs of the SFO act on hypothalamic regions influencing the activity of the autonomic nervous system.

- Behavioral outputs of the SFO act on the basal forebrain. If these efferent connections of the SFO are lesioned, we no longer see angiotensin II-induced drinking.

So, there are receptors in the kidney that detect changes in blood flow. There is a second set of volumetric receptors in the heart. These are baroreceptors, they are stretch receptors that detect the amount of blood in the heart's atria (the part of the heart that is receiving blood from the veins).

Normal Drinking

Just as we typically eat long before a physiological need for fuel would trigger hunger, we drink before change in the body's fluid stores would be detected. As with eating, we have learned elements of our drinking behavior. When do we habitually drink? Normally, we drink with meals. While eating does produce a need for fluid, we typically drink before that need would normally be detected. Food in the digestive system causes water to be diverted to these areas and absorbed food increases the solute concentration of the plasma and produces osmometric thirst.

Why do animals drink before a need is detected? Animals will actually learn to drink more if their diet is changed such that they need to drink more. With a high protein diet, more water is needed. Animals will learn to drink more with a meal in anticipation of the need.

What signals or causes drinking with a meal? The movement of water into the digestive system produces hypovolemia. The hypovolemia causes the kidneys to secrete renin and AII levels are increased. During a normal meal the levels of renin actually double. If we then block AII production, we'll see a decrease in drinking with a meal.

Summary

In order to maintain an appropriate fluid balance, intracellular and extracellular fluid levels are monitored. Intracellular or osmometric thirst is triggered when water moves out of cells. In contrast, extracellular thirst and an appetite for salt is triggered when the loss of blood volume creates a need for salt and water.

3.1.31: Ingestive Behavior Basics

Learning Objectives

1. Explain what a drive state is and the properties of a drive state.
2. Discuss drive-reduction theories and their limitations.
3. Define homeostasis and identify its elements.
4. Discuss body temperature as an example of a homeostatic system.
5. Compare and contrast homeotherms and poikilotherms.

Overview

"Ingestive Behavior", eating and drinking, is a fascinating topic when considered from the perspective of a biological psychologist. Why? The connection between the biological need for food (energy, nutrients) and water (hydration) lead to drive states (hunger and thirst) that motivate us to engage in behaviors to meet those needs. In other words, the connection between the body's need for food and water, the drive states of hunger and thirst, and seeking food and drink (the behaviors designed to meet the body's needs) is something that we are all familiar with. At the same time, the impact of learning on what we eat, when we eat, and even how we feel about food is also something that we're aware of. And there even is a link to mental illness - instances where the mind leads to ingestive behaviors (such as overeating or under-eating) that are harmful to the body. While it would be easy to create an entire book (or course) that focuses on ingestive behavior, we are going to explore the topic by focusing on the biological bases for eating and drinking - with an emphasis on how we know what we know about these surprisingly complex behaviors.

What are the biological mechanisms that determine when we need to eat or drink - and how does the detection of a need trigger behaviors intended to meet that need? And how are those hunger and thirst signals turned off? Consider what causes you to "feel" hungry - where would you look for detectors of hunger or satiety (being "full")?

Hunger is a drive state, an affective experience (a mood or a feeling) that motivates organisms to fulfill goals that are generally beneficial to their survival and reproduction. Like other drive states, such as thirst or sexual arousal, hunger has a profound impact on the functioning of the mind. It affects psychological processes, such as perception, attention, emotion, and motivation, and influences the behaviors that these processes generate. Drive states serve to motivate a variety of behaviors.

Drive-Reduction Theories

Drive-reduction theories focus on how motivation originates from biological needs or drives. In these theories, it is proposed that behavior is an external display of the desire to satisfy physiological needs. In other words, a biological need creates a drive and reducing that drive motivates an organism to engage in behaviors to reduce the drive, presumably by meeting the biological need. As this theory focuses on biological needs, it is connected to the principle of homeostasis and the use of behaviors to maintain or restore homeostasis. Homeostasis refers to the stable state across all physiological systems that organisms strive to maintain and will be discussed shortly.

A “drive” is a state of arousal or tension triggered by a physiological or biological need. These needs include those that we are all aware of and that are the focus of this chapter, hunger and thirst. Drive-reduction theory proposes that drives give rise to motivation. When a drive emerges, it creates an unpleasant state of tension that leads to behaviors intended to reduce this tension. To reduce the tension, the organism will begin seeking out ways to satisfy the biological need. For instance, you will look for water to drink if you are thirsty. You will seek food if you are hungry.

According to the theory, any behavior that reduces the drives will be repeated by humans and animals. This is because the reduction of the drive serves as a positive reinforcement for the behavior that caused such drive reduction.

While drive-reduction theory explains how primary reinforcers (those things that are naturally reinforcing because they meet biological needs) are effective in reducing drives, many psychologists argue that the theory is not applicable in the concept of secondary reinforcers. For example, money is a powerful secondary reinforcer, as it can be used to purchase primary reinforcers like food and water. However, money in itself cannot reduce an individual’s drives. Another problem with the theory is that it does

not provide an explanation about the reason behind people engaging in behaviors that are not meant to reduce drives, such as a person eating even if they are not hungry.

(Photo by Nikita Tikhomirov on Unsplash)

Key Properties of Drive States

Drive states differ from other affective or emotional states in terms of the biological functions they accomplish. Whereas all affective states are either desirable or undesirable and serve to motivate approach or avoidance behaviors (Zajonc, 1998), drive states are unique in that they generate behaviors that result in specific benefits for the body. For example, hunger directs individuals to eat foods that increase blood sugar levels in the body, while thirst causes individuals to drink fluids that increase water levels in the body.

Different drive states have different triggers. Most drive states respond to both internal and external cues, but the combinations of internal and external cues, and the specific types of cues, differ between drives. Hunger, for example, depends on internal, visceral signals as well as sensory signals, such as the sight or smell of tasty food. Different drive states also result in different cognitive and emotional states, and are associated with different behaviors. Yet despite these differences, there are a number of properties common to all drive states. Most notably, the link between drives and motivation (as already discussed) and the common features of homeostatic mechanisms.

Homeostasis

Humans, like all organisms, need to maintain a stable state in their various physiological systems. For example, the excessive loss of body water results in dehydration, a dangerous and potentially fatal state. However, too much water can be damaging as well. Thus, a moderate and stable level of body fluid is ideal. The tendency of an organism to maintain this stability across all the different physiological systems in the body is called homeostasis.

Homeostasis is maintained by two mechanisms. First, the state of the system being regulated must be monitored and compared to an ideal or optimal level, a set point. Second, there need to be mechanisms for moving the system back to this set point - that is, to restore homeostasis when deviations from it are detected. While our focus here is on homeostatic mechanisms that connect to behavior, there is a wide-range of such systems throughout the body. Most notably, you have already been introduced to the concept of osmosis and the mechanisms that exist to maintain a stable intracellular environment. To better understand the functioning of a homeostatic system, think of the thermostat in your own home. It detects when the current temperature in the house is different from the temperature you have it set at (i.e., the set point). Once the thermostat recognizes the difference, the heating or air conditioning turns on (or off) to bring the overall temperature back to the designated level.

Many homeostatic mechanisms, such as blood circulation and immune responses, are automatic and strictly physiological. Others, however, involve behavioral responses and deliberate action. Most drive states motivate action to restore homeostasis using both “punishments” and “rewards” to modify behavioral responses. Imagine that these homeostatic mechanisms are like

molecular parents. When you behave poorly by departing from the set point (such as not eating or being somewhere too cold), they raise their voice at you. You experience this as the bad feelings, or “punishments,” of hunger, thirst, or feeling too cold or too hot. However, when you behave well (such as eating nutritious foods when hungry), these homeostatic parents reward you with the pleasure that comes from any activity that moves the system back toward the set point. For example, when body temperature declines below the set point, any activity that helps to restore homeostasis (such as putting one’s hand in warm water) feels pleasurable; and likewise, when body temperature rises above the set point, anything that cools it feels pleasurable. While homeostatic mechanisms are often likened to a thermostat that determines what the desired value is and then systems are turned on and off in order to establish the optimal value, both hunger and thirst are not only triggered by need. Both systems anticipate need - they are both proactive and reactive. Before exploring these ingestive behaviors further, we'll consider temperature regulation in more detail as an introduction to how homeostatic mechanisms operate.

Elements of a Homeostatic System

Regardless of the homeostatic system we are discussing, it must have specific features.

- System variable - what's being regulated.
- Set point - optimal value.
- Detector - a mechanism must exist for monitoring the levels of the variable of interest.
- Correctional mechanisms - there must be a way for deviations to be altered.

When it comes to body temperature, there is an ideal temperature that an organism strives to maintain. Temperature would be the system variable and that ideal temperature would be the set point. The detector or detectors would be temperature sensors in the skin and brain. What are the correctional mechanisms? Temperature is interesting in that these mechanisms can be behavioral and physiological for some species, while for others they are only behavioral. If a human is cold, they can put on a coat (behavioral) and they may shiver, a physiological response that generates heat. In contrast, some animals do not have the benefit of those physiological mechanisms for adjusting temperature and must rely exclusively on behavioral responses. Mammals and birds are homeotherms, they possess both physiological and behavioral means of altering body temperature. Homeotherms are able to maintain the same body temperature, our temperatures don't fluctuate with changes in environmental temperature. Poikilotherms regulate their body temperature entirely with behavioral means. Reptiles, amphibians, and many fish are poikilotherms.

Regardless of the homeostatic system in question, all have a system variable, a set point, a detector, and at least one correctional mechanism. When we need food or water, physiological and behavioral mechanisms assist us in meeting the need. In contrast, not all species have physiological mechanisms for correction for deviations in body temperature.

Negative Feedback

All regulatory mechanisms employ negative feedback - if the optimal value is exceeded, responses will be turned off. But are corrective mechanisms only "turned off" when the desired value is obtained? The answer is no - we stop eating prior to the restoration of blood glucose levels and we start to drink before we actually have a fluid need. So, the systems predict needs and predict when needs have been satisfied.

Hunger and Thirst - The Drives Motivating Eating and Drinking

Hunger is a classic example of a drive state, one that results in thoughts and behaviors related to the consumption of food. In the simplest of terms, hunger is generally triggered by low glucose levels in the blood (Rolls, 2000), and behaviors resulting from hunger aim to restore homeostasis regarding those glucose levels. But various other internal and external cues can also cause hunger. For example, when fats are broken down in the body for energy, this initiates a chemical cue that the body should search for food (Greenberg, Smith, & Gibbs, 1990). External cues include the time of day, estimated time until the next feeding (hunger increases immediately prior to food consumption), and the sight, smell, taste, and even touch of food and food-related stimuli. Note that while hunger is a generic feeling, it can also lead to the eating of specific foods that correct for nutritional imbalances we may not even be conscious of. For example, a couple who was lost adrift at sea found that they began to crave the eyes of fish. Only later, after they had been rescued, did they learn that fish eyes are rich in vitamin C - a very important nutrient that they had been depleted of while lost on the ocean (Walker, 2014).

We'll begin our exploration of ingestive behaviors with eating, the behavior motivated by hunger. While you might think the control of eating is quite simple, the regulated variables involved in eating are not so well described. Why do we eat? We have a whole host of needs that must be satisfied by the ingestion of food.

External cues, like the sight and smell of food, can ignite feelings of hunger. [Image: Marco Verch, https://goo.gl/c4TC5A, CC BY 2.0, https://goo.gl/BRvSA7]

3.1.32: Digestion and the Hormonal Control of Metabolism

Learning Objectives

- Distinguish between digestion and metabolism.
- Described the process of digestion, noting the roles of the mouth, stomach, intestines (small and large), and accessory organs.
- Describe how hormones regulate metabolism.
- Describe the three phases of digestion.

Overview

While we know that eating is motivated by the drive state of hunger, what is being regulated? What is the system variable - or variables - that are monitored?

Food:

- Provides energy.
- Provides the building blocks that we use to construct and maintain our bodies - we don't just need calories (energy, fuel), we need to eat certain things - ideally we are monitoring not only the quantity (how much) of food we eat, but the quality (what we eat). In other words, an ideal system for the control of our eating would be one that triggers a hunger that is specific - ensuring that we both get the quantity we need to meet our energy needs, but also the right types of foods to meet our nutritional needs.

The process by which we obtain the substances that the body needs begins with the consumption of food and is achieved when the nutrients provided by food are absorbed. This is the process of digestion, the process of ingesting, breaking down food, and absorbing the nutrients.

Ultimately, food is delivered to the body in three forms:

- Lipids (fats),
- amino acids (proteins), and
- glucose (carbohydrates).

These fuels enter the body by way of the digestive tract, but the digestive tract is often empty. Because of this, and the importance of having fuel available, we have mechanisms that allow us to store energy to support us. This stored energy is primarily fats, but also glycogen and proteins. Before discussing how we store energy (and access stored energy), we need to understand the process of digestion.

The Human Digestive System

The process of digestion begins in the mouth with the intake of food (Figure $3.1.32.1$). The teeth play an important role in masticating (chewing) or physically breaking food into smaller particles. The enzymes present in saliva also begin to chemically break down food. The food is then swallowed and enters the esophagus - a long tube that connects the mouth to the stomach. Using peristalsis, or wave-like smooth-muscle contractions, the muscles of the esophagus push the food toward the stomach. The stomach contents are extremely acidic. This acidity kills microorganisms, breaks down food tissues, and activates digestive enzymes. Further breakdown of food takes place in the small intestine where bile produced by the liver, and enzymes produced by the small intestine and the pancreas, continue the process of digestion. The smaller molecules are absorbed into the blood stream through the epithelial cells lining the walls of the small intestine. The waste material travels on to the large intestine where water is absorbed and the drier waste material is compacted into feces; it is stored until it is excreted through the anus.

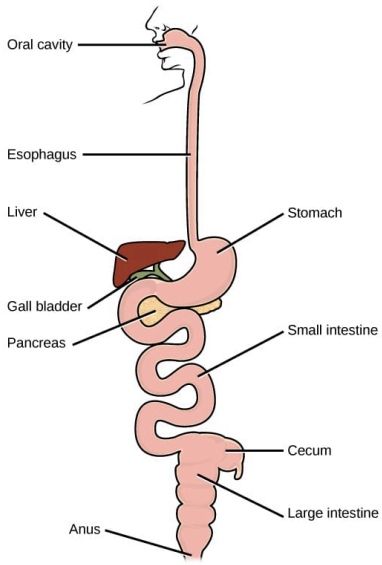

Figure 3.1.32.1: The components of the human digestive system are shown.

Oral Cavity

Both physical and chemical digestion begin in the mouth or oral cavity, which is the point of entry of food into the digestive system. The food is broken into smaller particles by mastication, the chewing action of the teeth. Almost all mammals have teeth and can chew their food to begin the process of physically breaking it down into smaller particles. (Mammals without teeth have very limited diets - ants or plankton - and include pangolins, anteaters and some species of whales.)

The chemical process of digestion begins during chewing as food mixes with saliva, produced by the salivary glands. Saliva contains mucus that moistens food and buffers the pH of the food. Saliva also contains enzymes that begin the process of breaking down some foods. The chewing and wetting action provided by the teeth and saliva prepare the food into a mass called the bolus for swallowing. The tongue helps in swallowing - moving the bolus from the mouth into the pharynx. The pharynx opens to two passageways: the esophagus and the trachea. The esophagus leads to the stomach and the trachea leads to the lungs. The epiglottis is a flap of tissue that covers the tracheal opening during swallowing to prevent food from entering the lungs.

Esophagus

The esophagus is a tubular organ that connects the mouth to the stomach. The chewed and softened food passes through the esophagus after being swallowed. The smooth muscles of the esophagus undergo peristalsis that pushes the food toward the stomach. The peristaltic wave moves food from the mouth to the stomach, and reverse movement is not possible, except in the case of vomiting (initiated by the gag reflex). The peristaltic movement of the esophagus is an involuntary reflex; it takes place in response to the act of swallowing.

Ring-like muscles called sphincters form valves in the digestive system. The gastro-esophageal sphincter (or cardiac sphincter) is located at the stomach end of the esophagus. In response to swallowing and the pressure exerted by the bolus of food, this sphincter opens, and the bolus enters the stomach. When there is no swallowing action, this sphincter is shut and prevents the contents of the stomach from traveling up the esophagus. Acid reflux or “heartburn” occurs when the acidic digestive juices escape into the esophagus.

Stomach

A large part of protein digestion occurs in the stomach. The stomach is a saclike organ that secretes gastric digestive juices.

Protein digestion is carried out by an enzyme called pepsin in the stomach chamber. The highly acidic environment kills many microorganisms in the food and, combined with the action of the enzyme pepsin, results in the catabolism (break down) of protein in the food. Chemical digestion is facilitated by the churning action of the stomach caused by contraction and relaxation of smooth muscles. The partially digested food and gastric juice mixture is called chyme. Gastric emptying occurs within two to six

hours after a meal. Only a small amount of chyme is released into the small intestine at a time. The movement of chyme from the stomach into the small intestine is regulated by hormones, stomach distension, and muscular reflexes that influence the pyloric sphincter.

The stomach lining is unaffected by pepsin and the acidity because pepsin is released in an inactive form and the stomach has a thick mucus lining that protects the underlying tissue.

Small Intestine

Chyme moves from the stomach to the small intestine. The small intestine is the organ where the digestion of protein, fats, and carbohydrates is completed. The small intestine is a long tube-like organ with a highly folded surface containing finger-like projections called the villi. The top surface of each villus has many microscopic projections called microvilli. The epithelial cells of these structures absorb nutrients from the digested food and release them to the bloodstream on the other side. The villi and microvilli, with their many folds, increase the surface area of the small intestine and increase absorption efficiency of the nutrients.

The human small intestine is divided into three parts: the duodenum, the jejunum, and the ileum. The duodenum is separated from the stomach by the pyloric sphincter. The chyme is mixed with pancreatic juices, an alkaline solution rich in bicarbonate that neutralizes the acidity of chyme from the stomach. Pancreatic juices contain several digestive enzymes that break down starches, disaccharides, proteins, and fats. Bile is produced in the liver and stored and concentrated in the gallbladder; it enters the duodenum through the bile duct. Bile contains bile salts, which make lipids accessible to the water-soluble enzymes. The monosaccharides, amino acids, bile salts, vitamins, and other nutrients are absorbed by the cells of the intestinal lining.

The undigested components of the food are sent to the colon from the ileum via peristaltic movements. The ileum ends and the large intestine begins at the ileocecal valve. The vermiform, “worm-like,” appendix is located at the ileocecal valve.

Large Intestine

The large intestine reabsorbs the water from indigestible food material and processes the waste material (Figure 3.1.32.2). Compared to the small intestine, the human large intestine is much smaller in length but larger in diameter. It has three parts: the cecum, the colon, and the rectum. The cecum joins the ileum to the colon and is the receiving pouch for the waste matter. The colon is home to many bacteria or “intestinal flora” that aid in the digestive processes. The colon has four regions, the ascending colon, the transverse colon, the descending colon and the sigmoid colon. The main functions of the colon are to extract the water and mineral salts from undigested food components, and to store waste material.

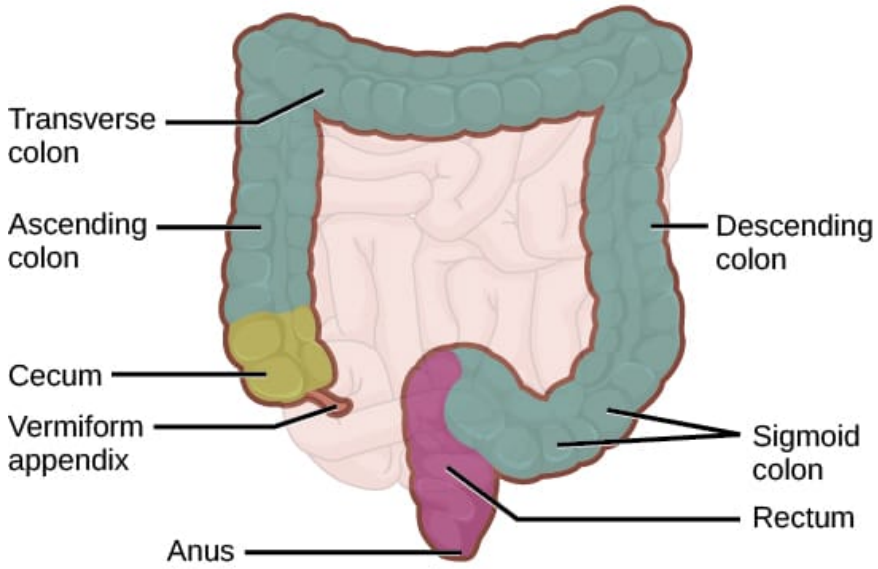

Figure 3.1.32.2: The large intestine reabsorbs water from undigested food and stores waste until it is eliminated. (credit: modification of work by Mariana Ruiz Villareal)

The rectum (Figure 3.1.32.2) stores feces until defecation. The feces are propelled using peristaltic movements during elimination.

The anus is an opening at the far-end of the digestive tract and is the exit point for the waste material. Two sphincters regulate the exit of feces, the inner sphincter is involuntary and the outer sphincter is voluntary.

Accessory Organs

The organs discussed above are the organs of the digestive tract through which food passes. Accessory organs add secretions and enzymes that break down food into nutrients. Accessory organs include the salivary glands, the liver, the pancreas, and the gall bladder (Figure 3.1.32.3). The secretions of the liver, pancreas, and gallbladder are regulated by hormones in response to food consumption.

The liver is the largest internal organ in humans and it plays an important role in digestion of fats and detoxifying blood. The liver produces bile, a digestive juice that is required for the breakdown of fats in the duodenum. The liver also processes the absorbed vitamins and fatty acids and synthesizes many plasma proteins. The gallbladder is a small organ that aids the liver by storing bile and concentrating bile salts.

The pancreas secretes bicarbonate that neutralizes the acidic chyme and a variety of enzymes for the digestion of protein and carbohydrates.

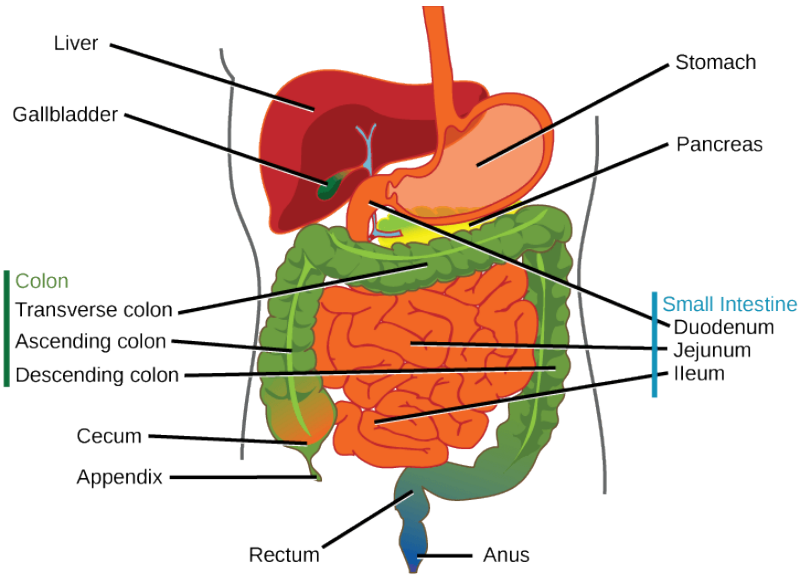

Figure 3.1.32.3: The stomach has an extremely acidic environment where most of the protein gets digested. (credit: modification of work by Mariana Ruiz Villareal)

Nutrition

The human diet should be well-balanced to provide nutrients required for bodily function and the minerals and vitamins required for maintaining structure and regulation necessary for good health and reproductive capability. The organic molecules required for building cellular material and tissues must come from food.

During digestion, digestible carbohydrates are ultimately broken down into glucose and used to provide energy to the cells of the body and the brain. Complex carbohydrates can be broken down into glucose through biochemical modification; however, humans do not produce the enzyme necessary to digest fiber. The intestinal bacteria in the human gut are able to extract some nutrition from these plant fibers. These plant fibers are known as dietary fiber and are an important component of the diet. The excess sugars in the body are converted into glycogen and stored for later use in the liver and muscle tissue. Glycogen stores are used to fuel prolonged exertions, such as long-distance running, and to provide energy during food shortage. Fats are stored under the skin of mammals for insulation and energy reserves and provide cushioning and protection for many organs.

Proteins in food are broken down during digestion and the resulting amino acids are absorbed. All of the proteins in the body must be formed from these amino acid constituents; no proteins are obtained directly from food.

Fats add flavor to food and promote a sense of satiety or fullness. Fatty foods are also significant sources of energy, and fatty

acids are required for the construction of lipid membranes. Fats are also required in the diet to aid the absorption of fat-soluble vitamins and the production of fat-soluble hormones.

While the human body can synthesize many of the molecules required for function from precursors, there are some nutrients that must be obtained from food. These nutrients are termed essential nutrients, meaning they must be eaten, because the body cannot produce them.

Metabolism - An Overview

Metabolism is the process of making energy available for use. If your metabolism is high, you are breaking stored fuel down at a high rate - you are burning more calories. Note that the different forms of stored energy are found in different places in the body and the flow of energy into and out of storage is under the control of hormones. What hormones are involved directly in this process? Glycogen is the form in which carbohydrate is stored in cells of the liver and muscles. Ingested carbohydrates, in the form of glucose, are converted into glycogen by insulin and then stored. Insulin both promotes the storage of glucose as glycogen and allows body cells to use glucose. In other words, the cells of the body do not have access to glucose if insulin is not present. While insulin promotes the storage and use of glucose, glucagon (a hormone created in the pancreas) promotes the conversion of stored fuels to a form that can be readily used. In other words, if glucose is gone, glucagon makes more fuel available.

Regulation of Blood Glucose Levels by Insulin and Glucagon

Blood glucose levels vary widely over the course of a day as periods of food consumption alternate with periods of fasting. Insulin and glucagon are the two hormones primarily responsible for maintaining homeostasis of blood glucose levels. Additional regulation is mediated by the thyroid hormones.

Cells of the body require nutrients in order to function, and these nutrients are obtained through feeding. Excess intake is converted to stores and removed when needed. Hormones moderate our energy stores. Insulin is produced by the beta cells of the pancreas, which are stimulated to release insulin as blood glucose levels rise (for example, after a meal is consumed). Insulin lowers blood glucose levels by enhancing the rate of glucose uptake and use by cells. Insulin also stimulates the liver to convert glucose to glycogen, which is then stored by cells for later use. Some cells, including those in the kidneys and brain, can access glucose without the use of insulin. Insulin also stimulates the conversion of glucose to fat in adipocytes and the synthesis of proteins. These actions mediated by insulin cause blood glucose concentrations to fall, called a hypoglycemic “low sugar” effect, which inhibits further insulin release from beta cells through a negative feedback loop.

Impaired insulin function can lead to a condition called diabetes mellitus, the main symptoms of which are illustrated in Figure 3.1.32.4. This can be caused by low levels of insulin production by the beta cells of the pancreas, or by reduced sensitivity of tissue cells to insulin. This prevents glucose from being absorbed by cells, causing high levels of blood glucose, or hyperglycemia (high sugar). High blood glucose levels make it difficult for the kidneys to recover all the glucose from the urine, resulting in glucose being lost in urine. High glucose levels also result in less water being reabsorbed by the kidneys, causing high amounts of urine to be produced; this may result in dehydration. Over time, high blood glucose levels can cause nerve damage to the eyes and peripheral body tissues, as well as damage to the kidneys and cardiovascular system. Oversecretion of insulin can cause hypoglycemia, low blood glucose levels. This causes insufficient glucose availability to cells, often leading to muscle weakness, and can sometimes cause unconsciousness or death if left untreated.

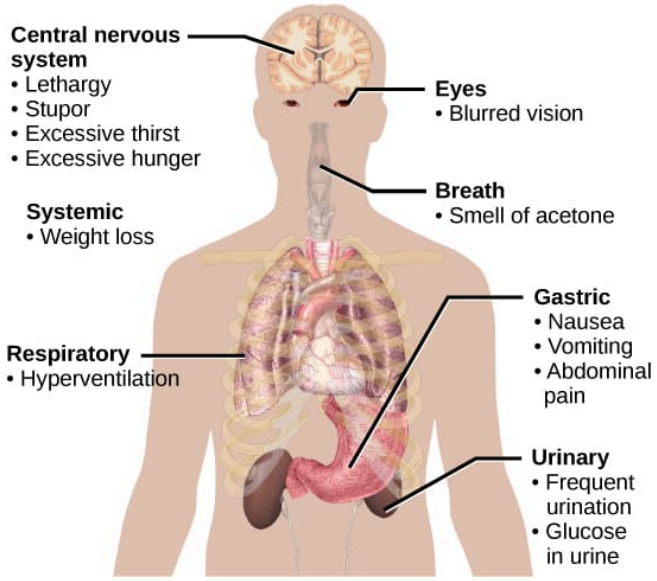

Figure 3.1.32.4: The main symptoms of diabetes are shown. (credit: modification of work by Mikael Häggström)

When blood glucose levels decline below normal levels, for example between meals or when glucose is utilized rapidly during exercise, the hormone glucagon is released from the alpha cells of the pancreas. Glucagon raises blood glucose levels, causing what is called a hyperglycemic effect, by stimulating the breakdown of glycogen to glucose in skeletal muscle cells and liver cells in a process called glycogenolysis. Glucose can then be utilized as energy by muscle cells and released into circulation by the liver cells. Glucagon also stimulates absorption of amino acids from the blood by the liver, which then converts them to glucose. This process of glucose synthesis is called gluconeogenesis. Glucagon also stimulates adipose (fat) cells to release fatty acids into the blood. These actions mediated by glucagon result in an increase in blood glucose levels to normal homeostatic levels. Rising blood glucose levels inhibit further glucagon release by the pancreas via a negative feedback mechanism. In this way, insulin and glucagon work together to maintain homeostatic glucose levels, as shown in Figure 3.1.32.5.

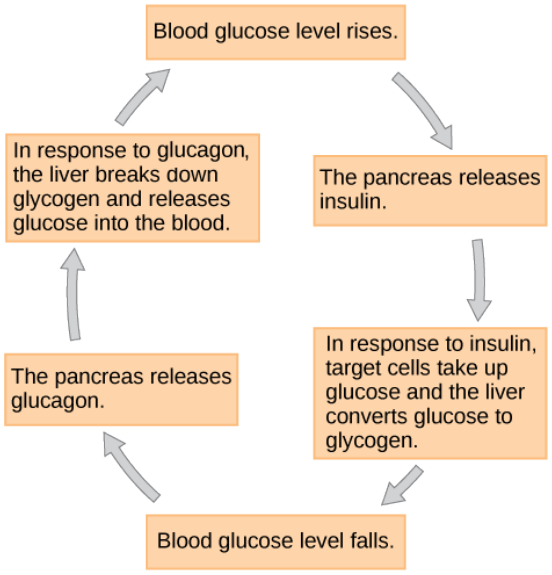

Figure 3.1.32.5: Insulin and glucagon regulate blood glucose levels. (credit: modification of OpenStax image)

Long-Term Energy Stores

"Fat" is composed of triglycerides, glycerol and fatty acids. Fat, or adipose, tissue is found beneath the skin and in various areas around the abdominal cavity. The cells in this tissue are able to absorb nutrients from the blood and are quite versatile - changing dramatically in size as the levels of stored triglycerides change. Once the short-term carbohydrate reserve is depleted, triglycerides begin to be converted to a form that cells can use and are released. Free fatty acids can be used for energy by all

cells, except those of the central nervous system. Where does the brain get energy in this case? While the cells in the body are using free fatty acids, the liver is taking up the glycerol and converting it to glucose. As discussed earlier, when glucose is gone, we get the release and action of glucagon - a hormone that converts stored fuels to those that can be readily used, like glucose.

What happens when glucagon is high and insulin is low, when stored fuels are being made available? The available free fatty acids (previously stored in adipose tissue) are converted to ketones which can be used by muscles. The breakdown of fat for energy results in a high level of ketones, a phenomenon that can also occur when one is starving. Normally, ketones are excreted in the urine. When the body is not able to process excess ketones, ketoacidosis occurs. Ketoacidosis literally leads to an increase in the acidity of the body which creates a whole host of problems - even death. Dehydration occurs as the body tries to adjust. What you have is also the movement of water out of cells - which will make more sense once we cover thirst.

The Three Phases of Digestion

When we look at the process of digestion, we can recognize three different phases. Each has its own unique hormonal profile.

- Cephalic - During the cephalic or "head" phase, the body is preparing to eat. The expectation of food, the anticipation of food, leads to the release of insulin. If the smell or sight of food leads to a hunger pang, this just might be a consequence of insulin causing any available glucose to be used or stored. This phase ends when those ingested nutrients are absorbed into the blood stream. So the cephalic phase begins when the body prepares for food ingestion and ends when that ingested food impacts fuel levels in the bloodstream.
- Absorptive - During the absorptive phase, insulin is actively promoting the use - and storage - of ingested fuels. This phase ends when the unstored energy from the meal has been used.
- Fasting Phase - When the fuel from the meal is gone, glucagon levels rise and energy stores are converted into usable fuels.

When there is no fuel available in the blood, when glucose levels drop, energy must be mobilized (removed) from energy stores. What part of the nervous system makes energy available? The sympathetic nervous system, the fight or flight component of the autonomic branch of the peripheral nervous system, causes the secretion of glucagon when there is a lack of fuel in the blood.

Summary

The process of digestion begins in the mouth where food begins to be broken down both chemically and physically into the lipids, amino acids, and glucose that are used by the body. Digestion begins in the mouth and ends when fuels are absorbed into the blood stream. Digestion consists of three phases: cephalic, absorptive, and fasting.

Metabolism, a process controlled by the hormones insulin and glucagon, makes energy available for use. Insulin is produced by the pancreas in response to rising blood glucose levels and allows cells to use the available blood glucose and store excess glucose as glycogen for later use. Diabetes mellitus is caused by reduced insulin activity and causes high blood glucose levels, or hyperglycemia. Glucagon is released by the pancreas in response to low blood glucose levels and stimulates the breakdown of glycogen into glucose, which can be used by the body.

3.1.33: Hunger - Theories, Detectors, and the Hypothalamus

Learning Objectives

1. Explain the concept of a set-point theory and how the detection of blood glucose levels and body fat explains some elements of feeding behavior.
2. Discuss the evidence for and against the existence of hypothalamic hunger and satiety centers.
3. Explain the effects of insulin, CCK, NPY, leptin, and serotonin on eating behavior.

Overview

What determines when we are hungry - how is the need for food detected? How does the detection of a need lead to eating? And what determines when we stop eating? In this section we will explore potential hunger signals and various theories that explain some elements of eating behavior. As previously noted, human eating behavior is complicated by a wide array of environmental factors. As a consequence, much of our understanding of the biological factors involved in eating comes from animal studies.

Eating behavior is controlled by two separate, yet related, systems - one that signals a need to eat and another that signals when that need has been met. The key to these systems may be two hypothalamic nuclei. In addition, various chemical factors, including cholecystokinin (CCK), Neuropeptide Y (NPY), and leptin appear to play a role in eating behavior.

Set-Point Theories

Before we look at the mechanisms that produce hunger, we'll first consider some of the major theories that strive to explain hunger and eating. There are many theories that we could consider and, perhaps, someday a single theory will emerge that is superior to all others, but at the present time we don't have a single theory that accounts for how all the different factors that impact feeding determine what we do. Most significantly, while human eating behavior tends to align with biological expectations over the long-term, the theories that focus on this fail to explain the increase in obesity that we see today (Speakman et al., 2011). In other words, there is a correlation between how much we eat (the calories we ingest) and how much we use (the calories we burn) when we consider our behavior over an extended period of time - but not when we look at individual meal-taking and daily eating behavior.

You've probably been exposed to the notion of a body weight "set-point", the idea that you have an "ideal" weight and it takes a lot of work to move away from that set-point, that optimal value that our body strives to achieve. Perhaps we have some ideal level of energy that is necessary and that we eat to restore this value. In other words, perhaps we have a set-point for available energy. Is hunger an attempt to restore energy reserves and is hunger merely signaled when energy reserves are depleted? This would predict a consistency in energy use and food intake that we simply do not see (Hall et al., 2021). Perhaps the maintenance of blood glucose (readily available fuel in the blood) could be what controls feeding for the short-term and the maintenance of body fat (stored energy) could provide a long-term explanation of eating behavior. These are both variations on the set-point theory. While each of these theories has its problems, they are consistent with some findings. Glucostatic theories propose that we work to maintain some ideal level of blood glucose. In contrast, lipostatic theories propose that we monitor the level of body fat that we have stored and then alter our eating to compensate when fat levels are not at the desired level. Having identified what is being regulated (our system variable, blood glucose or body fat) and presuming some set point, are there detectors to monitor our regulated variables?

Hunger Signals

It turns out that the brain responds to two types of hunger signals:

- Short-term. Receptors in the liver and the brain are involved in responding to short-term signals. In other words, they respond to levels of available fuel in the blood.
- Long-term. Long-term hunger signals are a consequence of the monitoring of fat stores. When fat cells are full, they produce a hormone called leptin. Leptin then inhibits the brain mechanisms that control eating - leptin makes the brain less responsive

to short-term signals. Leptin effectively turns hunger signals off (negative feedback).

Consistent with glucostatic theory, the usual trigger for hunger is a drop in blood glucose (hypoglycemia). We can produce hunger, short-term hunger, by one of two mechanisms:

- Decrease blood glucose with the administration of insulin. This causes available glucose to be stored and used by body cells. You should recall that the increase in insulin during the cephalic phase of digestion can increase your pre-meal hunger.
- Inject 2-deoyglucose (2-DG). 2-DG is structurally similar to glucose, but cells are unable to metabolize it. This produces glucoprivation - although glucose is available, cells are unable to use it. Both body and brain cells are deprived of glucose.

Both manipulations deprive body cells of glucose and both will produce eating, consistent with a glucostatic hypothesis (Thompson & Campbell, 1977).

Lipostatic theory proposes that when stored fat drops below an optimal value, hormones are secreted that increase food intake and promote weight gain (Gale et al., 2004). It also proposes that when energy stores exceed that optimal value, adipose (fat) cells release leptin to reduce eating.

From Set-Point to Settling Point

If you accept that a set-point theory does not explain our day-to-day eating behavior, what about the notion of a set-point as an explanation for why we can't seem to lose those last 5 pounds? We certainly tend to maintain a relatively constant body weight - why is that? And should we listen to our bodies? Should you eat whenever your body tells you to?

While these observations may suggest that we ultimately seek to defend a particular level of body fat, another notion is that we maintain a weight at which all the factors that influence body weight reach an equilibrium - a so-called "settling point".

Determining What to Eat

Let's look more closely at what determines the specifics of eating behavior. What we find is that, despite the findings with non-human subjects, human eating behavior has little to do with energy stores. What we do see is natural preferences for food that would facilitate survival in times of energy need - what types of food taste good? Sweet and fatty foods are energy dense and our cravings for them make sense from an evolutionary perspective - there was a time when we had to literally work for our food (hunting and gathering) as opposed to opening the refrigerator or placing an order for delivery. At the same time, bitter and sour tastes are typically associated with toxins. So, we have species-typical taste preferences and aversions (dislikes).

In addition to our inherited preferences, we also have those that are learned. We learn to eat what those around us eat - that which is familiar to us is going to be more appealing. Even if you like to try new things, I'm sure that there are limits to what you will eat.

How does an animal in the wild know what to eat in order to get the nutrients it needs? Researchers have looked at what happens when a diet lacks a nutrient and found that animals will respond - they will seek out variety when not getting all the needed nutrients and develop aversions to (dislike of) foods lacking in some nutrient. Most nutrients can't be tasted - especially with our diet today. But we do see cravings and desires at certain times - perhaps because those foods meet a need. Perhaps pickles have some benefit during pregnancy. And maybe ice cream fills a need created by a broken heart. Theoretically, we should have some ability to select the right foods, as we see in animals. But perhaps the learned elements of our eating (eating at meal times, clean your plate) have disrupted the body's ability to direct our eating choices. Further complicating ensuring we consume a balanced diet are personal decisions to restrict the types of foods eaten.

Detecting Satiety

What determines how much we eat? How do we get satiety, what makes us feel "full"? Food in the body can induce satiety, but so can simply causing the stomach to distend - as was initially demonstrated in the early 1900's by researchers who observed the impact of inflating and deflating a swallowed ballon on hunger pangs (Cannon and Washburn, 1912). The fact is that the size of the stomach impacts how much one eats. Satiety created by food ingestion does seem to be dependent on nutritive density - to some degree food ingestion will be altered when the caloric content is changed. If you increase or decrease the calories per unit volume of food, animals will adjust their diet accordingly. Yet other studies have demonstrated with the use of sham feeding (where an animal feeds, but the food is ultimately not digested or absorbed) that the changes in food ingestion are not merely due to changes in the immediate caloric impact of the food.

We all know that we do respond to how food tastes - and we get tired of eating even those things that we do like - as studies of sensory-specific satiety have demonstrated. Rats (and humans) will eat more when presented with a varied diet of tasty food - a cafeteria diet. Here you see the incentive value of food overriding the normal mechanisms that control food intake.

Physiological Mechanisms of Hunger and Eating

There are a number of physiological mechanisms that serve as the basis for hunger. When our stomachs are empty, they contract. Typically, a person then experiences hunger pangs. Chemical messages travel to the brain, and serve as a signal to initiate feeding behaviour. When our blood glucose levels drop, the pancreas and liver generate a number of chemical signals that induce hunger (Konturek et al., 2003; Novin, Robinson, Culbreth, & Tordoff, 1985) and thus initiate feeding behaviour.

For most people, once they have eaten, they feel **satiation**, or fullness and satisfaction, and their eating behavior stops. Like the initiation of eating, satiation is also regulated by several physiological mechanisms. As blood glucose levels increase, the pancreas and liver send signals to shut off hunger and eating (Drazen & Woods, 2003; Druce, Small, & Bloom, 2004; Greary, 1990). The food's passage through the gastrointestinal tract also provides important satiety signals to the brain (Woods, 2004), and fat cells release **leptin**, a satiety hormone.

Controlling the size of the stomach or the fullness of it can be used to help regulate eating. Bariatric surgery involves modifying the digestive system to achieve weight-loss. Approaches to such surgeries are varied, but decreasing the amount of food the stomach can hold is one such approach. Although recognized as an effective long-term approach for many, surgery may not be an option for many with a need for weight loss. Today, intragastric balloons are an alternative to surgical interventions.

The various hunger and satiety signals that are involved in the regulation of eating are integrated in the brain. Research suggests that several areas of the hypothalamus and hindbrain are especially important sites where this integration occurs (Ahima & Antwi, 2008; Woods & D'Alessio, 2008). Ultimately, activity in the brain determines whether or not we engage in feeding behavior.

The Role of the Hypothalamus

The hypothalamus plays a very important role in eating behavior. It is responsible for synthesizing and secreting various hormones. The lateral hypothalamus (LH) is concerned largely with hunger and, in fact, lesions (i.e., damage) of the LH can eliminate the desire for eating entirely - to the point that animals starve themselves to death unless kept alive by force feeding (Anand & Brobeck, 1951). Additionally, artificially stimulating the LH, using electrical currents, can generate eating behavior if food is available (Andersson, 1951).

Activation of the LH can not only increase the desirability of food but can also reduce the desirability of nonfood-related items. For example, Brendl, Markman, and Messner (2003) found that participants who were given a handful of popcorn to trigger hunger not only had higher ratings of food products, but also had lower ratings of nonfood products—compared with participants whose appetites were not similarly primed. That is, because eating had become more important, other non-food products lost some of their value.

While the feeling of hunger gets you to start eating, the feeling of satiation gets you to stop. Hunger and satiation are two distinct processes, controlled by different circuits in the brain and triggered by different cues. Distinct from the LH, which plays an important role in hunger, the ventromedial hypothalamus (VMH) plays an important role in satiety. Though lesions of the VMH can cause an animal to overeat to the point of obesity, the relationship between the LH and the VMH is quite complicated. Rats with VMH lesions can also be quite finicky about their food (Teitelbaum, 1955).

Is it that simple? Is the LH the key to hunger and the VMH the source of satiation (satiety)?

Evidence supporting the LH as a hunger center and the VMH as a satiety center:

- Lesioning (destroying) the lateral hypothalamus leads to anorexia (loss of appetite) and aphagia (absence of eating). At the same time, stimulating this region produces both eating and drinking. If you need a way to remember which is which - if you lesion the LH you get a lean hamster. If you lesion the VMH you get a very meaty hamster.
- Lesioning the ventromedial hypothalamus leads to hyperphagia (excessive eating) and weight gain. And stimulation of the VMH suppresses eating.

Evidence against the LH as a hunger center and the VMH as a satiety center:

- Lesions of the LH interfere with all motivated behaviors, not just feeding. In other words, perhaps the LH is a motivation center as opposed to a hunger center.
- Lesions of the VMH suppress the activity of sympathetic nervous system and increase the activity of the parasympathetic nervous system. In other words, the body is in rest and restore mode. Rats with VMH lesions become picky eaters, preferring carbohydrates. Due to the increased PNS activity, there is no fasting phase of metabolism; they are never living off of their reserves - rats continue to eat as they are not using their energy stores.

Other brain areas, besides the LH and VMH, also play important roles in eating behavior. The sensory cortices (visual, olfactory, and taste), for example, are important in identifying food items. These areas provide informational value, however, not hedonic evaluations. That is, these areas help tell an organism what is good or safe to eat, but they don't provide the pleasure (or hedonic) sensations that *actually* eating the food produces. While many sensory functions are roughly stable across different psychological states, other functions, such as the detection of food-related stimuli, are enhanced when the organism is in a hungry drive state.

After identifying a food item, the brain also needs to determine its reward value, which affects the organism's motivation to consume the food. The reward value ascribed to a particular item is, not surprisingly, sensitive to the level of hunger experienced by the organism. The hungrier you are, the greater the reward value of the food. Neurons in the areas where reward values are processed, such as the orbitofrontal cortex, fire more rapidly at the sight or taste of food when the organism is hungry relative to if it is satiated.

Hunger, Satiety, and the Body

What makes you feel full? Is it when you belly actually feels full? Can a full stomach signal to the brain that you are satiated? Yes. How does the stomach tell the brain that nutrients are there? Energy deficits are not corrected - nutrients are not absorbed at the stomach. But a stomach full of food will still put a stop to feeding, even if there are no nerves connecting it to the brain. And a full stomach - with no nutrients present - can also end feeding. What type of signals are getting to the brain when there are no nerves involved? And how can just filling the stomach lead to satiation?

The stomach and other parts of the gastrointestinal tract produce peptides that can function as hormones, traveling in the blood stream to their site of action. One peptide that has been studied quite extensively is cholecystokinin (CCK). In the absence of a neural connection, a chemical in the blood would be an ideal mechanism for the stomach to use to communicate with the brain. It turns out that CCK does cause food-deprived rats to eat smaller meals - but is that because they are feeling satiety? It turns out that CCK can make one feel ill - which would be likely to decrease eating.

While a whole host of peptides are thought to be involved in satiety, two have been found to play a role in hunger. Neuropeptide Y (NPY) and galanin both cause eating when injected into the paraventricular nucleus of the hypothalamus. NPY creates a hunger for carbohydrates and galanin for fats. Both decrease metabolism and increase fat production, suggesting they play a role in combating starvation. How does this work to regulate eating outside of a lab? Food deprivation results in an increase in NPY levels and eating decreases NPY levels (). If NPY receptors in the hypothalamus are blocked, eating caused by NPY or deprivation is not seen.

What role do neurotransmitters play with respect to eating? It turns out that serotonin inhibits food intake, especially carbohydrate ingestion. Why is this so? Serotonin inhibits NPY.

Leptin also decreases food intake by acting on NPY levels. NPY-secreting neurons in the arcuate nucleus have receptors for leptin.

Summary

Eating behavior is complicated, controlled by two systems, one that controls hunger and one that signals satiety. In other words, we have a system that turns hunger on and another that determines that the need has been met. The lateral hypothalamus plays a role in hunger and the ventromedial hypothalamus appears to play a central role in satiation. Further complicating the control of hunger is the presence of two ways of signaling an energy need, a system that responds to the available levels of fuel and responding to short-term need and one that monitors energy stores. In the short-term, levels of available glucose are monitored, while stored fats are the focus for the long-term system.

2.

Overview

Eating and drinking are complicated behaviors that are intended to meet biological needs. As already discussed, complex biological mechanisms serve to initiate and terminate these behaviors. As with many behaviors, humans make choices and they may make choices that are not consistent with their biological needs. We end this chapter with a discussion of diabetes and obesity. Both are conditions that were noted previously in this chapter. Here we consider them - and what we know about them - in greater detail.

Diabetes

Diabetes mellitus (diabetes) is a chronic disorder that can alter carbohydrate, protein, and fat metabolism. It is caused by the absence of insulin secretion due to either the progressive or marked inability of the islet cells of the pancreas to produce insulin, or due to defects in insulin uptake in the peripheral tissue. Diabetes is broadly classified under two categories, which include type 1 and type 2 diabetes (Mathieu & Badenhoop, 2005).

Type 1 diabetes occurs most commonly in children, but it can sometimes also appear in adult age groups, particularly in those in their late thirties and early forties. Patients with type 1 diabetes are generally not obese and frequently present with an emergency status known as diabetes ketoacidosis, a condition that develops when the body begins using fat for energy (American Diabetes Association, 2007).

The development of type 1 diabetes can be explained by damage to the pancreatic cells due to environmental or infectious agents. In individuals who are susceptible to genetic alterations, the immune system is triggered to produce an immune response against the altered islet cells that product insulin, or against molecules in those cells (Hutton & Davidson, 2010). Approximately 80% of patients with type 1 diabetes show circulating islet cell antibodies, and most of these patients have anti-insulin antibodies before receiving insulin therapy (van Belle, Coppieters, & von Herrath, 2011).

The major factor in the pathophysiology of type 1 diabetes is considered to be autoimmunity (Mathieu & Badenhoop, 2005).There is a strong relationship between type 1 diabetes and other autoimmune diseases such as Graves' disease, Hashimoto's thyroiditis, and Addison's disease. When these diseases are present, the prevalence rates of type 1 diabetes increase (Philippe, 2011).

Type 2 diabetes has a different pathophysiology and origin as compared to type 1 diabetes. The existence of many new factors – for example, the increased prevalence of obesity among all age groups and both sexes, physical inactivity, poor diet, and urbanization – means that the number of patients diagnosed with type 2 diabetes is rising (Ershow, 2009) . This finding is significant because it will allow health planners to make rational plans and reallocate health resources accordingly (Wild et al., 2004).

Type 2 diabetes is described as a combination of low amounts of insulin production from pancreatic islet cells and peripheral insulin resistance (Kasuga, 2006). Insulin resistance leads to elevated fatty acids in the plasma, causing decreased glucose transport into the muscle cells, as well as increased fat breakdown, subsequently leading to elevated liver glucose production. Insulin resistance and pancreatic cell dysfunction must occur simultaneously for type 2 diabetes to develop. Anyone who is overweight and/or obese has some kind of insulin resistance, but diabetes only develops in those individuals who lack sufficient insulin secretion to match the degree of insulin resistance. Insulin in those people may be high, yet it is not enough to normalize the level of blood glucose (Røder, Porte, Schwartz, & Kahn, 1998).

Dysfunction of insulin-producing islet cells is a main factor across the progression from prediabetes to diabetes. After the progression from normal glucose tolerance to abnormal glucose tolerance, post-meal blood glucose levels increase initially.

Thereafter, fasting hyperglycemia may develop as the suppression of hepatic (liver) gluconeogenesis fails (Porte, 1991). Despite the fact that the pathophysiology of diabetes differs between type 1 and type 2 diabetes, most of the complications are similar.

Obesity

Overweight and obesity are defined by an excess accumulation of adipose tissue to an extent that impairs both physical and psychosocial health and well-being (Naser, Gruber, & Thomson, 2006). Obesity is considered a health disaster in both Western and non-Western countries (Gallagher, 2000)

The prevalence is escalating significantly in many nations worldwide. This pandemic needs to be stopped if the economic costs, social hazards, morbidity, and mortality of the disease are considered.

Obesity and Type 1 Diabetes

The rising incidence of type 2 diabetes among children and adults is related to the epidemic of obesity. An increase in type 1 diabetes is thought to have similar origins (Arora, 2014). While the underling pathophysiology of type 1 diabetes, which is autoimmune in nature, continues to be investigated and studied, the exact mechanism causing the rise in the incidence of type 1 diabetes remains unclear, particularly in young age groups. One study, which collected data on childhood diabetes from 112 centers around the world, demonstrated an approximate 2.8% annual increase in type 1 diabetes over the period from 1989–2000 (Diamond Project Group, 2006).

The origin of type 1 diabetes, according to twin studies, indicates a joint contribution of environmental and genetic factors (Ershow, 2009). Furthermore, the importance of environmental factors in the development of diabetes is indicated by a significant rise in type 1 diabetes incidence in immigrants from lower to higher incidence regions. Multiple triggers for the development of type 1 diabetes have been investigated, including short-duration or the absence of breastfeeding, exposure to cow's milk protein, and exposure to some kind of infection such as enterovirus or rubella. However, none of these triggering factors has been shown to be the definitive cause (Harder, 2009).

The association between type 1 diabetes and weight gain was first investigated in 1975. The work of Baum and colleagues suggested that there was an association related to overfeeding or to hormonal dysregulation (Baum JD, Ounsted, & Smith, 1975).

The "accelerator hypothesis" proposed by Wilkin (2001) is considered one of the most accepted theories that demonstrates the association between body mass and type 1 diabetes. The authors of this theory suggested that increasing body weight in young age groups increases the risk of developing type 1 diabetes. There is an inverse relationship between body mass index and age at diagnosis. In other words, the higher the body mass index, the younger the age of diagnosis. Furthermore, as young children gain more weight, diabetes can be diagnosed earlier. This is explained by the fact that more weight accelerates insulin resistance, leading to the development of type 1 diabetes in individuals who are predisposed genetically to diabetes. Following this study, many papers were published supporting Wilkin's accelerator hypotheses. One study conducted in the United States in 2003 showed a significant increase in the prevalence of being overweight in children with type 1 diabetes, from 12.6% in the period 1979–1989 to 36.8% in the period 1990–1998. To date, the exact mechanism and relationship between type 1 diabetes and obesity remains inconclusive and needs further explanation (Wilkin, 2001).

Obesity and Type 2 Diabetes

The increased prevalence of obesity these days has drawn attention to the worldwide significance of this problem (Arora, 2014). In the United States, approximately two-thirds of the adult population is considered to be overweight or obese. Similar trends are being noticed worldwide (Tsai, Williamson, & Glick, 2011). Obesity is linked to many medical, psychological, and social conditions, the most devastating of which may be type 2 diabetes. At the start of this century, 171 million people were estimated to have type 2 diabetes, and this figure is expected to increase to 360 million by 2030 (McKeigue, Shah, & Marmot MG, 1991).

Both type 2 diabetes and obesity are associated with insulin resistance. Most obese individuals, despite being insulin resistant, do not develop hyperglycemia. Pancreatic cells release adequate amounts of insulin that are sufficient to overcome insulin level reductions under normal circumstances, thus maintaining normal glucose tolerance (Røder, Porte, Schwartz, & Kahn, 1998).

Obesity and Insulin Resistance

Insulin sensitivity fluctuation occurs across the natural life cycle. For example, insulin resistance is noticed during puberty, in pregnancy, and during the aging process (Kahn, Hull , & Utzschneider, 2006). In addition, lifestyle variations, such as increased carbohydrate intake and increased physical activity, are associated with insulin sensitivity fluctuations (Kasuga, 2006). Obesity is considered the most important factor in the development of metabolic diseases. Adipose tissue affects metabolism by secreting hormones, glycerol, and other substances including leptin, cytokines, adiponectin, and proinflammatory substances, and by releasing nonesterified fatty acids (NEFAs). In obese individuals, the secretion of these substances will be increased (Karpe, Dickmann, & Frayn, 2011).

The cornerstone factor affecting insulin insensitivity is the release of NEFAs. Increased release of NEFAs is observed in type 2 diabetes and in obesity, and it is associated with insulin resistance in both conditions (Jelic, 2007). Shortly after an acute increase of plasma NEFA levels in humans, insulin resistance starts to develop. Conversely, when the level of plasma NEFA decreases, peripheral insulin uptake and glucose monitoring will be improved (Roden et al., 1996).

Insulin sensitivity is determined by another critical factor, which is body fat distribution. Insulin resistance is associated with body mass index at any degree of weight gain. Insulin sensitivity also differs completely in lean individuals because of differences in body fat distribution. Individuals whose fat distribution is more peripheral have more insulin sensitivity than do individuals whose fat distribution is more central (ie, in the abdomen and chest area) (Karpe, Dickmann, & Frayn, 2011).

Differences in adipose tissue distribution help explain, to some extent, how the metabolic effects of subcutaneous and intra-abdominal fat differ. Intra-abdominal fat is more related to the genes that secrete proteins and the specific types of proteins responsible for the production of energy. Adiponectin secretion by omental adipocytes is larger than the amount secreted by subcutaneous-derived adipocytes. Moreover, the quantity secreted from these omental adipocytes is negatively associated with increased body weight (Jelic, 2007). The secretion of NEFAs to different tissue may be affected by their source.

Furthermore, abdominal fat is considered more lipolytic than subcutaneous fat, and it also does not respond easily to the antilipolytic action of insulin, which makes intra-abdominal fat more important in causing insulin resistance, and thus diabetes.[27,28]

Marcial et al[29] further explained the molecular mechanisms of insulin resistance, inflammation, and the development of diabetes. One of the mechanisms of insulin is its effect as an anabolic hormone that enhances glycogen synthesis in liver and muscle. This in turn augments protein synthesis inhibiting the process of proteolysis. Insulin resistance is indeed an important factor in disease process. Fat storage and mobilization are other important factors causing insulin resistance.

Go to:

Obesity and β-cell dysfunction

β-cells play a vital role in regulating insulin release, despite their fragility. The quantity of insulin released by β-cells fluctuates and changes according to the quantity, nature, and route of administration of the stimulus. Therefore, β-cells play a very important role in ensuring that in healthy subjects, concentrations of blood glucose are stable within a relatively normal physiological range. In obesity, insulin sensitivity, as well as the modulation of β-cell function, decreases.[30]

Insulin-resistant individuals, whether slim or fat, have more insulin responses and lower hepatic insulin clearance than those who are insulin sensitive. In a normal healthy subject, there is a continuous feedback relationship between the β-cells and the insulin-sensitive tissues.[10] If the adipose tissue, liver, and muscles demand glucose, this will lead to increased insulin supply by the β-cells. If the glucose levels require stability, changes in insulin sensitivity must be matched by a relatively opposite change in circulating insulin levels. Failure of this process to take place results in a deregulation of glucose levels and the development of DM. If the β-cells are healthy, there is an adaptive response to insulin resistance, which leads to the maintenance of normal levels of glucose. By contrast, when pancreatic β-cells are impaired, abnormal glucose tolerance or abnormal fasting glucose may develop, and it may even be followed by the development of type 2 diabetes.[30]

A continued decline in β-cell function is one of the main causes leading to type 2 diabetes. According to literature, when β-cell dysfunction causes inadequate insulin secretion, fasting blood glucose and postprandial blood glucose will elevate.[31] Subsequently, the decreased efficiency of hepatic and muscle glucose uptake will occur, with the absence or incomplete inhibition

of liver glucose production. Further increases in blood glucose levels will lead to disease severity through glucotoxic effects on the pancreatic β-cells and negative effects on insulin uptake and peripheral tissue sensitivity.[31]

Conversely, in healthy subjects, elevating their blood glucose levels for 20 hours or more has an absolutely inverse action, because it will lead to enhanced β-cell function capacity and improve peripheral insulin uptake.[16] These facts explain that a genetic risk factor is necessary for the occurrence of β-cell function impairment. The progression of time, as well as a pre-existing genetic abnormality in insulin secretion and a subsequently continuous elevation of blood glucose levels, lead to complete β-cell failure.[24]

A second factor that might contribute to a continuous loss of function of β-cells is increasing plasma NEFA levels. Despite the fact that NEFAs play a major role in insulin release, the continuous exposure to NEFAs is related to significant malfunction in glucose-stimulated insulin secretion pathways and reduced insulin biosynthesis. Moreover, the occurrence of insulin resistance in vivo and a failure of the compensatory mechanism of β-cells in humans contributes to increase amounts of NEFA levels produced by lipids.[32]

The two actions of NEFA contribute to a significant etiology that links β-cell dysfunction and insulin resistance in people with type 2 diabetes, and those who are at risk for the disease. The effect of lipotoxic increases in plasma NEFA levels and the rise of glucose levels might produce a more harmful effect known as glucolipotoxicity.[33,34]

Go to:

Conclusion

Diabetes and obesity are chronic disorders that are on the rise worldwide. Body mass index has a strong relationship to diabetes and insulin resistance. In an obese individual, the amount of NEFA, glycerol, hormones, cytokines, proinflammatory substances, and other substances that are involved in the development of insulin resistance are increased. Insulin resistance with impairment of β-cell function leads to the development of diabetes. Gaining weight in early life is associated with the development of type 1 diabetes. NEFA is a cornerstone in the development of insulin resistance and in the impairment of β-cell function. New approaches in managing and preventing diabetes in obese individuals must be studied and investigated based on these facts.

Have you ever pondered the complex interplay of factors that not only determine our sex but also shape how we behave and interact with the world? In this chapter, we will delve into the captivating world of sexual behavior and development, unraveling the intricate biological, psychological, and environmental threads that weave the rich tapestry of sex differences in both humans and other species.

Before outlining the structure of this chapter, I'd like to clarify some essential distinctions. First, we need to differentiate between 'sex' and 'gender.' While 'sex' refers to the biological differences between females and males, including chromosomes, hormone profiles, internal and external sex organs, 'gender' encompasses the socially and culturally constructed roles, behaviors, expressions, and identities of girls, women, boys, men, and gender-diverse people. Secondly, it's important to note that although this chapter occasionally uses the terms “males” and “females” to refer to the biological categories typically associated with female (XX chromosomes in mammals) or male (XY chromosomes in mammals), we must acknowledge the considerable variation in how these biological attributes are expressed, contributing to a broad spectrum of biological sex characteristics. Now, let's begin our exploration of how this chapter will unfold.

We begin by exploring the fundamentals of sexual reproduction and sexual dimorphism. Why does sexual reproduction exist, and what evolutionary advantages does it offer species that reproduce this way? You'll discover how the differentiation between sexes has evolved over millions of years, leading to a wide spectrum of physical and behavioral traits that define male and female forms across animal species. We will also examine sexual dimorphism beyond mere physical differences, focusing on how these distinctions manifest in behavior and even influence non-sexual traits.

As we delve deeper, the mechanisms that determine and differentiate sex will unfold. How are these mechanisms influenced by genetics and the environment? What roles do hormones play from the moment of conception and throughout life? Here, you'll

learn about the organizational and activational effects of hormones, understanding how they sculpt our bodies and minds from the womb onwards and continue to influence us through adulthood.

The chapter progresses to explore how these foundational concepts of sex and development impact brain function and behavior. We will discuss how genetic, hormonal, and environmental factors converge to mold sex-specific brain architectures, leading to distinct patterns in stress responses, motivation, and social behaviors. This section will also highlight the critical role of epigenetic mechanisms, which illustrate how our environments interact with our genetic blueprint to produce lasting effects on our behavior and mental health.

Lastly, we will touch on the vulnerability to psychiatric diseases, examining how sex differences in brain and behavior can influence susceptibility to conditions like anxiety, depression, and other mental health disorders. You will see how new research is further uncovering the roles of brain-resident immune cells like microglia and mast cells in these processes, offering new perspectives on why males and females might experience and respond to psychological stress differently.

Throughout this chapter, our discussion will be grounded in scientific research, while also considering the broader implications of these findings for understanding human diversity and improving health outcomes. By the end of this chapter, you will have a comprehensive understanding of the intricate biological and social constructs that influence sexual behavior and development, equipped with a deeper appreciation for the complexity of life and the nuanced ways in which sex and gender manifest across the spectrum of life.

3.3.2: Understanding Sexual Reproduction and Sexual Dimorphism

Learning Objectives

By the end of this section, you should be able to

- 11.1.1 Describe the basics of sexual reproduction and its evolutionary significance
- 11.1.2 Outline the steps involved in sexual reproduction, from gamete formation to zygote development
- 11.1.3 Explain the concept of sexual dimorphism and sex differences and its manifestations across species
- 11.1.4 Describe how sex differences can extend to physiological and behavioral traits beyond reproduction

Have you ever wondered why most species around you reproduce sexually, and why having two distinct sexes is so common? What are the benefits of sexual reproduction, and why are the two sexes in many species so different from each other?

In this section, we will explore the fascinating mechanisms of sexual reproduction, why it evolved, and how it drives sexual dimorphism. We'll uncover how these processes enhance genetic diversity and species adaptability. Additionally, we will delve into the concept of sex differences and how they often extend beyond traits directly related to reproduction, existing as a continuum rather than strict categories. We will examine how these differences influence physiological and behavioral processes such as sensory perception and responses to stress, and how understanding them can shed light on sex-specific vulnerabilities to psychiatric diseases in humans. By the end of this chapter, you'll have a deeper appreciation for the biological underpinnings of diversity and the complex interplay between sex and survival in the natural world.

Neuroscience across species: Evolution of Sexual Reproduction and Sexual Differentiation

Sexual reproduction is a fundamental process found across species from single-celled protists to all plants, fungi, and animals. As you can tell, sexual reproduction is incredibly common and a crucial part of today's life on Earth! But what is sexual reproduction and why is it so widespread?

To understand the fundamentals of sexual reproduction, we must first review how cells carry genetic information. Genetic material is stored in DNA (deoxyribonucleic acid), organized into structures called chromosomes (see Figure 11.2 top panel). These chromosomes are kept within the cell's nucleus.

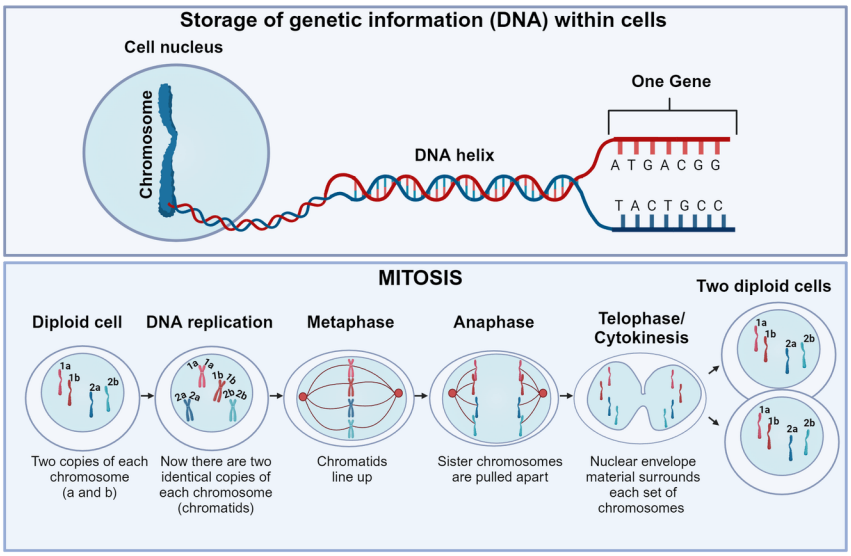

Figure 11.2 DNA and mitosis

Most cells in animals and plants are diploid, meaning they contain two sets of chromosomes: one inherited from each parent (we will go over how that works later in this section). This is why we often refer to having “23 pairs” of chromosomes in humans, rather than stating a total of 46. Every diploid cell in our bodies contains the exact same genetic information—exact copies of all chromosomes. But how is this uniformity achieved? The process begins at the very start of an individual’s life, starting from a single cell. To replicate itself, this cell first precisely duplicates each of its 46 chromosomes, resulting in two identical structures known as sister chromatids for each chromosome. Once every chromosome has been copied, the cell initiates mitosis, a type of cell division in which sister chromatids are evenly divided into two daughter cells, ensuring that each new cell receives a complete set of chromosomes (Figure 11.2 bottom panel). This division results in two identical diploid cells, each capable of further undergoing mitosis. Mitosis is crucial for the growth, development, and maintenance of multicellular organisms.

But you also learned that each copy of the chromosomes is inherited from one parent. This is possible thanks to sexual reproduction. So how does it work? At its most basic, sexual reproduction involves the steps shown in Figure 11.3: 1. Gamete Production: It all starts when each parent produces special reproductive cells called gametes—sperm in males and eggs in females. These aren't your typical diploid body cells; they're haploid, meaning they carry just one set of chromosomes. This haploidy is the result of a unique type of cell division known as meiosis, distinct from mitosis. Meiosis is special because it includes two rounds of genetic shuffling and cell division, but only one round of DNA replication. During the first division (meiosis I), the chromosomes that have already been duplicated are divided up into two new cells, each receiving one half of each chromosome pair. In the second division (meiosis II), which is similar to mitosis, the sister chromatids (the two identical halves of each duplicated chromosome) are separated. The end product? Four unique haploid gametes, each containing half as many chromosomes as the original cell. 2. Fertilization: Next comes the magic of fertilization, where two haploid gametes (one sperm and one egg) merge. This fusion creates a genetically unique, diploid cell known as a zygote. 3. Development: From there, the zygote embarks on an incredible journey, dividing through mitosis and differentiating into specialized tissues and organs, ultimately growing into a new individual.

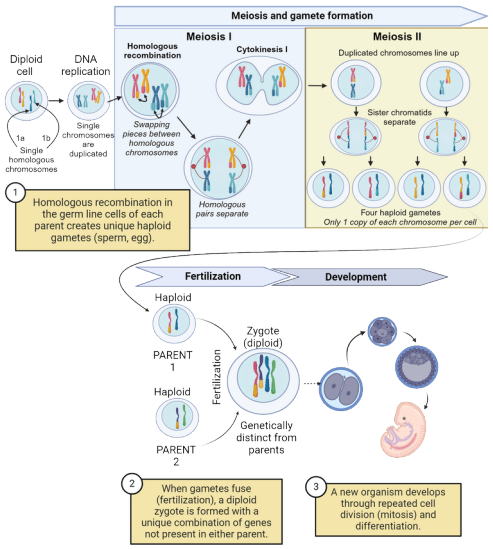

Figure 11.3 Meiosis and sexual reproduction

You might be asking yourself, why do organisms go through the complex process of producing specialized reproductive cells, searching for a compatible mate, and ultimately producing just one offspring by merging two gametes? Why not simply use mitosis to create genetically identical offspring, which seems much simpler and less risky?

There are two main hypotheses explaining this phenomenon. The first suggests that sexual reproduction evolved as a way to mask the expression of harmful mutations, effectively buffering genetic defects within a population (Michod and Gayley 1992). The second proposes that sexual reproduction serves as a mechanism to increase genetic variation, thus equipping organisms with the ability to adapt more rapidly to changing environmental conditions (McDonald, Rice, and Desai 2016). To understand how this works, we need to consider what it means to have two copies of each chromosome, one inherited from each parent.

First, due to the diploid nature of sexually reproducing organisms, where each parent contributes one version of each chromosome, or an allele, sexual reproduction plays a crucial role in shielding organisms from harmful mutations. Imagine if a harmful mutation is passed down from one parent; the normal allele from the other parent might counteract this defect, maintaining a healthy appearance or phenotype in the offspring. On the other hand, asexual reproduction, which clones the parent to produce offspring, doesn't provide this safeguard. Since the offspring are genetic copies of the parent, any mutations are directly passed on without the possibility of being diluted by a normal allele from another parent. Consequently, harmful mutations are more likely to show up and affect the organism, as there's no genetic variation to help mask their effects.

Second, diploidy can contribute to genetic diversity. There are two main ways diploidy generates this increased diversity. First, diploidy allows for generation of offspring which collectively can have differing combinations of alleles for an individual gene. Consider a hypothetical example involving thermal tolerance in fish—a trait that might be influenced by different alleles. For simplicity, let's assume there are two alleles: one for low thermal tolerance (T), which is dominant and allows the fish to thrive in cooler waters, and one for high thermal tolerance (t), which is recessive and makes the fish more suited to warmer waters. Suppose both parents are heterozygous, carrying one T allele and one t allele. Because the T allele is dominant, these parents can comfortably handle cooler temperatures. When these fish reproduce, their offspring inherit various combinations of these alleles, which we can visualize using a Punnett square (Figure 11.4). In this scenario, approximately 50% of the offspring will inherit one T and one t allele, mirroring the thermal tolerance of their parents. About 25% will inherit two T alleles, potentially enhancing their tolerance for even colder temperatures than their parents can handle. The remaining 25% will receive two t alleles, making them better adapted to warmer waters. If environmental changes lead to warmer river temperatures, the offspring with a higher tolerance for heat are more likely to survive and reproduce. Over time, this could result in a population that is better adapted to the new, warmer environment. Without this genetic variation resulting from sexual reproduction, the fish population would be less capable of adapting to such changes.

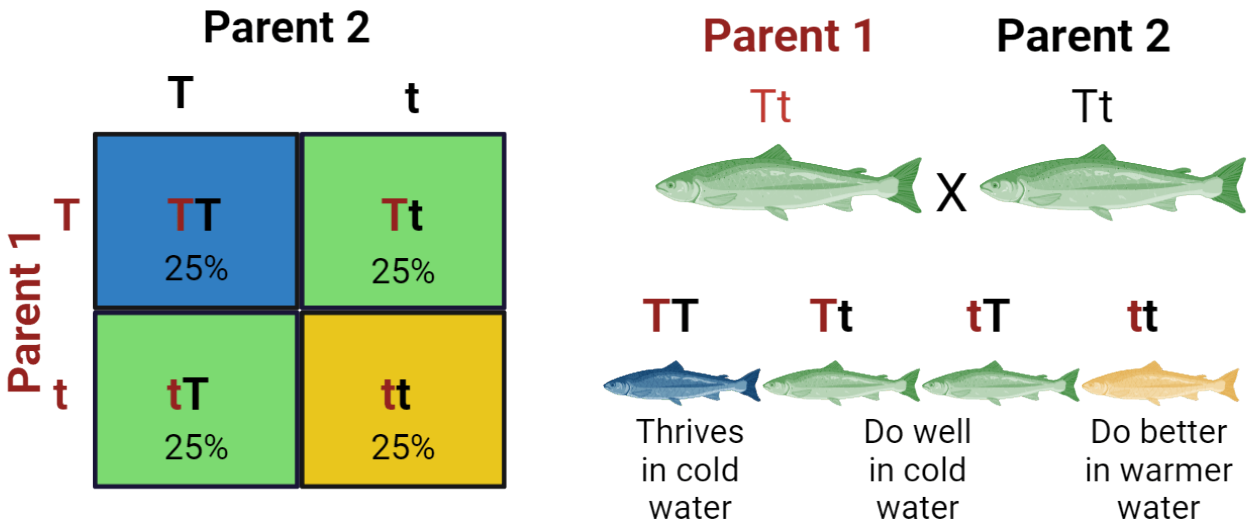

Figure 11.4 Punnett square

The second way genetic diversity is increased during meiosis I happens in a process called homologous recombination. The top panel of Figure 11.3 (step 1) diagrams an overview of this idea, showing how pieces of the two parental copies of a chromosome in a developing gamete swap places, resulting in two new chromosomes that each contain a unique mix of sections from the parental chromosomes. This mixing creates new combinations of genes that are not found in either parent. As a result, each gamete formed during meiosis carries a unique set of genetic instructions. This genetic diversity increases the likelihood that offspring will have genetic variations, some of which may be beneficial for survival in a changing environment.

So now we know why sexual reproduction may have evolved; to protect against harmful mutations and to enhance genetic diversity. However, this doesn't explain why most species have two distinct gametes. If organisms produced identical gametes—for instance, if all individuals only produced eggs instead of eggs and sperm—the eggs could theoretically fuse together to form a diploid zygote. This method would seem less costly because it wouldn't limit individuals to mating only with those of a different type, thus expanding the potential pool of reproductive partners. *So, why do most organisms have two distinct gametes?*

One hypothesis proposed is that gamete types serve to avoid inbreeding by preventing fertilization between genetically identical or closely related members (Czárán and Hoekstra 2004). To illustrate this, consider a population of aquatic organisms where no distinction exists based on gamete types. In this scenario, all individuals release their gametes into the water, where any gamete can fuse with any other gamete. This lack of discrimination could lead to gametes coming from the same parent inadvertently fusing, undermining the benefits of sexual reproduction—namely, the reduction of harmful genetic mutations and the promotion of genetic diversity. Therefore, a population of organisms producing two distinct gamete types, each of which can only fuse with the opposite type, may have had an evolutionary advantage by reducing the likelihood of clonally related gametes fusing and thus promoting genetic diversity.

Interestingly, the existence of two distinct gametes profoundly influences the evolution of both physical and behavioral differences between sexes in many species, leading to a phenomenon known as sexual dimorphism.

Sexual Dimorphism

You may have noticed that in many species, males and females exhibit distinct physical features. For example, it is more common for male lions display a mane than female lions, and male Northern Cardinals are bright red with a distinctive crest and a loud, clear song, while females are pale brown with a slightly reddish tinge and a more subdued call (Figure 11.5). This phenomenon, known as sexual dimorphism, is prevalent throughout the animal kingdom and often extends beyond primary sex traits (i.e., traits directly involved in sexual reproduction, such as gonads or reproductive organs). But what drives these differences between males and females, and what purpose do they serve?

Among lions, males have a mane and females do not.

Among cardinals, females are pale brown and males are bright red.

Before we dive in, it's essential to grasp the concept of natural selection. Natural selection is a key mechanism in evolution where individuals with certain traits that are beneficial in their environment tend to survive and reproduce more successfully than others. This process begins with genetic variation within a population, where different traits—such as tolerating higher or lower water temperatures in the fish example we discussed—can significantly influence an individual's survival. Those who survive longer have more opportunities to reproduce, and therefore pass these advantageous traits to their offspring. On the other side, if a trait does not help the individuals' survival, this individual will likely not get a chance to reproduce and therefore, over time, this trait may be lost. This leads us to a special subset of natural selection known as sexual selection, which focuses on traits that are advantageous for mating rather than just survival. These concepts can help us understand the classical view of why sexual dimorphism is so widespread.

This view, first proposed by Darwin (Darwin, Bonner, and May 1981) and further developed by an English geneticist Angus John Bateman (Bateman 1948), centers on the observation that in most sexually reproducing species, males produce many small, mobile gametes (sperm), while females produce fewer, larger, and less mobile gametes (eggs), although accumulating studies suggest that this phenomenon is more complex than initially thought (Clutton-Brock 2007). As an example, look at Figure 11.6 to see the relative size of a mouse egg surrounded by many sperm. Because sperm production is relatively inexpensive energetically, males have the potential to fertilize multiple females, a strategy that minimizes their investment in any single offspring (Trivers 1972). This leads to intense competition among males for access to mates. When two individuals of the same sex compete for access to the opposite sex, this is known as intrasexual selection, a type of sexual selection. Because of male-male competition, males often develop secondary sex traits that enhance their competitiveness in obtaining mates, such as larger body size, elaborate ornamentation, or dominant behaviors.

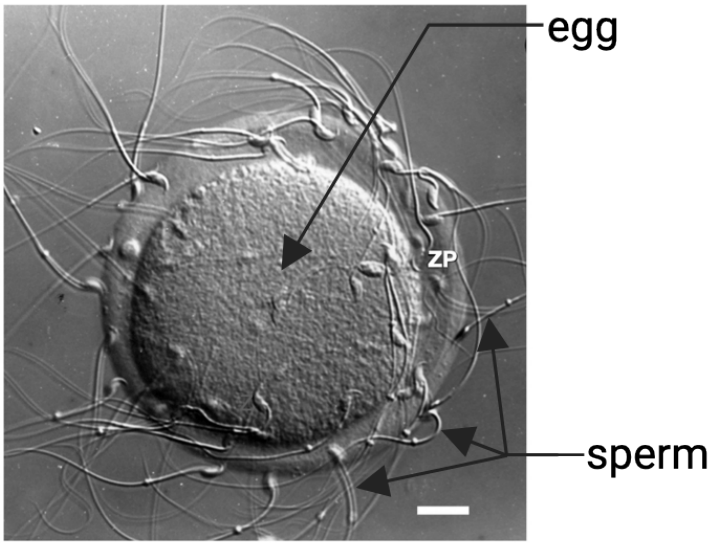

Figure 11.6 Female versus male gametes A mouse egg surrounded by many sperm exemplifies the difference in gamete size between females and males. Image credit: Image from Paul M Wassarman, Eveline S Litscher (2022) Female fertility and the zona pellucida eLife 11:e76106. CC BY 4.0

One notable example of intrasexual selection driving male-biased physical and behavioral traits is observed in elephant seals (*Mirounga angustirostris*). During the breeding season, male elephant seals gather on beaches to establish territories and compete for access to females. These males use their behavior, size, and strength to intimidate rivals and establish dominance. The bigger and more dominant males can mate with multiple females, while less dominant males are often excluded from mating opportunities (Le Boeuf, 1974) (Figure 11.7). As a result of this biased reproductive success, male elephant seals have evolved to be much bigger and dominant than females. This is intrasexual selection because females do not choose their mates; rather, it is the strength and dominance of the males that determine their access to females.

Figure 11.7 Male and female elephant seal Male elephant seals can weigh up to 10 times more than females. Image credit: By original image by Jan Roletto, uploaded 18:58, Feb 26, 2004 - de:Wikipedia by de:User:Baldhur, edited by Matthew Field - National Oceanic and Atmospheric Administration (www.noaa.gov), Public Domain, https://commons.wikimedia.org/w/inde...?curid=3440642

In contrast to males, females in most species are constrained in their reproductive potential by producing a finite number of energetically expensive gametes. Consequently, females typically invest more time and resources in parental care (Trivers 1972) and exhibit greater selectivity in mate choice, preferring to mate with males that possess the most favorable genetic or phenotypic traits. This one-sided mate selectiveness is known as intersexual selection.

A compelling example of intersexual selection are Satin Bowerbirds (*Ptilonorhynchus violaceus*). In this species, the females, who are solely responsible for rearing the young, also make critical mating decisions. Their choice of partner is heavily influenced by the male's ability to construct and decorate elaborate structures known as bowers. These bowers are not merely nests, but elaborate displays crafted from twigs and adorned with an array of colorful objects collected by the males. Additionally, the males perform intricate courtship displays, which include unique dances and a variety of vocalizations. To see a video of these behaviors, look here: link to https://www.youtube.com/watch?v=nWfyw51DQfU. Females prefer males who excel not only in their architectural skills but also in their performance abilities. This preference drives the evolution of increasingly complex bower designs and more sophisticated courtship behaviors, which comes at a cost to the male. This is intersexual selection because females actively choose their mates based on these elaborate displays and behaviors, influencing the traits that evolve in males (Borgia 1985).

While there are many examples of male-biased development of secondary traits, it's important to note that this is not always the case. An interesting example of female-biased development of secondary traits is the spotted hyena (*Crocuta crocuta*). Spotted hyenas are social animals that live in large communities called "clans," where females and males have distinct dominance hierarchies. In this species, females typically dominate males, with even low-ranking females often dominating high-ranking males. Females exhibit high levels of aggressiveness and develop virilized genitalia that closely resemble male genitals, with the clitoris forming an erectile pseudo-penis (Goymann, East, and Hofer 2001). As another examples of non-male bias in secondary traits, there are also many species where males and females are almost indistinguishable, and both contribute to raising their young. For instance, the California mouse (*Peromyscus californicus*) is a monogamous rodent in which both males and females share parental responsibilities, are similar in size and weight, and both aggressively defend their shared territories (Ribble 2003).

Lastly, a very interesting concept within sexual selection is sexual conflict, which occurs when the reproductive interests of males and females diverge, leading to evolutionary arms races between the sexes. A striking example of this is seen in the genitalia of ducks. In many duck species, males have evolved long, corkscrew-shaped penises, which facilitate forced copulations. In response, females have developed complex, labyrinthine vaginal tracts that can control the outcome of these forced encounters. This intricate anatomy allows females to limit successful fertilization to preferred males, despite the coercive strategies of others. This evolutionary battle between male persistence and female choice exemplifies how sexual conflict can drive the development of highly specialized and often bizarre reproductive traits in both sexes.

Moving beyond these examples, it's clear that both intersexual and intrasexual selection, as well as sexual conflict, which can all occur simultaneously in most species, have played significant roles in shaping distinct physical and behavioral traits in females and males over evolutionary time. However, sex differences encompass more than just sexual dimorphism related to reproductive success. They may arise as secondary consequences of traits linked to reproductive success, from trade-offs between reproductive investment and other biological functions, or from various social and environmental factors, among others. Regardless of the underlying causes, we are increasingly discovering that sex differences are present in a wide spectrum of physiological and behavioral characteristics. As we will explore, these differences have profound implications for our understanding of health and disease in both human and non-human animals.

Sex Differences in Non-Sexual Traits

Before delving deeper into sex differences, it is crucial to distinguish them from sexual dimorphism. Sexual dimorphism, which we focused on in the previous section, refers to the presence of two distinct forms of a characteristic (behavioral, physiological, or morphological) that are exclusively or predominantly found in either males or females (for example, male lions have manes, females don't). In contrast, sex differences span a continuum. In other words, while there are average differences between the sexes, males and females may exhibit a range of variations. For example, women typically have more adipose mass, higher circulating free fatty acids, and greater insulin sensitivity in metabolism compared to men. Despite these average differences, when you look at the whole population you can still find individual men that exhibit higher levels of these factors than some women. Similarly, women tend to have a higher resting heart rate and contractility but lower cardiac output than men and generally display stronger immune responses (which may contribute to the higher incidence of diseases such as multiple sclerosis (Català-Senent et al. 2023) and Alzheimer's in women (Casaletto et al. 2022)), but this may not apply to every single individual studied. This difference between a sexual dimorphism and a sex difference is illustrated in Figure 11.8. The image shows the distributions of a trait that shows sexual dimorphism versus a trait that shows a sex difference. Note how the sexual dimorphism distribution is almost completely separate between males and females. The trait with a sex difference, in contrast, shows a difference between the average male and female but the distribution of the observed trait in the two sexes overlaps substantially.

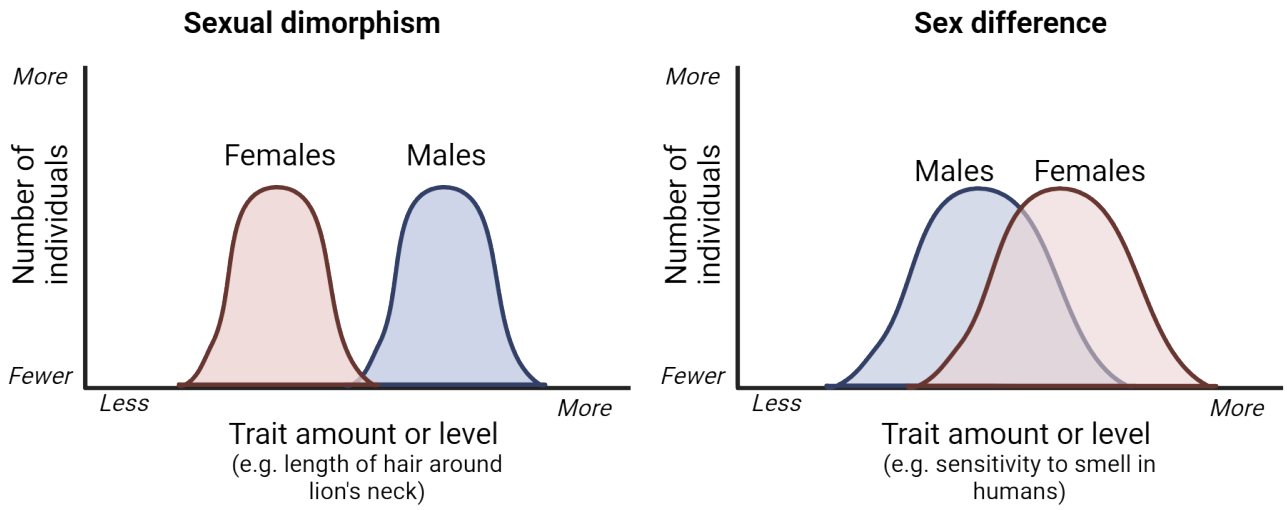

Figure 11.8 Sexual dimorphism versus sex difference

Sex differences are extensive. Indeed, since the inclusion of both sexes in preclinical and clinical studies (see Why Including Sex as a Biological Variable Matters in Biomedical Research), sex differences have been observed in virtually every biological system studied. However, for the scope of this chapter, here we will specifically focus on sex differences in behaviors by exploring examples that are fundamental to everyday functioning and may have significant implications for psychiatric diseases. Later in this chapter, we will delve into the biological mechanisms underlying these sex differences in behavior.

One interesting difference between sexes is associated with sensory perception and processing. For example, compared to men, women tend to show increased sensitivity to smell (Sorokowski et al. 2019), auditory stimuli (Aloufi et al. 2023), and pain (Mogil 2012). This could contribute to women showing higher incidence of chronic pain conditions (Osborne and Davis 2022), and men displaying much greater age-related hearing loss than women do (Pedersen, Rosenhall, and Møller 1989). While the increased sensitivity to sensory stimuli in women may result from psychosocial influences- like gender roles that shape distinct emotional and/or sensory experiences for men and women (Ohla and Lundström 2013; Schroeder 2010)- findings in other animals suggest that at least some of these differences are mediated by biological factors. For instance, compared to their male counterparts, female rodents display heightened pain sensitivity (Ro et al. 2020; Tang et al. 2017) and more acute sense of smell (Baum and Keverne 2002), which could have evolved to meet the distinct demands of each sex's reproductive roles. For example, heightened sensitivity to olfactory and auditory stimuli in females could facilitate maternal behaviors by improving a female's ability to detect and respond to offspring cues as well as predators that pose a threat to vulnerable pups, while males may have evolved reduced pain sensitivity as an adaptation to engage more effectively in physical confrontations with rivals without being incapacitated by injuries, thereby increasing their chances of securing mating opportunities with females. Importantly, these differences in sensory processing could also be linked to differences in perception of stressors and the subsequent physiological and psychological responses in males vs. females.

Sex differences in human behavior extend beyond sensory system effects. For example, how males and females respond to the experience of stress differs on average. Importantly, these sex differences may play a role in the marked disparity in the prevalence of stress-related psychiatric disorders between males and females. We will explore this topic much further in 11.4 Sex Differences in Brain Circuits and Susceptibility to Psychiatric Disease.

In sum, there are important sex differences in the way males vs. females perceive and respond to the world. Many of these differences can be found in non-human animal models, suggesting biological causes. However, as we discussed in the introduction to this chapter, it is crucial to recognize that in humans, gender—defined by the socially transmitted characteristics associated with femininity and masculinity—interacts with biological sex to influence health and disease processes throughout the lifespan (Arcand et al. 2023; Nielsen et al. 2021). This interaction highlights the complexity of human health and underscores the importance of considering both biological sex and gender in medical research and healthcare practices.

Sex for Non-Reproductive Purposes

Sexual behavior has traditionally been viewed primarily as a mechanism for reproduction between individuals of different sexes. However, a wealth of evidence across a diverse array of species indicates that sexual interactions frequently occur in contexts that cannot lead to reproduction, such as outside the fertile period or between individuals of the same sex. Indeed, same-sex sexual behavior is widely present in nature and has been documented in over 1500 species, ranging from invertebrates such as insects and spiders to vertebrates including fish, birds, and mammals (Bagemihl 1999; Sommer and Vasey 2006). Among vertebrates, same-sex sexual behavior is particularly prevalent in primates, where it appears to be equally frequent in both sexes and sometimes even more common than sexual behavior between two individuals of opposite sex. For example, a recent study on the tropical island of Cayo Santiago, Puerto Rico, which followed a colony of free-living rhesus macaques, found that male same-sex mounting was widespread: 72% of sampled males mounted other males, compared with 46% for mounting females (Clive, Flintham, and Savolainen 2023).

This widespread occurrence of same-sex sexual behavior suggests that sex serves roles beyond pure reproduction, especially when considering the costs associated with it, such as energy expenditure and the transmission of disease, as well as opportunity costs (i.e., engaging in sexual interactions that will not produce offspring as opposed to activities that might directly contribute to survival or reproductive success). What advantages can sexual behavior bring if not for reproduction? One hypothesis is that sexual behavior serves to enhance social bonds, foster cooperation, and mitigate conflict within groups (Gómez, Gónzalez-Megías, and Verdú 2023). In this context, sexual behavior would be crucial for maintaining group harmony and stability, which in turn impacts survival and reproductive success. Given these insights, the typical view of sex as solely a reproductive act between individuals of different sexes must be reconsidered. This broader perspective not only enriches our understanding of sexual behavior in the animal kingdom but also challenges us to reevaluate long-standing assumptions about the purposes and benefits of sex in evolutionary biology.

3.3.3: Mechanisms of Sexual Determination and Differentiation

Learning Objectives

By the end of this section, you should be able to

- 11.2.1 Identify the basic principles and diversity of sex determination mechanisms, including genetic and environmental sex determination
- 11.2.2 Describe the extensive variety in sex determination mechanisms across species, and how this diversity challenges the conventional view of a widespread male-female fixed dichotomy
- 11.2.3 Define what steroid hormones are and describe the concept of organizational and activational effects driving the differentiation of tissues into male or female-like forms

In the previous section, we explored hypotheses explaining the evolution and conservation of sexual reproduction and sexual dimorphism across eukaryotes, highlighting their impacts on male and female biology beyond reproductive contexts. But how is it decided whether an individual becomes a biological male or female? In this section, we will delve into the fascinating biological mechanisms underlying sex determination. We will explore how these mechanisms vary widely across different species, from the well-studied genetic sex determination in humans to the remarkable environmental influences observed in other organisms. Additionally, we will examine how a special group of hormones produced by the reproductive organs in each sex further drive the differentiation of tissues into male or female-like forms, acting both early in development and later in life.

Developmental perspective: Genetic and Ecological Factors of Sex Determination

One of the most fascinating aspects of sex determination is its remarkable diversity across species (Nagahama et al. 2021). Animals belonging to species that reproduce sexually, and therefore have two sexes, all start development with what we call bipotential gonads. Gonads are the reproductive tissue that will produce gametes (eggs in female mammals or sperm in male mammals, for example). Bipotential gonads are the undifferentiated gonads that are apparently identical at early stages of embryonic development in both sexes. During the early embryonic stage of development, these gonads differentiate into either testes or ovaries. While all species require a cue to trigger the differentiation of the bipotential gonads, this cue varies significantly. In some species, it is based on genetic factors (genetic sex determination); in others, environmental cues such as temperature play a critical role (environmental sex determination); and in some species, sex determination involves a combination of genetic and environmental factors. Remarkably, although rare, some fish species even change sex within an individual's lifetime through a process called sequential hermaphroditism. Let’s delve into each of these mechanisms.

Genetic Sex Determination

To grasp the concept of genetic sex determination, let’s first revisit how genetic information is organized within our cells. Our genetic material, DNA, is packaged into structures called chromosomes. In cells with two sets of chromosomes, known as diploid cells, there is a pair of each chromosome type. Among these pairs, one special pair comprises the sex chromosomes, which play a critical role in determining an individual's sex by carrying genes specific to sexual development and reproductive functions. The other chromosomes are known as autosomes, and they carry genes that are responsible for a wide array of bodily functions and characteristics, such as enzyme production and hair color, but do not directly determine sex.

In most mammals, including humans, the sex chromosomes are designated as X and Y. Females have two X chromosomes (XX), while males possess one X and one Y chromosome (XY). During meiosis—the process that produces reproductive cells, or gametes—these chromosomes are segregated so that each gamete ends up with just one copy of each chromosome, including one sex chromosome. Consequently, all eggs produced by females contain an X chromosome. However, males produce sperm that may carry either an X or a Y chromosome. The sex of the resulting embryo is then determined at fertilization, depending on whether it receives an X or a Y from the sperm, alongside an X from the egg. The combination of these chromosomes (XX for

females and XY for males) establishes the genetic sex of the embryo (Figure 11.9). So how does this work?

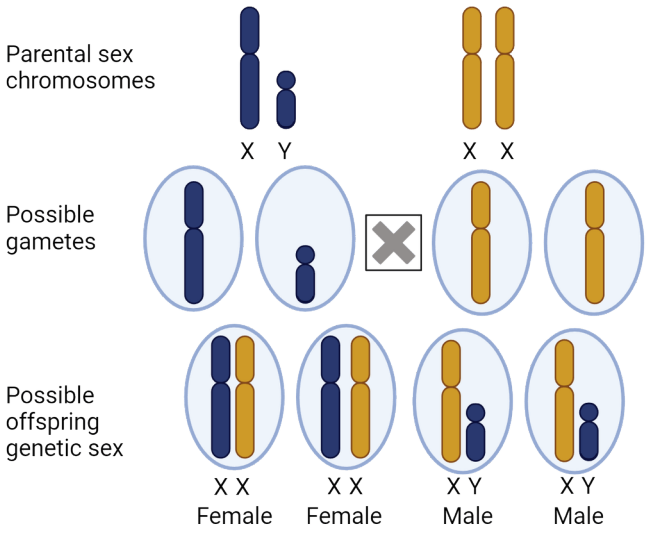

Figure 11.9 Genetic determination of sex in mammals

The Y chromosome carries a crucial gene called the sex-determining region Y (SRY in humans, Sry in mice), sometimes also referred to as “testes determining factor” or “TDF” , which is key to initiating the development of testes (Step 1 in Figure 11.10) (Kashimada and Koopman 2010). SRY expression activates another gene called Sox9, a gene located in a non-sex chromosome, which in turn guides the differentiation of somatic cells in the bipotential gonads into Sertoli cells, which are essential for supporting and nurturing the developing sperm cells, defining the initial stage in the development of the embryonic testis (Step 2 in Figure 11.10). Sertoli cells will orchestrate the further differentiation of the male reproductive organs through two main mechanisms: the induction of Leydig cell development in the testes—which will secrete of testosterone—and the secretion of anti-Müllerian hormone directly from the Sertoli cells (Step 3 in Figure 11.10). During the earlier stages of development, the internal reproductive tract is similar in both sexes and consists of a set of two ducts, the Wolffian and Müllerian ducts, which will eventually become the male or female internal reproductive organs, respectively. Leydig cells will produce androgens (sex hormones more abundant in males) such as testosterone, which will promote the differentiation of the Wolffian duct to develop into male internal genitalia, such as the epididymis, vas deferens, and seminal vesicles (Step 4 in Figure 11.10). At the same time, the anti-Müllerian hormone will result in the degeneration of the Müllerian duct, preventing the development of female internal genitalia such as the uterus and fallopian tubes (also Step 4).

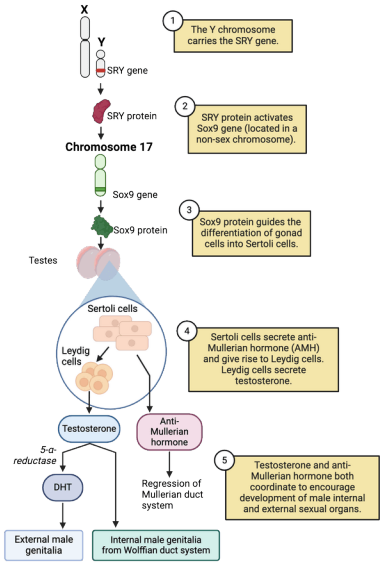

Figure 11.10 X- and Y-driven genetic sex determination of tissue differentiation

The basic anatomy of these changes in the ducts with differentiation into a male phenotype is shown on bottom of Figure 11.11. It is important to mention that although SRY is key in this process, it is not the only mechanism underlying gonadal determination, and instead it is complemented by a complex network of genes whose balanced expression levels either activate the testis pathway and simultaneously repress the ovarian pathway or vice versa(Nagahama et al. 2021).

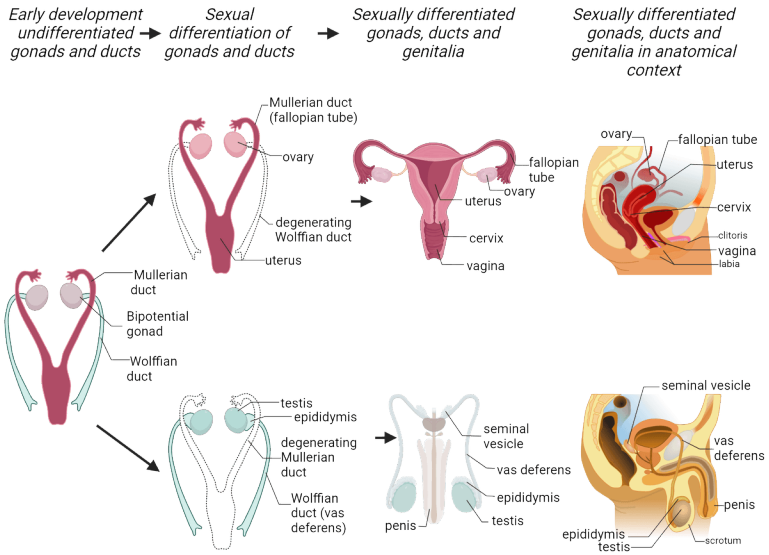

Figure 11.11 Wolffian and Müllerian duct system development Image credit: Anatomical context cartoons on far right by Tsaitgaist (labels added) - This file was derived from: Anatomy of male and female human genitalia - blanc.png, CC BY-SA 3.0, https://commons.wikimedia.org/w/inde...curid=73139956

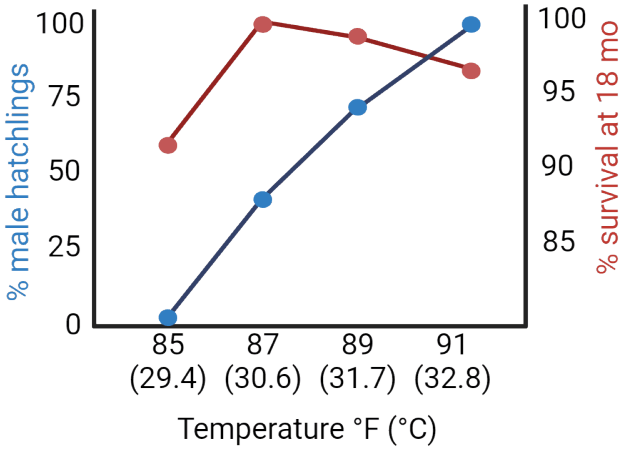
In contrast, embryos inheriting a copy of the X chromosome from their male parent will develop into XX individuals. Because in XX individuals SRY is not present, no androgens or anti-Müllerian hormones will be secreted, and the bipotential gonads, as well as the internal ducts, will follow a developmental pathway towards female differentiation. Gonadal somatic cells differentiate into granulosa cells instead of Sertoli cells, and theca cells instead of Leydig cells and the Müllerian duct will develop into female internal genitalia such as the uterus, fallopian tubes, and the internal portion of the vagina. The basic anatomy of these changes in the ducts with differentiation into a female phenotype is shown on top of Figure 11.11. While the granulosa and theca cells do not secrete hormones during early development, they will secrete two key hormones starting in adolescence: estrogen and progesterone, respectively.



While the XY system is the most common genetic sex determination structure in mammals, most birds and reptiles utilize a different sex chromosome system. In these groups, the heterogametic sex is the female, which carries one Z chromosome and one W chromosome, while males carry two Z chromosomes. Thus, in this system, the female parent determines the sex of the offspring by passing on either a Z or a W chromosome, which will result in the embryo developing into a male or a female, respectively (Ezaz et al. 2006).

However, things can get a bit more complicated: in some animals, such as the African pygmy mice (*Mus minutoides*) (Baudat, de Massy, and Veyrunes 2019) and some cichlid fishes (like M. pyrsonotus) (Ser, Roberts, and Kocher 2010), sex is determined by multiple genetic factors scattered across the genome, a process known as polygenic sex determination (Moore and Roberts 2013). This means that several genetic elements, not just one chromosome, collectively influence the sexual development of these organisms. Take the African pygmy mice as an example. Besides the usual X and Y chromosomes, these mice have a unique feminizing X chromosome variant referred to as X*. This variant can override the Y chromosome, resulting in different types of females. Specifically, in this species, there is only one type of male (XY), but three types of females: XX, XX*, and X*Y. In such a system, one might expect that litters would end up with significantly more female pups than males, right? Intriguingly, this is not the case. Research shows that male mice transmit a Y chromosome 80% of the time when mating with XX females, but only 36% of the time when mating with X*Y females. This suggests that males are selectively 'saving' their Y chromosomes for mates with at least one regular X chromosome, thereby ensuring a higher proportion of XY male offspring (Saunders et al. 2022).

This is just one example of the many diverse mechanisms involved in sex determination across species. As we will see in the next section, some species' sex determination is not influenced by genetic factors at all!

Environmental Sex Determination

In many animals, the switch to develop into a female or male is not solely determined by genes. Instead, sex determination relies on external stimuli to control this process. One of the most widespread mechanisms, found among crocodiles, most turtles, and some lizards, is temperature-dependent sex determination. This process relies on the environmental temperature during egg incubation, which in turn guides gene expression —many of which are the same genes driven by the Sry gene in mammals—driving the development of males or females (Yatsu et al. 2016). For example, in the American alligator (*Alligator mississippiensis*), eggs incubated at a constant temperature of 30°C (86°F) result in 100% female hatchlings, while incubation at higher temperatures, 34°C (93°F) or above, results in 100% male hatchlings (Ferguson and Joanen 1982) (Figure 11.12). Recent artificial incubation experiments have revealed an adaptive benefit to this mechanism. Researchers found that hatchlings incubated at male-promoting temperatures have higher survival rates compared to those incubated at female-promoting temperatures (Bock et al. 2023). Since male alligators reach sexual maturity much later than females, these findings suggest an evolutionary advantage: favoring females in conditions of lower survival ensures that some will reproduce in time, while favoring males in higher survival conditions ensures more males live long enough to reproduce. Fascinating!

In the American Alligator, temperature of the egg determines the sex of the offspring and likelihood of their survival.

Figure 11.12 Temperature-dependent sex example Image credit: Data based on findings ofJoanen, T., McNease, L., Ferguson, M.W.J. (1987): The effects of egg incubation temperature on post-hatching growth in American alligators. In: Wildlife Management: Crocodiles and Alligators, p. 535-538. Gebb, G.J.W., Manolis, S.C., Whitehead, P.J., Eds, Surrey Beatty and Sons, Sydney. Photo of alligators by Ianaré Sévi - Own work, CC BY-SA 3.0, https://commons.wikimedia.org/w/inde...?curid=6424341

Temperature, however, is not the only environmental factor influencing sex determination. For instance, in the amphipod *Echinogammarus marinus*, the photoperiod (the length of day and night) influences their sex determination, with more males developing over a long-day photoperiod regime (usually spring and early summer) and more females developing over a short-day photoperiod regime (Guler et al. 2012) (late summer and fall). Additionally, social factors can determine sex in many coral-reef-dwelling fish and limpets. For example, in the coral–dwelling fish *Gobiodon erythrospilus*, contact with a potential mating partner determines both the timing of maturation and the sex of a maturing individual, with juveniles maturing into the sex opposite to that of the adult partner (Hobbs, Munday, and Jones 2004).

The remarkable diversity of sex determination mechanisms extends beyond early development into the adult stages of some species, particularly among fish. An extraordinary example of this is sequential hermaphroditism, where adult animals have the ability to switch sexes. This adaptation can take two main forms: protandry, where individuals initially mature as males and later transform into females, and protogyny, where they start as females and later become males. Take, for instance, the clownfish (*Amphiprion percula*), which are protandrous. These fish typically live in social groups consisting of a dominant female, always the largest in size, surrounded by a large male (which will breed with the female) and several smaller, non-breeding males. In this fascinating social structure, if the dominant female is removed or dies, the breeding male changes sex to become female. Concurrently, the next largest male in the hierarchy grows rapidly, taking over as the new breeding male. Now consider the clownfish featured in Disney's 'Finding Nemo'. Had the movie reflected actual clownfish behavior, Nemo's plot would diverge sharply from the familiar storyline: following the death of his mate, Marlin would have transformed into a female, and Nemo, growing up, would likely have taken his place as the new breeding male.

But there are even more extreme examples. The Okinawa rubble gobiid fish (*Trimma okinawae*) has a mating system in which

the social group consists of one dominant male who mates with multiple females, typically referred to as a harem. Removal of the dominant male from the harem results in female-to-male sex change by the largest female within just five days, but, if the dominant male is returned to the harem, the fish that underwent the sex change transforms back into a female (Manabe et al. 2007). Thus, this species is capable of bidirectional sex change within the lifetime of a single individual!

As you can appreciate now, there is immense variety across species in the mechanisms underlying sex determination. Understanding and embracing this variety can greatly enrich our understanding of the biology of sex, demonstrating that the widespread notion of a purely dichotomous male vs. female division in nature is overly simplistic and not reflective of the true biological diversity.

Having explored the diverse genetic and environmental factors that influence sex determination, we can now turn our attention to the next stage of development: sexual differentiation. This phase involves the specific processes through which the predetermined sex develops distinct biological and physiological characteristics. In the next section, we will learn that hormones play a pivotal role in this process through organizational and activational mechanisms, each contributing uniquely to the development and functioning of sexual characteristics.

Role of Hormones in Sexual Differentiation: Organizational vs Activational Mechanisms

We have already examined how the presence of specific sex chromosomes (XX in females and XY in males) or environmental cues leads to the development of an individual as male or female. This process initiates the differentiation of the bipotential gonads into either testes in males or ovaries in females. Following this differentiation, the gonads start to produce hormones in a sex-specific manner, which then triggers a cascade of events affecting not only the gonads themselves but also various other tissues and organs throughout the body. The key hormones involved are androgens and estrogens, which belong to a class of hormones known as steroid hormones. These hormones are derived from cholesterol and are notable for their fat-soluble properties, allowing them to easily penetrate cell membranes.

Before we dive deeper into how hormones from the gonads drive sex differences, it is important to mention that research in the past two decades has shown that many sex differences throughout tissues in the body, including the brain, are a result of the inherent differences between the X and Y chromosomes, independent of hormones. For example, in tammar wallabies, researchers have found that some sexual differences in body tissues appear many days before there is any visible development of the testes, suggesting that these differences are independent of testes-derived testosterone (Renfree and Short 1988). This indicates that certain characteristics in the body can develop differently based simply on whether the cells contain two X chromosomes or one X and one Y chromosome, even before hormonal influences come into play. Similarly, mice that have been gonadectomized (surgically removing their gonads to eliminate the influence of endogenous hormones) and treated equally with exogenous testosterone, show differences in sexual behavior depending on the number of X chromosomes, indicating that chromosomes can influence sexually related behaviors independently of hormones (Bonthuis, Cox, and Rissman 2012).

Lastly, it is also important to know that while androgens and estrogens are typically referred to as male and female sex hormones, respectively, both hormones are important for various functions in both sexes, albeit to varying degrees. Testosterone, the most well-known androgen, is predominantly produced in the testes in males and in smaller quantities in the ovaries in females. Both sexes also produce testosterone in their adrenal glands. Meanwhile, estrogens are mainly produced in the ovaries in females and, to a lesser extent, in the testes and adrenal glands in males. In females, estrogens are essential for the development and maintenance of reproductive tissues such as the breasts and uterus and play a crucial role in the estrous cycle and overall reproductive health. Additionally, both androgens and estrogens contribute significantly to other physiological processes, including bone density, muscle mass, and even mood regulation, underscoring their broad and critical impact on health.

Now we are ready to explore how androgens and estrogens contribute to sexual differentiation! These hormones influence development through two main mechanisms: organizational and activational effects.

Organizational Mechanisms of Sex Hormones

The organizational effects of androgens and estrogens are crucial for sexual differentiation, exerting their influence primarily during sensitive developmental stages such as embryogenesis and puberty. These hormonal effects lead to the permanent organization of neural and anatomical structures essential for sex-specific physiological functions and behaviors.

The initial organizational effects begin with the differential secretion of steroid hormones by the developing gonads during the

prenatal period. In males, the testes begin to produce high levels of androgens during the fetal and early neonatal periods, significantly influencing sexual differentiation. In contrast, female gonads remain relatively quiescent, not producing substantial hormone levels until puberty (Figure 11.13). During these critical early stages, tissues exhibit heightened sensitivity to circulating androgens, which drive the "permanent" masculinization of various structures. For example, testosterone secreted by fetal Leydig cells in males triggers the development of male external genitalia, such as the penis and scrotum. Conversely, in females, the absence of significant testosterone levels allows the external genitalia to develop along a female typical trajectory, resulting in the formation of structures like the clitoris and labia. These developmental changes are considered permanent because they establish stable anatomical features that are maintained throughout life without the need for ongoing hormonal influence.

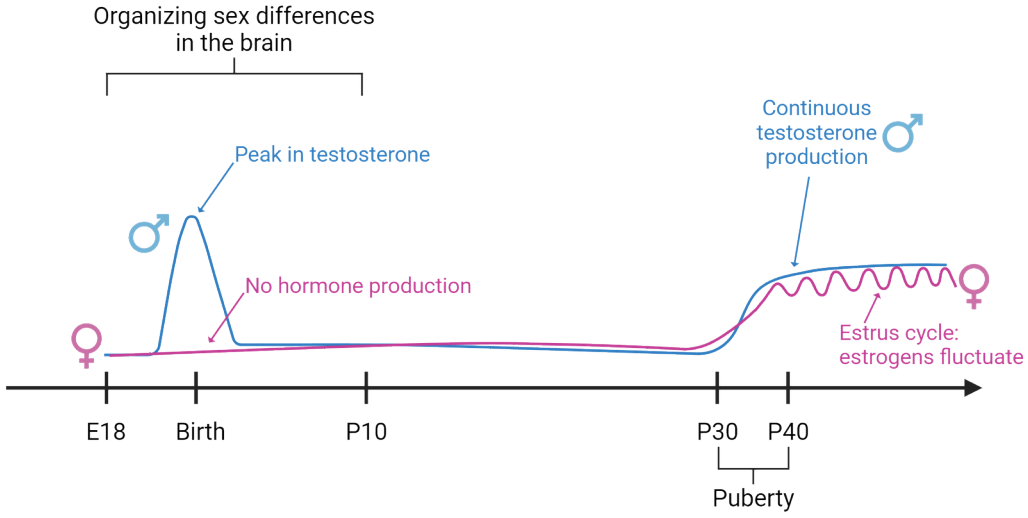


Figure 11.13 Organizational effects of gonadal testosterone in rodents

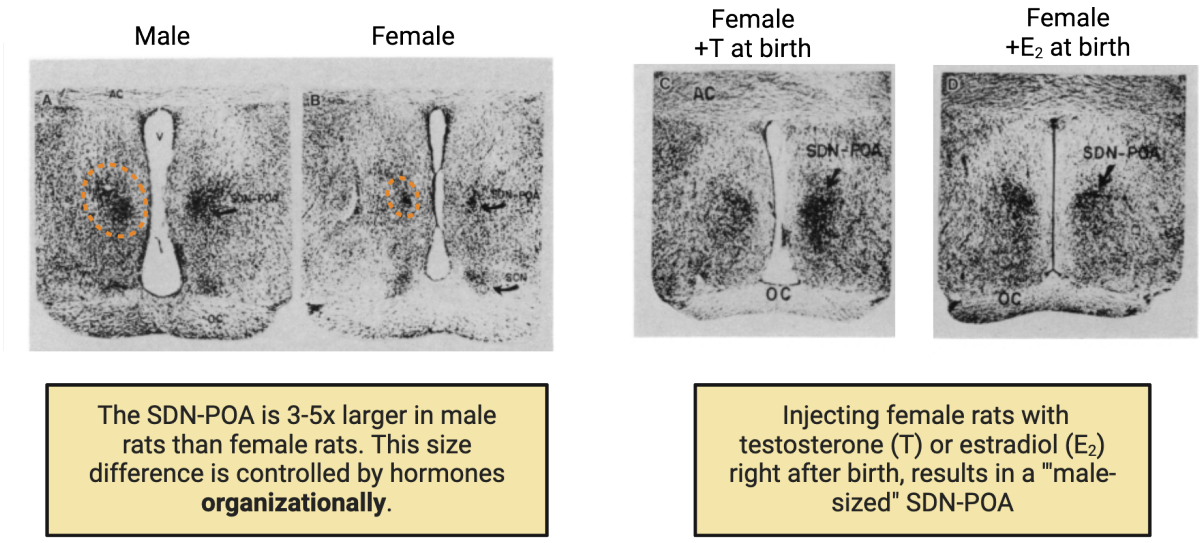
The organizational effects of hormones during critical developmental periods significantly influence not only the reproductive organs but also extend to the phenotypic differentiation of non-gonadal tissues, including the brain. In the brain, the influence of androgens during these sensitive periods does not typically manifest as major anatomical differences; instead, these hormones "prime" neural tissues to respond to androgens later in life (in other words, the organizational effects establish a framework within which androgens can later act, ensuring that sex-specific behaviors and functions are expressed appropriately). Take the preoptic area of the hypothalamus, a brain region involved in male copulatory behavior, as an example. In adult male rats, a subsection of the preoptic area called the sexually dimorphic nucleus (SDN-POA) is several-fold larger than in adult females. You can see an example of what this looks like in the left two photomicrographs of Figure 11.14.



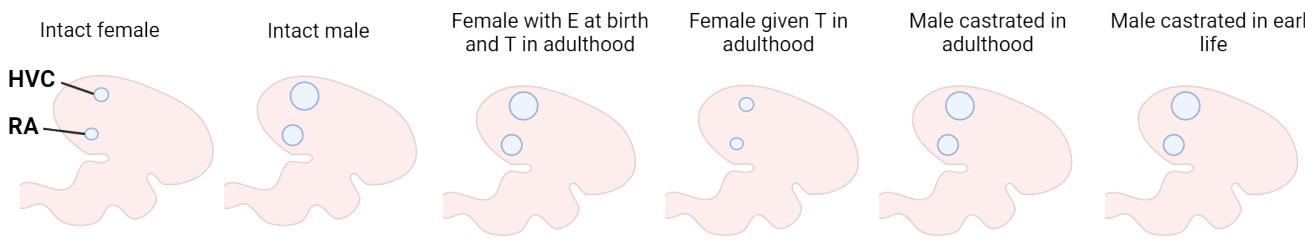


Figure 11.14 Organization hormones dictate SDN POA size Image credit: Image from: Gorski. 1974. "The neuroendocrine regulation of sex behavior." Advances in Psychobiology, 2: 1-58.

The patches of dark pigment on either side of the ventricle mark the cells of the SDN-POA of a male and a female rat. Treating female rats with testosterone just before and just after birth causes this nucleus to become as large as in normal males in adulthood, whereas removing testes (and testosterone) in male rats at birth causes the development of a smaller, feminine SDN-POA in adulthood (Döhler et al. 1984). A photomicrograph on the right side of Figure 11.14 shows an example of the SDN-POA of a genetically female rat treated with testosterone at birth; it looks large like an intact male. In contrast, hormone manipulations in adulthood, after the period of naturally occurring neuronal death, have no effect on the volume of this nucleus (Gorski et al. 1978). Thus, the sexual differentiation of this nucleus resembles that of the genitalia—male hormones early in life permanently masculinize this brain region. One difference is that it is not testosterone itself but a metabolite of testosterone that masculinizes the SDN-POA. The enzyme aromatase, which is abundant in the hypothalamus, converts androgens (such as testosterone) into estrogens (such as estradiol). Estrogen then interacts with estrogen receptors, not androgen receptors, to induce a masculine SDN-POA. In fact, you can masculinize the SDN-POA by injecting females at birth with just estradiol, a potent estrogen hormone. You can see this effect on the far right of Figure 11.14.

Why doesn't estrogen make all female brains masculinized then? Remember that while ovaries are present early on in females, they will not start secreting large amounts of estrogens until puberty (Figure 11.13). This means that estrogens are low in females around birth. The testes of males, in contrast, make plenty of steroid hormones, testosterone specifically, around birth. This peak in testosterone production drives many masculinization processes in the body and brain. In places like the hypothalamus, aromatase converts that testosterone to estrogen and drives masculinization of neural regions.

Similarly, in zebra finches (*Poephila guttata*), a species of songbirds where males sing more than females, the forebrain regions controlling song, including the higher vocal center (HVC) and the nucleus robustus archistriatum (RA), are larger in males. Treatment of newly hatched female zebra finches with estrogen, followed by testosterone treatment in adulthood, masculinizes the females in terms of both singing and the volume of RA and HVC (Gurney 1981). In contrast, castration of adult male finches reduces singing only modestly, and testosterone treatment of adult females cannot induce them to sing nor their brain regions to grow (A. P. Arnold 1975), suggesting that hormone influences during early developmental stages permanently masculinize the zebra finch brain. However, something very interesting was observed in zebra finches that did not fit what was observed in rats: neither early-life castration nor pharmacological blockade of steroid hormone receptors prevents these nuclei from developing a masculine phenotype in genetic males (A. P. Arnold 1996). Remember what we talked about the genotype itself causing sex differences independent of gonadal hormones? It turns out that the male genotype causes the zebra finch brain to locally produce steroid hormones, which then masculinize the birdsong system (Holloway and Clayton 2001). Figure 11.15 summarizes these different treatments and outcomes. This highlights, once again, the complex interplay between genetic and hormonal factors in the development of sex-specific behaviors.

	Intact female	Intact male	Female with E at birth and T in adulthood	Female given T in adulthood	Male castrated in adulthood	Male castrated in early life
HVC/RA size	Small/female typical	Large/male typical	Large/male typical	Small/female typical	Large/male typical	Large/male typical
Sings?	No	Yes	Yes	No	Yes	Yes
Genome	Female	Male	Female	Female	Male	Male
Early T exposure	no T	T	T	no T	T	no T

Figure 11.15 Sexually dimorphic RA/HVC size in zebra finches

Activational Mechanisms

Activational effects of hormones occur after the initial organizational phase and are pivotal during adulthood, continuing to influence the body throughout an individual's life. These effects are triggered by the fluctuation of hormone levels, particularly during puberty, adulthood, and into old age. Unlike organizational effects, which are permanent and shape developmental pathways, activational effects are reversible and depend on the presence of hormones at any given time.

Let's explore what happens during puberty. During this critical phase, the hypothalamic-pituitary-gonadal axis is activated both in males and females, initiating the pulsatile secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus. This hormone stimulates the pituitary gland to release luteinizing hormone (LH) and follicle-stimulating hormone (FSH), collectively known as gonadotropins. These gonadotropins then promote the production of estrogens and progesterone in the ovaries for females, and testosterone in the testes for males (see Figure 11.16). Each of these hormones exerts activational effects across various tissues.

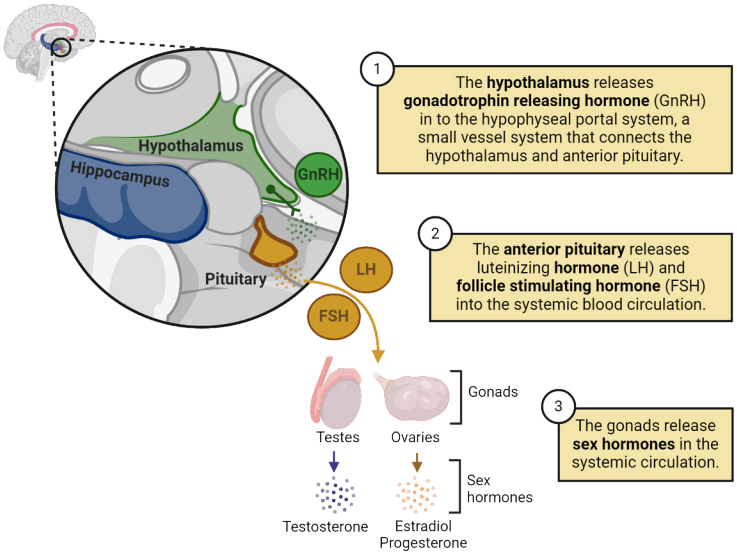

Figure 11.16 HPG axis

For example, in adult female mammals, the cyclic release of estrogen and progesterone by the ovaries during the estrous cycle has activational effects on the reproductive tract. Estrogen causes the uterine lining to thicken, preparing it for the potential

implantation of an embryo. Progesterone, released after ovulation, further prepares the uterus for pregnancy and maintains the uterine lining. If pregnancy does not occur, the levels of these hormones drop, leading to the shedding of the uterine lining in menstruation. If we inject adult males with estrogen and progesterone, however, they will not undergo these changes. This example shows how activational mechanisms can dynamically regulate female physiology as long as the tissue has been previously organized to be female.

Just like organizational effects, activational mechanisms are not limited to the reproductive tract but also extend to other tissues, including the brain. For instance, the posterodorsal medial amygdala (MePD), a brain area that plays a crucial role in male sexual arousal triggered by olfactory cues in rodents, is about 1.5 times larger in males than in females. However, if testes are removed, the size of this nucleus can be completely feminized within 30 days, which is accompanied by a reduction in male arousal to airborne cues from receptive females. Conversely, administering testosterone to adult females for a month increases the MePD to a masculine size (Cooke, Tabibnia, and Breedlove 1999). This shows that androgens play an activational role in affecting the size of MePD.

In sum, both genetic and hormonal factors play key roles in shaping sex-specific physiological processes and behaviors, but it is important to recognize that the social and physical environment also exerts profound effects, especially in humans. From birth, human infants are immersed in a highly gendered social and physical environment. Boys and girls are often expected and encouraged to behave differently and tend to choose different occupations and life paths. These choices lead to variations in physical and emotional stress, diet, and numerous other factors (Arthur P. Arnold 2017). The substantial differences in environmental experiences between the sexes can contribute to functional differences in the brain and other tissues, as well as susceptibility to diseases.

Sex as a biological variable: Why Including Sex as a Biological Variable Matters in Biomedical Research

Incorporating sex as a biological variable in biomedical research is crucial for achieving robust, rigorous, and reproducible science. Before we continue, it is crucial to remember the differences between 'sex'—the biological differences including chromosomes, hormonal profiles, and internal and external organs—and 'gender,' which encompasses the socially constructed roles, behaviors, identities, and norms. Historically, the majority of research has focused disproportionately on male subjects, from laboratory animals to human clinical trial participants, leading to significant gaps in our medical knowledge. This oversight can result in skewed data and potentially harmful clinical outcomes, especially for women (Zucker, Prendergast, and Beery 2022). Sex differences can profoundly influence various biological processes, from cellular responses and gene expression to the manifestation of diseases and how drugs are metabolized. Ignoring these differences has led to a systemic lack of representation not only of females but also of transgender and intersex populations, and individuals with variations in sex characteristics. This oversight has compromised the quality of healthcare, often resulting in delayed or misdiagnosed conditions in these groups. Additionally, the underrepresentation of female participants in clinical trials and the absence of sex-based data analysis have culminated in medications that are less effective and potentially more harmful for female patients. A compelling illustration of the importance of including sex as a biological variable is evident in stroke research. Stroke, a leading cause of death and disability worldwide, has a higher lifetime risk in women than in men. Research has uncovered significant differences in how strokes affect males and females, with variations in incidence, outcomes, and treatment responses. For example, estrogen's neuroprotective effects influence stroke outcomes differently across sexes. Drugs that showed promise in male models often failed to translate the same benefits to females, likely due to these hormonal differences. These findings emphasize the critical need for sex-specific treatment approaches in stroke therapies, showcasing how integrating sex as a biological variable provides essential insights into how diseases and treatments uniquely impact males and females. This approach is vital for developing effective, personalized medical treatments that cater to the specific needs of all patients.

3.3.4: Sex Differences in Brain and Behavior- Genetic, Hormonal, and Environmental Mechanisms

Learning Objectives

By the end of this section, you should be able to

- 11.3.1 Explain how sex chromosome-linked genes can directly influence brain function
- 11.3.2 Understand the mechanisms through which steroid hormones can affect cellular functions, including both classical and rapid signaling pathways
- 11.3.3 Identify how social and physical environments influence hormonal actions and lead to variations in brain development and behavior

In the previous section, we explored the biological mechanisms of sex determination, highlighting the diverse genetic and environmental factors involved across various species. We also examined how gonadal hormones drive sex differentiation in various tissues, including specific brain regions like the preoptic area of the hypothalamus in rats, which controls male copulatory behavior, and the higher vocal center in zebra finches, which is involved in male song production. However, as we discussed at the beginning of this chapter, sex differences in the brain and behavior extend far beyond those related to reproduction. For instance, there are notable sex differences in sensory perception, motivated behavior, and stress responses, which can influence the susceptibility to psychological disorders. But how do these differences arise?

In this section, we will investigate the mechanisms through which sex chromosome-linked genes, hormones, and the environment contribute to sex differences in the brain. This foundational understanding will prepare us for the final section, where we will delve into how sex differences in neuronal circuits and glial functions can lead to sex-biased susceptibility to psychiatric diseases.

Contribution of Sex Chromosomes to Sex Differences in the Brain

We have previously examined how sex chromosomes influence sex differences by determining gonadal development and synthesis of steroid hormones such as testosterone and estrogen. We also touched upon the fact that in mammalian cells, the XY or XX chromosomal complement alone can drive sex-specific cellular physiology. This process applies to the brain as well.

For example, a group of researchers found that in male rats, Sry is highly expressed in brain areas with an abundance of dopamine-producing neurons, such as the substantia nigra and the ventral tegmental area. As you may recall, SRY is the protein encoded by the Y chromosome-linked Sry gene, which was primarily known as the key orchestrator of male sexual determination by acting within the gonadal tissue, so this finding was quite surprising. Interestingly, the researchers further discovered that inhibiting SRY expression—by directly injecting compounds that prevent the synthesis of the SRY protein—led to a decrease in tyrosine hydroxylase levels, an enzyme critical for the production of dopamine. Dopamine is crucial for motor movement, so this inhibition also resulted in motor deficits (Dewing et al. 2006). These results suggest that the production of dopamine in certain neurons is distinctly regulated in males versus females simply by the presence of the Y chromosome in males, without any mediation by gonadal hormones. Remarkably, this group recently discovered that overexpression of SRY in dopamine neurons may explain the male-biased predisposition to Parkinson's disease, a disorder characterized by motor dysfunction due to the degeneration of dopamine-producing neurons in the substantia nigra (Lee et al. 2019) (see Chapter 10 Motor Control).

But Sry is not the only gene affecting brain cells in a sex-specific way. As an example, it was recently found that genes linked to the X chromosome are extensively expressed in the brain, where they modulate brain anatomy, connectivity, and functionality. Indeed, the X chromosome in mice and humans express more brain-specific genes than any other chromosome (Nguyen and Disteche 2006)! But there is a problem: the difference in the number of X chromosomes between XX and XY mammals presents an inequity in gene dose between the sexes. That is, XY animals have half as much X genetic material as XX individuals. Generally in cell biology, having too many or two few of any chromosome is detrimental to cellular function. So how do cells adapt to potentially having one or two Xs depending on their genetic sex? In most mammalian cells, this dose problem is solved by inactivating one of the Xs in XX carrying cells. Figure 11.17 depicts this process, in which one X chromosome is condensed in a largely random fashion. With one X inactivated in XX cells, both XX and XY genotypes have one chromosome-worth of X material “available”, and their cellular physiology is setup to work well with that level of X gene expression. This is important because now we know that

some of the functions associated with the X chromosome are affected by dosage—i.e., the number of “available” X chromosomes present. But how did scientist learn about this dosage effect if both XX and XY genotypes technically have the same number of functional X chromosomes?

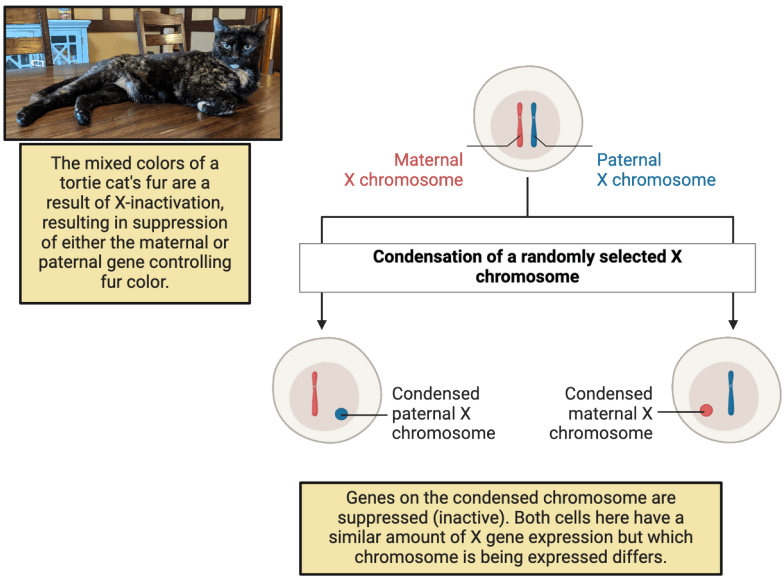

Figure 11.17 X-inactivation Image credit: Cat reproduced with permission from Elizabeth Kirby.

First, studies of human aneuploidies provided insights. Examples of these conditions include Klinefelter syndrome (XXY), where males have an extra X chromosome, and Turner syndrome (XO), where females have only one X chromosome. These syndromes illustrate the effects of abnormal sex chromosome numbers on development and physiology. For instance, individuals with Klinefelter syndrome often exhibit reduced muscle mass, decreased bone density, and brain function abnormalities, including cognitive abnormalities and exacerbated responses to motor and auditory stimuli(Wallentin et al. 2016). Those with Turner syndrome may experience short stature, heart defects, and reduced hippocampal volumes, a brain structure critical for memory formation (Kesler et al. 2004). However, people with Klinefelter and Turner syndrome also show abnormal gonadal function and secretion of steroid hormones, making it impossible to separate the effects of the differences in X chromosomes from the effects of hormones. To solve that issue, experimental mouse models of aneuploidies, where there are differences in X chromosomes but the gonads are intact, were developed, offering significant clues about the importance of proper X chromosome dosing. For example, a series of studies using high-resolution brain imaging to compare male mice with two X chromosomes (XXY) and females with only one X chromosome (XO) to their wild-type XY and XX littermates, respectively, found that both XXY and XO show anatomical changes across the brain. Intriguingly, many of the brain areas affected show changes in both XXY vs. XY and XO vs. XX comparisons, but in opposite ways (Raznahan et al. 2015; 2013). This suggests that the dosage of X chromosomes determines anatomical characteristics in a subset of brain areas. But why is this important if we discussed that XY and XX individuals have the same amount of functional X chromosomes?

Well, it turns out that while it is true that one X chromosome in XX individuals is typically 'inactivated', some genes on the X chromosome have been shown to escape inactivation (Berletch et al. 2011). This means that there could still be an imbalance in the expression of X-linked genes in males versus females, leading to important differences between XX and XY individuals in neuronal and glial function throughout the brain, a fascinating area of study that will surely expand in the coming years.

Contribution of Sex Hormones to Sex Differences in the Brain

While sex chromosome effects on brain function are an exciting and developing field, we have a much deeper understanding of the many ways that sex hormones shape the brain. In 11.2 Mechanisms of Sexual Determination and Differentiation, we categorized the effects of hormones into organizational versus activational effects based on when hormones have their effects and how long they last. A separate dimension to steroid hormone function that we must now consider as we delve more into how sex hormones impact brain cells is how sex hormones signal to cells. Specifically, steroid hormones can exert their effects on cells through two main mechanisms that become important to appreciate in the brain: the classical and rapid signaling mechanisms.

The Classical Mechanism.

Figure 11.18 shows a diagram of the classical steroid hormone signaling mechanism.

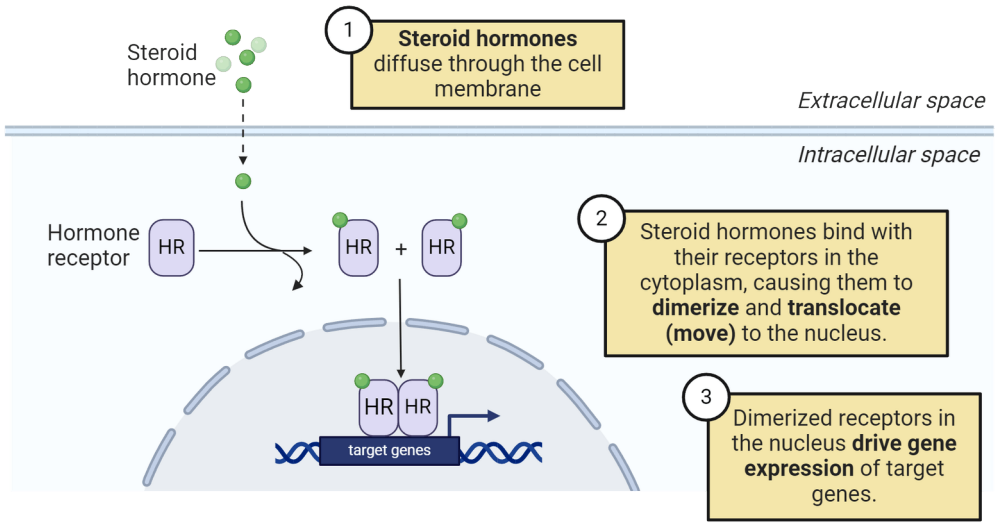

Figure 11.18 Classic steroid hormone receptor signaling

In this mechanism, steroid hormones like estrogen and testosterone, which remember, are fat-soluble, which make it easy for them to slip-through the lipid bilayer in membranes, enter the cell (step 1) and bind to specific receptors in the cytoplasm (step 2). Once bound, these hormone-receptor complexes form pairs and move into the nucleus of the cell (step 2). Inside the nucleus, they act as transcription factors, meaning they can regulate gene expression by binding to specific DNA sequences (step 3). This genomic action is slow, taking hours to days, and can lead to long-term changes in neuronal structure and function. Many of the organizational effects of hormones are achieved via this mechanism. For example, the neonatal surge of testosterone in male mice results in larger volumes of the posterior bed nucleus of the stria terminalis (BNSTp) compared to females, a brain area associated with stress responses and social behaviors. But how does this happen?

As we first learned in 11.2 Mechanisms of Sexual Determination and Differentiation, many of the effects of the neonatal surge of testosterone within the brain involve the conversion of testosterone to estradiol by an enzyme called aromatase. This estradiol then acts through a type of estrogen receptor called estrogen receptor alpha (ERα), which functions as a transcription factor—a protein that binds to specific DNA sequences to regulate the expression of certain genes. In the case of the BNSTp in mice, ERα initiates a gene expression program during early life that promotes neuronal survival (Gegenhuber et al. 2022), an organizational effect resulting in males' BNSTp having more neurons than females'. But this is not exclusive to organizational effects, as activational actions of hormones can also rely on this mechanism.

The Rapid Signaling Mechanism

Figure 11.19 shows a diagram of the rapid steroid hormone signaling mechanism.

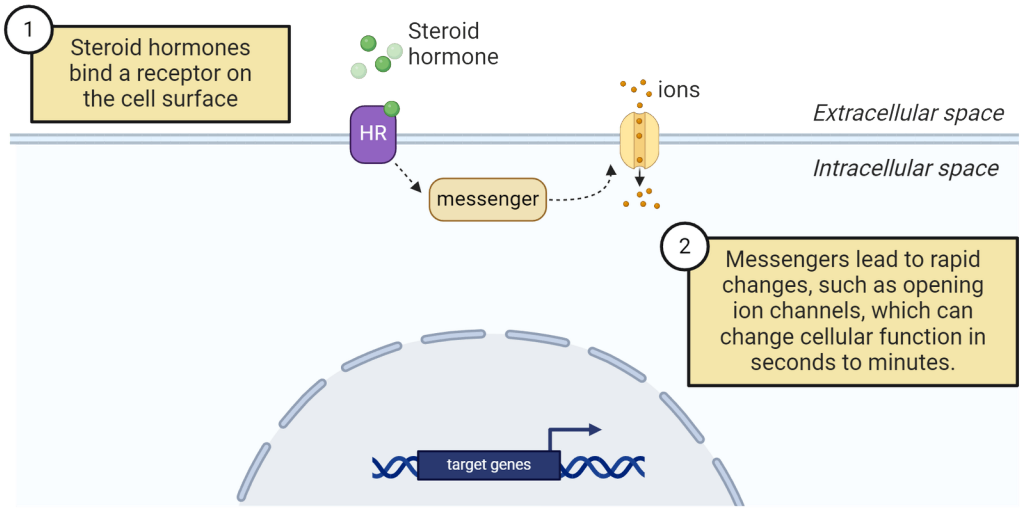

Figure 11.19 Rapid steroid hormone receptor signaling

In this mechanism, steroid hormones bind to receptors located on the cell membrane rather than inside the cell (step 1). These membrane-bound receptors trigger immediate signaling pathways without directly altering gene activity (step 2). Using this mechanism, steroid hormones can modulate neuronal functions within seconds to minutes. This is crucial because steroid hormone levels fluctuate periodically—for example, testosterone tends to be higher in males during earlier times of the day, and ovarian hormones in females change throughout the estrous cycle (Figure 11.20)—as well as in response to environmental stimuli. For example, winning an aggressive encounter can rapidly increase testosterone levels in males and progesterone levels in females, which in turn could rapidly modulate neuronal functions. Rapid activation of cells by membrane steroid hormone receptors allows cells to respond to these kinds of transient changes in hormone levels rapidly. The classical mechanism simply takes too long to be a reasonable readout of such fluctuations.

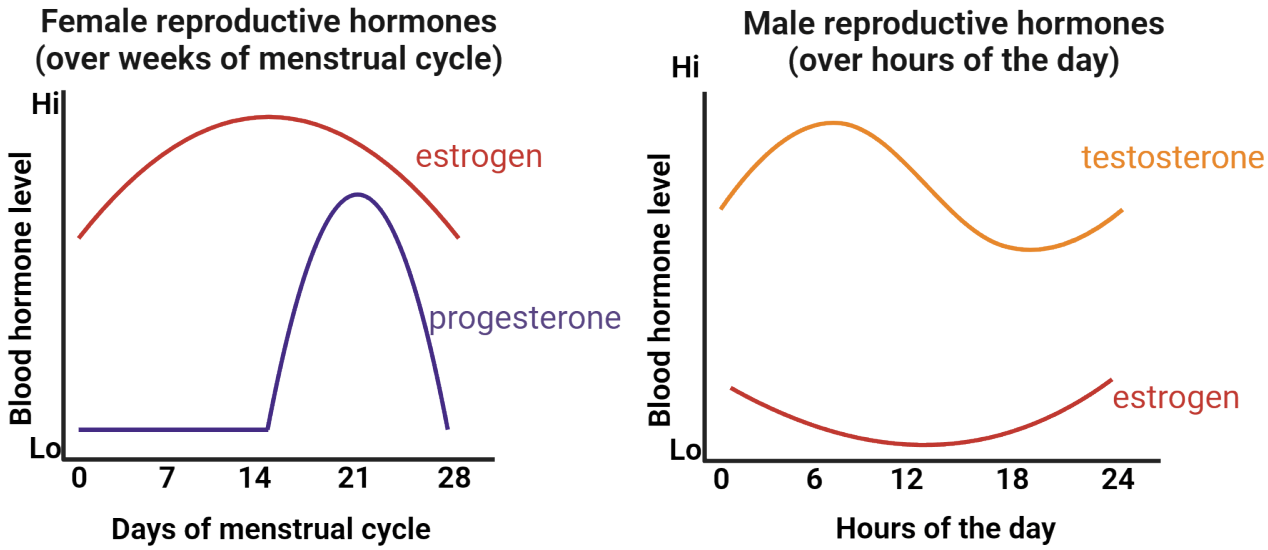

Figure 11.20 Gonadal steroid hormone fluctiations

A notable example of rapid steroid hormone effects driving sexually dimorphic changes in neurons is the modulation of synaptic plasticity. Within the hippocampus, a subtype of neurons in the CA1 subregion exhibits rapid and reversible changes in synaptogenesis—the formation of new synapses—in response to ovarian hormones. This rapid modulation involves membrane-bound estrogen receptors activating intracellular signaling pathways that quickly alter neuronal activity and synaptic strength. This change has been best studied in rodents, particularly rats. The female rat shows an estrous cycle that lasts ~4 days, the rat equivalent of a human menstrual cycle. The cyclical changes in circulating ovarian hormones in the female rat estrous cycle result in increases in spine density during proestrus, when ovarian steroid levels are highest, and subsequent decreases in later stages

of the estrous cycle (e.g., diestrus or metestrus, when estrogen and progesterone levels are relatively low) (McEwen et al. 2012). Figure 11.21 shows an example of what these differences look like in a mouse expressing a green fluorescent protein in neurons within the hippocampus (specifically, CA1) to help us see the spines.

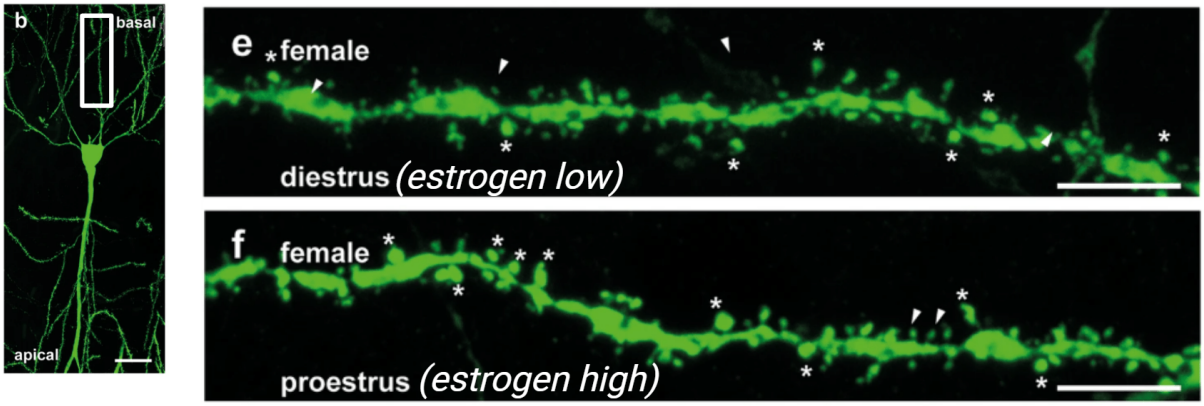

Figure 11.21 Dendritic spines vary with estrogen level Image credit (ROI box and estrogen labels added): Brandt, N., Löffler, T., Fester, L. et al. Sex-specific features of spine densities in the hippocampus. Sci Rep 10, 11405 (2020). https://doi.org/10.1038/s41598-020-68371-x. CC BY 4.0

The white *s mark spines in this image. It is important to mention, however, that some of these changes in spines might also be a result of classic actions of steroids (Sandstrom and Williams 2001). This change in spine density with estrus cycle, in turn, could have consequences on behavior. For example, some studies have found that female rodents show better performance in memory tasks during proestrus compared to diestrus or metestrus (Koss and Frick 2017), and others found that a single post-training treatment with estrogen administered immediately after training enhances memory consolidation in ovariectomized rodents (Frick and Kim 2018).

Similarly, an increase in circulating testosterone in male humans was shown to heighten the reactivity of the amygdala, hypothalamus, and periaqueductal gray to angry facial expressions within 90 minutes of testosterone administration (Goetz et al. 2014), suggesting that testosterone can quickly modify the function of neural circuits mediating threat processing and aggressive behavior via rapid non-genomic mechanisms.

Contribution of Environmental Factors to Sex differences in the Brain

Environmental factors also play a significant role in shaping sex differences in the brain, especially during early developmental periods. For example, social stressors, which can profoundly affect hormonal factors contributing to sex differences (see Chapter 12 Stress), can also result in long-lasting effects on brain circuits. Interestingly, sometimes the same stressor can either eliminate or exacerbate sex differences in brain physiology depending on the context. For instance, males and females show sex differences in gene expression in brain areas associated with reward both at baseline and after exposure to cocaine. A recent study found that exposure to social isolation stress eliminates the sex differences seen at baseline (i.e., it makes male and female reward brain regions more similar to each other when animals have not been exposed to cocaine), but it actually exacerbates the differences in response to cocaine (Walker et al. 2022). This finding sheds light on how different responses to stressors in males versus females can contribute to the sex differences seen in addiction-related behaviors.

Similarly, physical activity can affect cognitive functions in sex-specific ways. A meta-analysis assessing the effects of exercise efficacy to improve cognition in elderly humans found that exercise interventions were associated with larger effect sizes in studies comprised of a higher percentage of women compared to studies with a lower percentage of women, suggesting that elderly women's executive processes may benefit more from exercise than elderly men's (Barha, Davis, et al. 2017). Studies in rodents have also found sex-specific effects of exercise on brain function.

The effects of environmental factors in contributing to sex-specific responses further extend to how males and females respond to exposure to contaminants, an increasingly emerging concern considering that the rate of production and use of new chemicals is constantly increasing.

As an example of a particularly well known endocrine-disrupting chemical, let's discuss perinatal exposure to PCBs. PCBs are chemicals used for their coolant properties in products such as transformers, capacitors, electrical devices, and appliances. PCBs

can directly and irreversibly affect sexual differentiation of the brain. For example, a study that exposed pregnant rats to PCBs found that perinatal exposure led to changes in the hypothalamus that altered the female onset of puberty and estrous cyclicity (the regular, recurring changes in the female reproductive system to prepare them for pregnancy) (Dickerson et al. 2011). Although PCBs were banned in the late 1970s, they are still present in the environment due to their persistence and bioaccumulation. Aggravating the concern, studies keep finding deleterious effects of PCB exposure in humans. For example, a recent systematic review found that perinatal PCBs are associated with adverse cognitive development and attention issues in middle childhood, affecting boys to a greater extent than girls (Balalian et al. 2024). This is just one example that highlights the imperative need to conduct rigorous research and implement stringent regulation for all new chemicals before they become widespread and can potentially pose significant risks for human and animal health.

As you can appreciate, we are increasingly recognizing that the social, physical, and chemical environment, alongside genes and hormones, play a crucial role in shaping sex differences in the brain. In humans, this takes yet another level of complexity given that, from birth, human infants are immersed in a gendered world where boys and girls are often expected and encouraged to behave differently. These societal expectations lead them to pursue different occupations and life paths, resulting in variations in physical and emotional stress, diet, and other factors. Such substantial differences in environmental experiences between the sexes can further contribute to functional differences in the brain and other tissues, as well as differing susceptibility to diseases.

People Behind the Science: Margaret McCarthy

You might wonder how steroid hormones can imprint on the developing brain to organize sex differences between males and females. Dr. Margareth McCarthy has conducted groundbreaking research in this area. Some of her early studies showed that steroid hormones can epigenetically imprint on the developing brain, leading to differences in adult physiology and behavior between the sexes (McCarthy et al. 2009). Epigenetics refers to processes that change gene activity through changing the structure of the DNA and/or the proteins around which DNA is wound, without altering the DNA sequence. Two common types of epigenetic modifications are DNA methylation and histone modification. DNA methylation involves adding a methyl group to the DNA molecule, typically resulting in reduced gene expression because it can prevent the binding of transcription factors to the DNA. Histone modification involves changes to histones, which are proteins that help package DNA into a compact, efficient structure. By modifying histones, DNA can either be loosened or tightened, making genes more or less accessible for transcription (Figure 11.22). These epigenetic changes can be stable and long-lasting, affecting how genes are expressed over time.

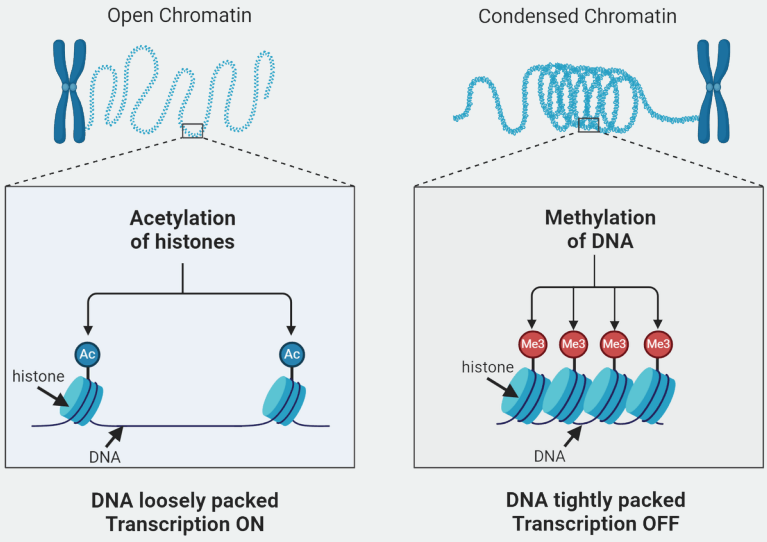

Figure 11.22 Epigenetic modifications to DNA

In one groundbreaking study from Dr. Margareth McCarthy's lab, which focused on the highly dimorphic preoptic area (POA) — a key brain region that governs adult sexual behaviors — they discovered that the organizational effects of testosterone in driving male differentiation of the POA are not solely dependent on testosterone's interactions with nuclear receptors. Instead, a main mechanism involves testosterone reducing the activity of an enzyme known as DNA methyltransferase. This reduction decreases DNA methylation, effectively "releasing" an active repression on genes responsible for masculinizing the brain. In other words,

they discovered that feminization of the POA, instead of being just a passive "default" state, results from the active suppression of masculinization via DNA methylation, and that one of the roles of early life testosterone in males is to stop that suppression (Nugent et al. 2015). This insight is just one of many groundbreaking discoveries made by Dr. Margareth McCarthy's lab. Her team has extensively explored various aspects of brain development and function, including inflammatory and immune-mediated sex differences in the brain, sensitive periods in brain development, neurogenesis in the postnatal brain, and the role of GABA in creating brain differences. Each of these studies has tremendously contributed to a deeper understanding of the intricate mechanisms that underlie brain development and sexual differentiation.

3.3.5: Sex Differences in Brain Circuits and Susceptibility to Psychiatric Disease

Learning Objectives

By the end of this section, you should be able to

- 11.4.1 Describe sex differences in brain circuits underlying responses to stress as well as motivated and social behaviors, and how this can be affected by circulating steroid hormones.
- 11.4.2 Explain how these neurobiological differences could contribute to sex-specific prevalence, symptoms, and treatment responses in psychological and psychiatric disorders.
- 11.4.3 Discuss how, beyond neurons, there are immune cells in the brain which could also contribute to sex differences in brain functions as well as sex-specific susceptibilities to psychiatric diseases

In the last section, we learned about how sex chromosome-linked genes, hormones, and the environment can drive sex differences in the brain and behavior. But how do differences at the molecular level translate into differences in behavior? Here, we will explore current evidence showing sex differences in brain circuits that regulate stress, motivation, and social behaviors, along with their interaction with steroid hormones, and how these could contribute to sex differences in psychological and psychiatric diseases.

You may be wondering, what do we mean by sex differences in psychological and psychiatric diseases, and why is it important to understand the mechanisms driving them?

For decades, we have known that there are notable sex differences in the prevalence (i.e. how common a disease is within a population), presentation (i.e. the symptoms and behaviors that characterize a disease), and response to treatment (how effectively a treatment works) of psychiatric diseases. For example, major depressive disorders and anxiety disorders, including post-traumatic stress disorder and generalized anxiety disorder, are more common in women than in men, and the most effective treatments differ by sex, as well (Kessler et al. 2012; Altemus, Sarvaiya, and Neill Epperson 2014) (see Chapter 13 Emotion and Mood). But what drives these differences? Although environmental and cultural factors can certainly contribute, accumulating evidence—thanks to the increasing incorporation of sex as a biological variable in preclinical studies—shows that there are important sex differences in the underlying biological factors (Bangasser and Wiersielis 2018), which we will explore in this section.

But before we dive in, let's clarify what we mean by sex differences in brain circuits, as these can present themselves in several ways. One type of sex difference is when the same neural circuit can drive a behavior in both males and females but is more sensitive to changes in one sex, which can result in differences in how strong or long-lasting the response is. For example, some stress sensitive brain regions are activated more strongly by stress in females than in males. Another type of sex difference is when only one sex responds to an environmental change, leading to sex-specific activation of certain brain circuits. For instance, escapable stress (i.e., a stressor that the animals can avoid once they learn the appropriate behavior) activates the prelimbic cortex projection to the dorsal raphe—a pathway involved in stress and mood regulation—to limit stress responses in males but not in females. Additionally, research shows that sometimes the same neural pathways can lead to completely different behaviors in males and females. An example of this is oxytocin's effect in the medial prefrontal cortex—a region involved in social cognition and emotional regulation—which mediates distinct behavioral responses in males and females. Lastly, males and females might use different neural circuits to achieve the same behavioral outcome, a concept known as convergent sex difference. For example, recalling the emotional content activates the right amygdala—associated with emotional processing—in men but the left amygdala in women.

Lastly, as we explore the intricacies of sex differences in brain circuits and behavior, let's recap the fluctuations of circulating steroid hormones secreted by the gonads—the ovaries in females and the testes in males—in both sexes, as they play a significant role in affecting brain circuits. In females, the estrous cycle in rodents and the menstrual cycle in humans involve regular fluctuations of estrogens and progesterone, with estrogens levels being higher at the beginning of the cycle and progesterone levels rising closer to the end. Males also experience hormonal fluctuations, with testosterone levels cycling on a daily basis, peaking in the early morning and declining throughout the day.

Now that we have clarified some important concepts, let's dive in!

Sex Differences in Stress-Related Circuits

Numerous studies have demonstrated sex differences in the neuronal and hormonal systems that activate in response to stress, with females reacting more rapidly and robustly compared to males (see Chapter 12 Stress). A major part of the stress response is secretion of stress hormones from the adrenal glands, an endocrine organ that sits on top of the kidneys. For example, the release of adrenal stress hormones following a stressor is higher and remains elevated for longer in female rats (Figueiredo, Dolgas, and Herman 2002). Figure 11.23 shows an example of a study looking at stress hormone levels in the blood of male and female rats after exposure to bobcat urine, a very stressful stimulus for a rat. Females showed a larger rise in corticosterone (a major adrenal stress hormone in rats) in response to this stressor than males.

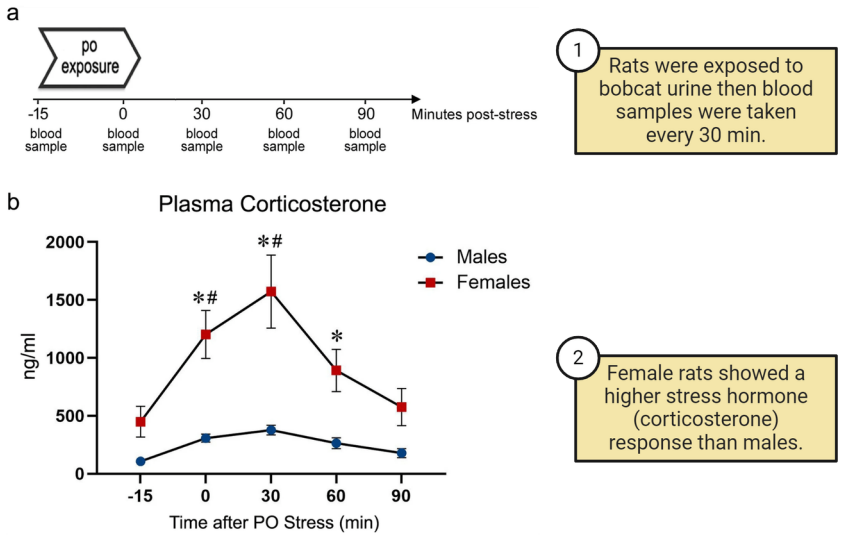

Figure 11.23 Sex difference in stress hormone response Image credit: Data from: Albrechet-Souza, L., Schratz, C.L. & Gilpin, N.W. Sex differences in traumatic stress reactivity in rats with and without a history of alcohol drinking. Biol Sex Differ 11, 27 (2020). https://doi.org/10.1186/s13293-020-00303-w. CC BY 4.0

At least some of these sex differences in stress hormone response seem to be mediated by circulating gonadal steroid hormone effects during adulthood (Oyola and Handa 2017). In males, removal of the testes, which decreases overall levels of androgens like testosterone, results in increased activation of neural and hormonal stress responses (Bingaman et al. 2008). Interestingly, the effects of androgens on limiting the hormonal stress responses seem to be largely mediated by activational effects. Androgen replacement in castrated males normalizes adrenal stress hormone levels (Bingaman et al. 2008). Moreover, treating adult female mice with testosterone reduces adrenal stress hormone release and depression-like behavioral responses to stress, aligning them more closely with male levels, whereas early developmental testosterone treatment does not have this effect (Goel and Bale 2008). However, testosterone is not the only steroid hormone modulating stress responses. Ovariectomy in females, which decreases circulating levels of estrogen and progesterone, reduces activation of stress systems (Haas and George 1989; Handa and Weiser 2014), which is reversed by adult treatment with estradiol. This suggests an activational effect of estrogens in exacerbating hormonal responses to stress.

Sex Differences in Monoamines

Monoamines are a group of neurotransmitters, including serotonin, dopamine, and norepinephrine, that play crucial roles in regulating mood, arousal, and cognition. Figure 11.24 shows a reminder of where the major nuclei are for these systems and where their neurons project to (see Chapter 3 Basic Neurochemistry).

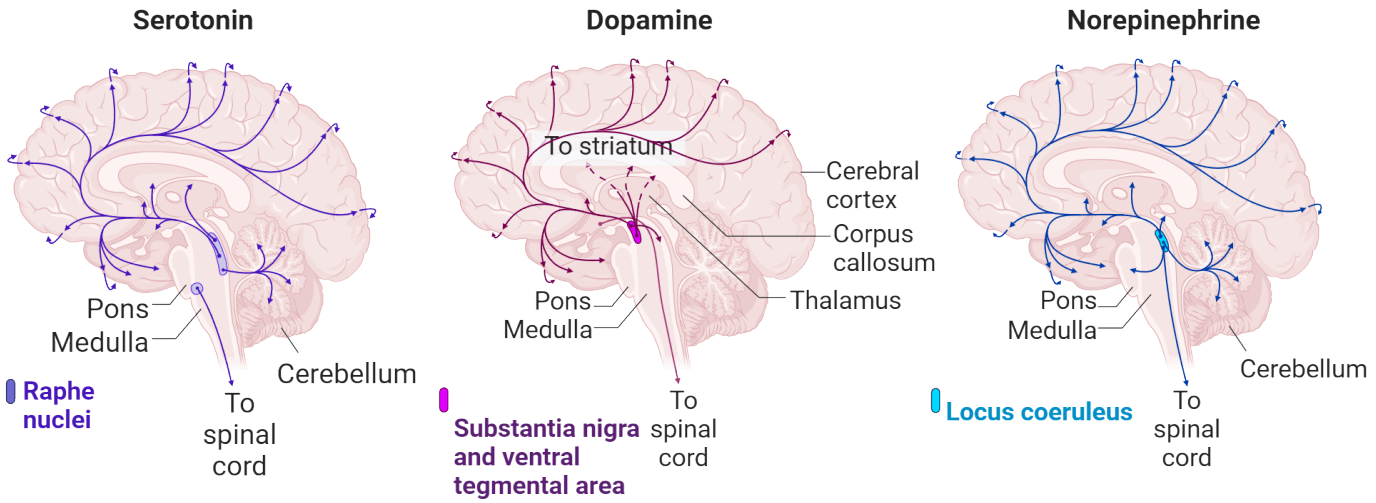

Figure 11.24 Monoamine neurotransmitter system nuclei and projections

These neurotransmitter systems have long been associated with depression and anxiety disorders, as outlined in the biogenic amine theory of mood disorders. This theory posits that monoamine levels in the synaptic gap, i.e., the space between neurons where neurotransmitters are released and received, are decreased in patients with mood disorders. According to this theory, increasing the availability of monoamines, either by limiting their breakdown (the process by which enzymes like monoamine oxidase degrade neurotransmitters) or by blocking their reuptake (the process by which neurotransmitters are reabsorbed by the neuron that released them via transporters such as the serotonin transporter), would result in symptom improvement. Indeed, this is how the majority of currently used antidepressant and anxiolytic drugs exert their efficacy: by increasing the synaptic levels of monoamines (Peng et al. 2015). Although this hypothesis is now considered to be at least partially incomplete (Boku et al. 2018), sex differences in monoaminergic neurotransmission could certainly contribute to sex differences in mood disorders. Below, we will discuss some of the known sex differences in serotonergic and dopaminergic circuits that could contribute to sex differences in psychiatric disorders.

Sex Differences in Serotonergic Circuits

Serotonergic circuits in the brain involve neurons that produce and release serotonin, a neurotransmitter crucial for regulating mood, appetite, sleep, memory, and learning. These neurons primarily originate in a group of nuclei in the brainstem called the raphe nuclei. From the raphe nuclei, serotonergic neurons project to various parts of the brain, including the cerebral cortex, limbic system, and spinal cord, influencing a wide range of physiological and psychological functions (Figure 11.24). Interestingly, many neuropsychiatric disorders with aggravated manifestations in women, such as depression and anxiety, are associated with deficient serotonergic neurotransmission. Conversely, neuropsychiatric conditions that affect more males than females, such as autism spectrum disorder (ASD) and attention-deficit/hyperactivity disorder (ADHD), are often associated with excessive production of serotonin.

Interestingly, the synthesis, metabolism, and reuptake of serotonin are influenced by steroid hormones. In mice, for example, levels of tryptophan hydroxylase (a major enzyme required to make serotonin in neurons, see Chapter 3 Basic Neurochemistry) fluctuate across the estrus cycle, with increased levels during the earlier stages characterized by higher estrogen levels (Berman et al. 2006). There are also sex differences in how the serotonergic system responds to stress. A study in rats, for example, showed that females, compared to males, are more vulnerable to developing depressive and anxiety-like behaviors after exposure to chronic mild stress and that this is associated with decreased serotonergic activity in the hippocampus and hypothalamus (Dalla et al. 2005). This study, along with others, suggest that females may be more vulnerable to develop depression and anxiety in part because their serotonergic system does not engage the same protective circuits that help males mitigate the negative effects of stress.

Sex Differences in Dopaminergic Circuits

Dopaminergic circuits in the brain involve neurons that produce and release dopamine, a neurotransmitter essential for regulating reward, motivation, attention, and motor control. These neurons primarily originate in areas such as the substantia nigra and

the ventral tegmental area (VTA). From these regions, dopaminergic neurons project to various parts of the brain, including the nucleus accumbens, prefrontal cortex, and limbic system, influencing a wide range of physiological and psychological functions (Figure 11.24).

Like with serotonin, several sex differences in dopaminergic-related activity have been found. For example, important sex differences have been found in the release of dopamine, which is mediated by circulating ovarian hormones. In rats, extracellular dopamine concentrations in the nucleus accumbens vary with estrous cycle stages in females, with the highest levels occurring during proestrus and estrus (when ovarian hormones are highest and immediately after) and lower levels during metestrus and diestrus (Xiao and Becker 1994), suggesting that estrogen and progesterone increase dopamine release. Sex differences in dopaminergic responses to stress have also been noted, which could contribute to sex differences in depressive disorders. For example, exposure to chronic mild stress in rats results in stronger depressive-like behavior responses in females compared to males, which is accompanied by a greater attenuation of activity of dopaminergic neurons in the VTA in females (Rincón-Cortés and Grace 2017).

Ovarian hormone-dependent sex differences in dopaminergic neurotransmission could also contribute to sex differences in behaviors associated with addiction. For example, a study assessing conditioned place preference to cocaine found that females show higher levels of place preference compared with males only when they are conditioned during proestrus/estrus. Conditioned place preference is a behavioral paradigm used to measure the rewarding effects of drugs by associating a specific environment with drug exposure. Figure 11.25 diagrams the basics of this test. In short, mice are injected with either saline (a control) or cocaine (a rewarding drug) while in two different chambers of a 3-chamber apparatus. Then the mice are allowed to choose which chamber they prefer to spend time in: the one where they got a saline injection or the one where they got a cocaine injection. Animals spend more time in the environment where they received the drug if they find it rewarding. Interestingly, the increased place preference in females was accompanied by increased VTA dopamine neuron activity, increased dopamine release in the nucleus accumbens, and increased drug potency. These factors result in long-lasting associations that enhance drug responses in female mice that extend beyond the estrus phase (Calipari et al. 2017).

Social Behaviors: Vasopressin and Oxytocin

Vasopressin and oxytocin are two distinct neuropeptides that play crucial roles in regulating a wide range of social and stress-related behaviors. One of the main sources of both vasopressin and oxytocin are the magnocellular cells of the hypothalamic nuclei. From here, vasopressin and oxytocin each reach the posterior lobe of the hypophysis (pituitary gland) via the hypothalamic-hypophyseal tract, where it is stored until released into the blood. Figure 11.26 shows the anatomy of this system alongside the GnRH-anterior pituitary system of the HPG axis we learned about in previous sections.

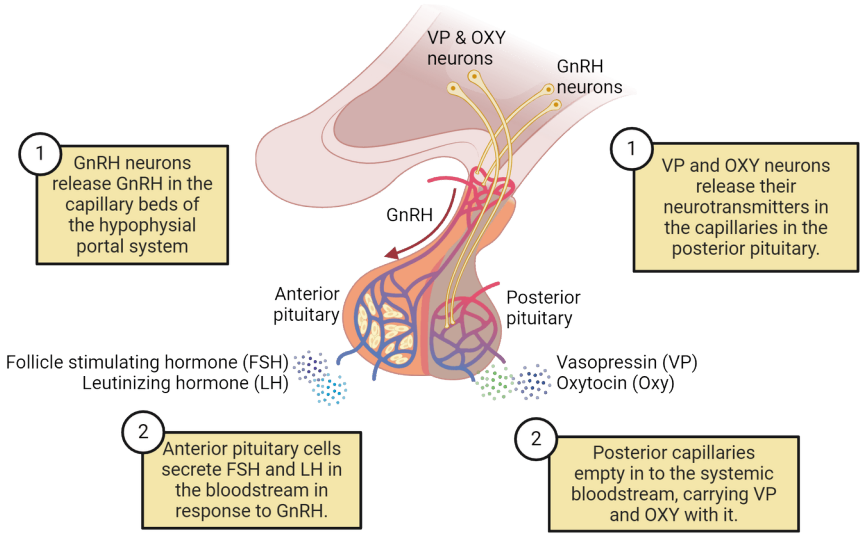

Figure 11.26 Hormones of the hypothalamus and pituitary

Vasopressin and oxytocin released via this system can affect the brain and behavior by acting as neurohormones which reach the brain via the blood. It is important to note, however, that vasopressin and oxytocin can also act as neurotransmitters. This works by neurons that synthesize oxytocin or vasopressin directly sending projections to other brain regions, (including brain regions modulating anxiety behaviors, such as the amygdala, and motivated behaviors, such as the nucleus accumbens), where they locally release them to modulate behavior.

Sex Differences in Vasopressin Circuits

Some studies have highlighted sex-specific effects of vasopressin modulation on anxiety and social responses to stress. For example, deleting vasopressin-expressing cells in the hypothalamus of adult mice increases social investigation only in females and anxiety-related behaviors in the elevated plus maze only in males (Rigney et al. 2020). Additionally, social defeat stress increases expression of vasopressin receptors in the nucleus accumbens only in females (Duque-Wilckens et al. 2016) and results in a long-term reduction of vasopressinergic synthesis in the hypothalamus only in males (Steinman et al. 2015). Together, these findings suggest that the behavioral endpoints affected by vasopressin are different between the sexes, indicating sex-specific underlying mechanisms. Much more work is needed to identify these mechanisms and determine whether vasopressin in other regions can drive sex differences in behavior.

Sex Differences in Oxytocin Circuits

The oxytocin neurons of the hypothalamic-hypophyseal tract play a crucial role in facilitating lactation and parturition. Beyond these well-documented roles, oxytocin also influences a range of behaviors through its action within the brain, significantly modulating stress responses, anxiety levels, and social behaviors. This is important, because the way our brains process stress and social interactions can affect our predisposition to develop disorders such as anxiety and depression, both of which we learned are more common in women compared to men. Supporting a role of oxytocin in sex differences in depression and anxiety disorders, there are sex differences in oxytocin brain circuits. For example, compared to males, females exhibit reduced expression of oxytocin receptors in several brain regions, including the hypothalamus and the posterior nucleus accumbens, where oxytocin modulates stress, motivated, and social behaviors. Interestingly, the expression of oxytocin receptor in these areas seems to also be modulated by ovarian hormones, as their expression is higher in females when estrogen levels are higher within the estrous cycle (Dumais et al. 2013). In addition, stress-related activation of oxytocin circuits that contribute to social anxiety resolves quickly in males but can persist for several weeks in females (Duque-Wilckens et al. 2018; 2020). This finding suggests that in females, this circuit is more sensitive to long-lasting activation, potentially explaining female-biased presentation of social anxiety disorders in humans.

In addition to neuronal circuits, resident immune cells in the brain could contribute to sex differences in behavior and susceptibility to psychiatric disease (see Chapter 17 Neuroimmunology). These include microglia and mast cells.

Microglia are a major component of the innate immune system in the brain and actively regulate neuroinflammation, synaptic refinement, synaptic pruning, and neuronal connectivity, all of which can affect behavior and contribute to psychiatric disease (Wang et al. 2022). Emerging data has convincingly demonstrated the existence of sex-dependent structural and functional differences of microglia (Han et al. 2021), and some of them have been directly implicated in female-biased vulnerability to depressive disorders. For instance, a recent study in mice demonstrated that females exhibit more persistent depressive-like behaviors following chronic stress compared to males (see Figure 11.27). This is linked to heightened activation of microglia in the female prefrontal cortex (Yang et al. 2024).

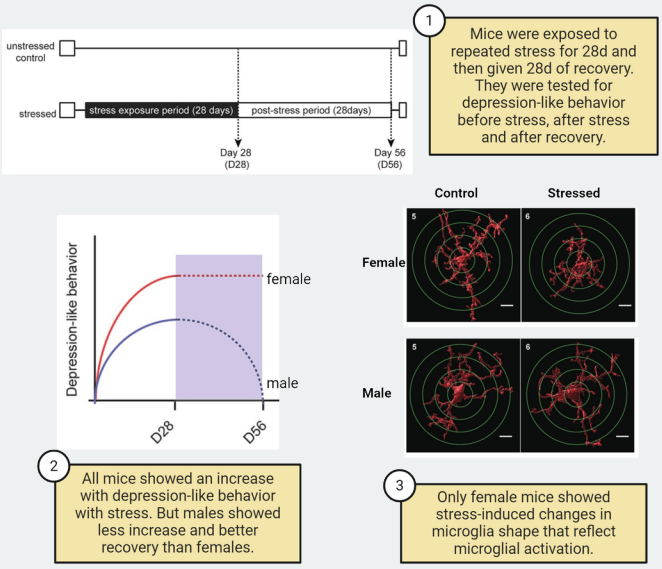

Figure 11.27 Sex differences in neuroimmune stress response Image credit: Timeline, graph and images from Yang EJ, Frolinger T, Iqbal U, Estill M, Shen L, Trageser KJ, Pasinetti GM. The role of the Toll like receptor 4 signaling in sex-specific persistency of depression-like behavior in response to chronic stress. Brain Behav Immun. 2024 Jan;115:169-178. doi: 10.1016/j.bbi.2023.10.006. Epub 2023 Oct 12. PMID: 37838079; PMCID: PMC11146676. CC BY 4.0

Mast cells are the first responders of the immune system, and while less numerous in the brain compared to microglia, they also reside in the brain across vertebrate species (Silver et al. 1996), suggesting a fundamental role in the physiology of complex nervous systems. Notably, there are observed sex differences in mast cell functionality, where female mast cells, in comparison to male, exhibit a heightened release of pro-inflammatory mediators upon activation (Mackey et al. 2020). Interestingly, a fascinating study further found that mast cells orchestrate sex-specific differentiation of microglia in the hypothalamus, which in turn organizes neuronal circuits underlying male sexual behavior in rats (Lenz et al. 2018). This sex difference in mast cell activity could also contribute to sex differences in psychiatric disorders: a recent study in mice found that exposure to early life stress results in persistent activation of mast cells located in the meninges in females but not males. Importantly, this study further found that only females exposed to early life stress show increased susceptibility to develop depressive-like behaviors in adulthood, which can be prevented using a drug that prevents mast cell activation. This suggests that mast cell activity can directly influence how animals respond to stressors during adulthood, contributing to female-biased susceptibility to depression (Duque-Wilckens et al. 2022).

3.3.6: Section Summary

11.1 Understanding Sexual Reproduction and Sexual Dimorphism

Access multimedia content

Interactive Content

This interactive element is not available in this format. Visit the link or scan the QR code to access it online.

View this Interactive Content online

In this section, we first explored the concept of sexual reproduction, examining its underlying mechanisms and the evolutionary advantages, including genetic diversity and masking of harmful mutations, that have made it so widespread across nature. We also learned that many times, animals engage in sexual behavior without the intent of reproduction, and that same-sex sexual behavior is widespread in nature. We then discussed how the initial reproductive investment of each sex, such as the larger, more energetically costly eggs produced by females compared to the smaller, less costly sperm produced by males, can lead to different strategies between males and females to maximize reproductive success and evolutionary fitness. We also explored the dynamics of intrasexual competition, where individuals of the same sex compete for access to mates, often resulting in the development of traits like larger body size or aggressive behaviors. Additionally, we examined intersexual competition, where mate choice drives the evolution of traits that are attractive to the opposite sex, such as elaborate plumage or intricate courtship behaviors. Finally, we explored how sex differences affect many physiological and behavioral processes beyond reproductive traits, including sensory perception and stress responses, highlighting the critical importance of incorporating biological sex as a variable in biomedical research.

11.2 Mechanisms of Sexual Determination and Differentiation

In this section, we embarked on a fascinating journey to understand the complex mechanisms that determine whether an individual develops as male or female. We began by exploring how, in many species, the presence of specific genes located on sex chromosomes (X and Y in the case of humans) initiates a series of events that lead to the development of male or female gonads. However, we also learned that in many other species, sex determination is not driven by genetics but by environmental factors. For example, we learned that temperature can dictate sex in certain reptiles, and that some species of fish can even change their sex based on social dynamics. Lastly, we delved into the world of steroid hormones and discovered how these powerful chemicals, secreted by male and female gonads, differentially shape the early development of tissues throughout the body, including the brain, and how these hormones further continue to influence the physiology of tissues throughout an individual's lifespan.

11.3 Sex Differences in Brain and Behavior: Genetic, Hormonal, and Environmental Mechanisms

In this section, we explored how genes located on sex chromosomes, steroid hormones, and environmental factors contribute to sex differences in the brain. We learned that proteins encoded by sex chromosome-linked genes can directly affect the physiology of neurons and brain function. Additionally, we examined mouse models with variations in the number of X or Y chromosomes, where the function of the gonads remains intact. These models have shown that changes in the dosage of sex chromosomes can significantly contribute to sex differences in brain anatomy and function.

Further, we explored how steroid hormones can act through both genomic and non-genomic mechanisms to influence brain function. Genomic actions involve hormones like estradiol binding to intracellular receptors, such as estrogen receptor alpha (ERα), which then act as transcription factors to regulate gene expression. This process is typically slower and results in long-lasting changes in cell function. Non-genomic actions, on the other hand, involve rapid responses initiated by hormone-receptor

interactions at the cell membrane, leading to quick changes in cell signaling pathways.

Lastly, we learned that environmental factors, including the physical and social environment, can play a significant role in contributing to brain sex differences. Importantly, we also discovered that exposure to various man-made chemicals can disrupt hormonal balance and brain development, underscoring the urgent need for comprehensive studies and stringent regulations to better understand and mitigate the impact of these environmental factors on brain development and overall health.

11.4 Sex Differences in Brain Circuits and Susceptibility to Psychiatric Disease

In this section, we delved into the neurobiological underpinnings of sex differences in brain circuits underlying behavioral responses related to stress, motivation, and social interactions, which has implications for understanding sex differences in the prevalence and manifestation of psychological and psychiatric disorders. We learned about specific brain circuits that use neurotransmitters like CRH, serotonin, and oxytocin, and how these are different between sexes largely stemming from differences in circulating steroid hormones secreted by male and female gonads throughout the lifespan. Lastly, we introduced the possible role that immune cells like microglia and mast cells, who also reside in the brain along neurons, have in contributing to these sex differences.

3.3.7: Key Terms

11.1 Understanding Sexual Reproduction and Sexual Dimorphism

Sexual reproduction, sexual dimorphism, sex differences, stress, mitosis, gamete production, fertilization, development, intrasexual selection, intersexual selection, sexual conflict

11.2 Mechanisms of Sexual Determination and Differentiation

Sex determination, gonads, gametes, sex chromosomes, SRY gene, testosterone, estrogen, sexual differentiation, testes, ovaries steroid hormones, organizational, activational

11.3 Sex Differences in Brain and Behavior: Genetic, Hormonal, and Environmental Mechanisms

Classical steroid hormone signaling mechanism, rapid steroid hormone signaling mechanism, environmental factors, PCBs, DNA methylation, histone modification

11.4 Sex Differences in Brain Circuits and Susceptibility to Psychiatric Disease

Monoamines, serotonin, dopamine, mast cells, microglia

3.3.9: Multiple Choice

11.1 Understanding Sexual Reproduction and Sexual Dimorphism

1.
What is a way in which diploid organisms benefit from having two copies of each chromosome?

a. They are able to clone themselves
b. They mask harmful mutations
c. They reduce the likelihood of mating
d. They simplify cell division

2 .
Why is the concept of natural selection crucial to understanding sexual dimorphism?

a. It explains why traits develop independently of reproductive success
b. It shows how traits beneficial for survival are unrelated to reproduction
c. It highlights how traits beneficial for mating increase reproductive success
d. It negates the importance of sexual selection

3.
In sexual reproduction, what type of cell division results in haploid gametes?

a. Mitosis
b. Binary Fission
c. Meiosis
d. Cloning

4 .
What is the key difference between mitosis and meiosis?

a. Mitosis results in haploid cells, meiosis in diploid cells
b. Mitosis occurs only in gametes, meiosis in somatic cells
c. Mitosis creates two identical cells, meiosis produces four genetically unique cells
d. Mitosis is a form of sexual reproduction, meiosis is asexual

5.
Which species is known for female-biased development of secondary traits?

a. Elephant seals
b. Satin bowerbirds
c. Spotted hyenas
d. Northern Cardinals

6 .
Which of the following best describes sexual dimorphism?

a. Traits that are identical in both sexes
b. Traits exclusively or predominantly found in one sex
c. Behavioral traits that both sexes share
d. A form of asexual reproduction

7.
In which scenario is intersexual selection most evident?

a. Male lions competing for territory
b. Females selecting males based on complex courtship displays

c. Males developing larger body sizes
d. Both sexes contributing equally to offspring care

8 .
Which of the following statements best reflects the current understanding of sexual behavior in the animal kingdom?

a. Sexual behavior is exclusively a mechanism for reproduction between individuals of different sexes.
b. Same-sex sexual behavior is rare and occurs only in a few species.
c. Sexual behavior, including same-sex interactions, can serve roles beyond reproduction, such as enhancing social bonds and mitigating conflict within groups.
d. Sexual behavior is only observed during the fertile period in most species.

11.2 Mechanisms of Sexual Determination and Differentiation

9.
Which of the following best describes bipotential gonads?

a. Gonads that can develop into either testes or ovaries
b. Gonads that produce both sperm and eggs
c. Gonads that are specialized in hormone production
d. Gonads that are identical in both sexes throughout life

10 .
Which environmental factor is most commonly associated with sex determination in reptiles?

a. Photoperiod
b. Temperature
c. Humidity
d. Social hierarchy

11.
What hormone is primarily responsible for the masculinization of the brain during early development?

a. Progesterone
b. Estrogen
c. Anti-Müllerian hormone
d. Cortisol

12 .
What role does aromatase play in the masculinization of the brain?

a. It converts testosterone into estrogen
b. It degrades testosterone
c. It inhibits androgen receptors
d. It promotes the secretion of anti-Müllerian hormone

13.
What is the primary difference between organizational and activational effects of hormones?

a. Organizational effects are temporary, while activational effects are permanent
b. Organizational effects occur during adulthood, while activational effects occur during early development
c. Organizational effects are permanent and shape developmental pathways, while activational effects are reversible and occur throughout life
d. Organizational effects involve the secretion of hormones, while activational effects do not

14 .
Which hormone is responsible for the development of male external genitalia during fetal development?

a. Estrogen

b. Testosterone
c. Progesterone
d. Cortisol

11.3 Sex Differences in Brain and Behavior: Genetic, Hormonal, and Environmental Mechanisms

15.
How does X chromosome inactivation work in XX individuals?

a. Both X chromosomes are fully active
b. One X chromosome is randomly inactivated
c. The Y chromosome compensates for the second X
d. Both X chromosomes are partially active

16 .
Which brain area is associated with male copulatory behavior in rats?

a. Amygdala
b. Hypothalamus
c. Preoptic area
d. Hippocampus

17.
Which brain region is enlarged in male rats due to early exposure to testosterone?

a. Amygdala
b. Posterior bed nucleus of the stria terminalis (BNSTp)
c. Hippocampus
d. Cerebellum

18 .
What does rapid signaling of steroid hormones involve?

a. Long-term changes in gene expression
b. Binding to receptors in the cell nucleus
c. Binding to membrane-bound receptors
d. Inhibition of hormone production

19.
What role do dendritic spines in the hippocampus play in response to ovarian hormones?

a. They undergo rapid and reversible changes in response to hormone levels
b. They remain unchanged regardless of hormone fluctuations
c. They are involved in regulating stress hormones
d. They decrease in number as hormone levels rise

20 .
Which mechanism allows steroid hormones to modulate neuronal functions within seconds to minutes?

a. Classical mechanism
b. Rapid signaling mechanism
c. Epigenetic mechanism
d. Receptor desensitization

11.4 Sex Differences in Brain Circuits and Susceptibility to Psychiatric Disease

21.
Which sex is more likely to exhibit depression-like behaviors following early life stress according to research?

a. Males
b. Females
c. Both equally
d. Neither sex is affected

22 .
How do circulating steroid hormones affect brain circuits in males and females?

a. They only affect males
b. They cause sex-specific activation of brain circuits
c. They have the same effect on both sexes
d. They do not affect brain circuits

23.
Which of the following best describes a type of sex difference in brain circuits?

a. The same neural circuit always drives identical behaviors in both males and females.
b. Some neural circuits are more sensitive to changes in one sex, leading to differences in the strength or duration of the response.
c. All neural circuits respond equally to environmental changes in both sexes.
d. Oxytocin has the same effect on social behaviors in both males and females.

24 .
Which of the following statements best describes the role of gonadal steroid hormones in sex differences in stress hormone responses?

a. Removal of the testes in males decreases activation of stress responses.
b. Androgen replacement in castrated males normalizes stress hormone levels, suggesting activational effects of androgens.
c. Early developmental testosterone treatment reduces stress responses in female mice.
d. Ovariectomy in females increases the activation of stress systems.

3.3.10: Fill in the Blank

11.1 Understanding Sexual Reproduction and Sexual Dimorphism

1.
_____ during meiosis contributes to genetic diversity by creating new combinations of alleles.

11.2 Mechanisms of Sexual Determination and Differentiation

2 .
_____ is the process by which an organism's sex is determined by its chromosomes, such as the XY system in mammals, where the presence of the SRY gene on the Y chromosome triggers male development.

11.3 Sex Differences in Brain and Behavior: Genetic, Hormonal, and Environmental Mechanisms

3.
_____ is a condition where females have only one X chromosome, leading to various developmental and physiological effects, including reduced hippocampal volume.
4 .
_____ such as DNA methylation and histone modification can influence how steroid hormones imprint on the developing brain, leading to lasting differences in adult physiology and behavior between the sexes.

11.4 Sex Differences in Brain Circuits and Susceptibility to Psychiatric Disease

5.
_____ like testosterone and estrogen are derived from cholesterol and are fat-soluble, allowing them to penetrate cell membranes and exert their effects on target tissues.
6 .
Besides neurons, _____ in the brain can contribute to sex-biased susceptibilities to psychiatric disorders by exhibiting sex-dependent structural and functional differences.

This page titled 3.3.10: Fill in the Blank is shared under a CC BY-NC 4.0 license and was authored, remixed, and/or curated by Ivette Merced via source content that was edited to the style and standards of the LibreTexts platform.

3.3.11: Sex Hormones, Sexual Motivation, and Reproductive Behaviors

Learning Objectives

1. Distinguish between the organizational and activational effects of sex hormones
2. Describe some reciprocal interactions between sex hormones and reproductive behavior
3. Understand basic biological mechanisms regulating sexual behavior and motivation
4. Identify the role of the brain in responding to sexual stimuli
5. Explain the role of hormones in parental behavior

Overview

This module discusses the relationship between sex and hormones (including organizational and activational effects, maturation of the reproductive systems, interactions between hormones and behavior, and anabolic steroids), sexual behavior as a form of motivation (including physiological mechanisms and human sexual behavior and motivation), sex and the brain (including erogenous zones, and the role of the hypothalamus and the pituitary gland), and parental behavior (including hormones and rodent maternal behavior, maternal aggression, and hormones and human maternal behavior).

Human Sexuality in Context

Human sexuality refers to people's sexual interest in and attraction to others, as well as their capacity to have erotic experiences and responses. Sexuality may be experienced and expressed in a variety of ways, including (but not limited to) thoughts, desires, practices, roles, and behaviors. This chapter mostly focuses on the biological and physical aspects of sexuality- human reproductive anatomy and functions, including the human sexual response cycle and the basic biological drive that exists in all species- but also addresses the psychological domains of gender identity and sexual orientation. We begin with hormones, as they play such an integral role in the development and expression of human sexuality.

Sex and Hormones

Because of their inextricable link to the development and maturation of reproductive anatomy (both prenatally and during puberty), as well as the promotion and maintenance of adult reproductive functions, Biological Psychology textbooks often include hormones in the chapter on sex and reproductive behaviors. However, many other bodily functions (such as growth, sleep, hunger, satiation, and maintenance of blood pressure, to name a few) are regulated by hormones, so we have opted to cover basics of the endocrine system (the organs which produce and secrete hormones) in the Nervous System Anatomy chapter. Please refer to that chapter if you need a brief overview of hormones and the endocrine system.

Organizational and Activational Effects of Sex Hormones

Although the dichotomy cannot be strictly applied, the effects of steroid sex hormones have typically been characterized as organizational versus activational. Organizational effects result in permanent changes that usually occur early in development, such as the prenatal development of human reproductive structures (also known as **primary sex characteristics**- differences in male and female bodies that are present at birth). Activational effects are usually temporary and occur throughout life, dependent on specific conditions. Thus, structures in the body, brain, and nervous system are thought to be *organized* (in a male-typical or female-typical manner) through the action of steroid hormones early in development, and then later on *activated* by steroid hormones, resulting in structures and behaviors that differ between the sexes (Arnold and Breedlove, 1985). While this simple dichotomy works well with animals with very distinct sexual dimorphism in behavior (such as rats, where only males attempt to mount other rats and only females exhibit a sexually receptive posture called lordosis), it cannot be applied in such a straightforward manner to people. For one thing, humans do not exhibit any sexual behaviors that are strictly stereotyped and unique to either males or females. Nonetheless, some of the differences between human males and females can be attributed, at

least in part, to either the organizational or activational effects of sex hormones.

One example of a permanent organizational effect is the difference between males and females in the secretion of certain hormones (related to reproductive function) by the hypothalamus; adult females follow a pattern of cyclical hormone release (related to their fertility cycles), whereas males do not. Changing the hormones that are present in the body later in life will not change the capacity of the hypothalamus to cycle the release of these hormones. Some **secondary sex characteristics** (changes that occur in male and female bodies during the sexual maturation that occurs with puberty) are also permanent changes- requiring surgery to alter- such as the development of breasts and wider hips in women or a prominent Adam's apple (cartilage around the thyroid in the neck area) and broader shoulders in men. In contrast, some secondary sex characteristics, like the presence of facial hair in men (but not in women), can be modified with changes to hormone levels in the adult body of either sex.

One example of a temporary activational effect is lactation, or the production and secretion of milk from the mammary glands (breasts). Normally this only occurs in females after childbirth, when the necessary combination of the hormones estrogen, progesterone, and prolactin are present. "However, if a man is treated with this hormone combination, his mammary glands not only can produce milk, but he can nurse a baby! Thus, lactation is an "activated-only" action of hormones, and there is no organized sex difference in the mammary gland tissue itself." (Jones and Lopez, 2006, page 466). So, while modern science cannot yet assist transgender women (whose biological birth sex was male) in carrying and giving birth to an infant, they can nonetheless participate in nursing the baby.

Sex Hormones and Maturation

The main categories of sex hormones are **androgens** (more prevalent in biological males), of which **testosterone** is a primary example, and **estrogens** (more prevalent in biological females), of which **estradiol** is a primary example. It is important to note that *all* individuals have both androgens ("male hormones") and estrogens ("female hormones"), but the relative proportion of the hormones present in a given body varies, usually correlated with biological sex. Testosterone is secreted by the testes in males and in small amounts by the ovaries in females (although most is converted to estradiol). A small amount of testosterone is also secreted by the adrenal glands (endocrine glands positioned on top of the kidneys) in both sexes. Estrogens are secreted by the ovaries in females and by fat cells in both sexes.

Male and female reproductive systems are different at birth (due to differences in primary sex characteristics), but the gonads (testes in males and ovaries in females) are immature and incapable of producing gametes (sperm in males and eggs in females) or sex hormones. Maturation of the reproductive system occurs during puberty when hormones from the hypothalamus and pituitary gland stimulate the testes or ovaries to start producing sex hormones again. Sex hormones, in turn, lead to the growth and maturation of the reproductive organs, rapid body growth, and the development of secondary sex characteristics, such as pubic and underarm hair in both sexes, facial hair in males and breasts in females.

Interactions Between Sex Hormones and Reproductive Behaviors

As discussed in Chapter 4.6, the interaction between hormones and behavior is bidirectional: hormones can influence behavior, and behavior can sometimes influence hormone concentrations. Hormones travel through the blood, influencing the nervous system to regulate an individual's behaviors, some of which are related to sexuality and reproduction (such as aggression, mating, and parenting). Some hormone-behavior interactions that are related specifically to reproductive behaviors are described below.

Hormonal Influence on Reproductive Behaviors

Hormones coordinate the physiology and behavior of individuals. Over evolutionary time, hormones have been co-opted by the nervous system to influence behavior to ensure reproductive success. For example, the same hormones, testosterone and estradiol, that cause gamete (egg or sperm) maturation also promote mating behavior. This dual hormonal function ensures that mating behavior occurs when animals have mature gametes available for fertilization. Similarly, during pregnancy estrogens and progesterone concentrations are elevated, and these hormones are also involved in maternal behavior in the mothers.

How might hormones affect behavior? While hormones do not *cause* behavioral changes, they influence the components that interact to produce behavior- sensory systems (input), the central nervous system (integration), and muscles and glands (output). In this manner, specific stimuli are more likely to elicit certain responses in the appropriate behavioral or social context. In other words, hormones change the *probability* that a particular behavior will occur in the appropriate situation (Nelson, 2011). This is a critical distinction that can affect how we think of hormone-behavior relationships. In most cases, hormones can be considered to affect behavior by influencing any or all of these components.

An example of the influence of hormones on a simple behavior is singing in zebra finches. Only male zebra finches sing. If the testes of adult male finches are removed, then the birds reduce singing, but castrated finches resume singing if the testes are reimplanted, or if the birds are treated with either testosterone or estradiol. Although we generally consider androgens to be “male” hormones and estrogens to be “female” hormones, it is common for testosterone to be converted to estradiol in nerve cells. Thus, many male-like behaviors are associated with the actions of estrogens! Singing behavior is most frequent when blood testosterone or estrogen concentrations are high. Males sing to attract mates or ward off potential competitors from their territories.

Behavioral Influence on Sex Hormones

How might behaviors affect hormones? If a male mouse or rhesus monkey loses a fight, blood testosterone levels decrease for several days or even weeks afterward. Comparable results have also been reported in humans. Testosterone concentrations are affected not only in humans involved in physical combat, but also in those involved in simulated battles. For example, testosterone concentrations were elevated in winners and reduced in losers of regional chess tournaments.

People do not have to be directly involved in a contest to have their hormones affected by the outcome of the contest. Male fans of both the Brazilian and Italian teams were recruited to provide saliva samples to be assayed for testosterone before and after the final game of the World Cup soccer match in 1994. At the end of the game, Brazil and Italy were tied for regulation and overtime, but then Brazil won in penalty shots. The Brazilian fans were elated and the Italian fans were crestfallen. When the samples were assayed, 11 of 12 Brazilian fans who were sampled had increased testosterone concentrations, and 9 of 9 Italian fans had decreased testosterone concentrations, compared with pre-game baseline values (Dabbs, 2000).

Figure 3.3.11.1: The expectation of events can influence one’s hormonal activity. How do you think yours is affected if you anticipate going on a date with a romantic interest soon?

In some cases, hormones can be affected by anticipation of behavior (Figure 3.3.11.1). For example, testosterone concentrations also influence sexual motivation and behavior in women. In one study, the interaction between sexual intercourse and testosterone was compared with other activities (cuddling or exercise) in women (van Anders, Hamilton, Schmidt, & Watson, 2007). On three separate occasions, women provided a pre-activity, post-activity, and next-morning saliva sample. After analysis, the women’s testosterone was determined to be elevated prior to intercourse as compared to other times. Thus, an anticipatory relationship exists between sexual behavior and testosterone. Testosterone values were higher post-intercourse compared to exercise, suggesting that engaging in sexual behavior may also influence hormone concentrations in women.

Anabolic Steroids

The endocrine system can be exploited for illegal or unethical purposes. A prominent example of this is the use of steroid drugs by professional athletes. Commonly used for performance enhancement, anabolic steroids are synthetic versions of the sex hormone testosterone. By boosting natural levels of this hormone, athletes experience increased muscle mass. Synthetic versions of human growth hormone are also used to build muscle mass.

The use of performance-enhancing drugs is banned by all major collegiate and professional sports organizations in the United States because they impart an unfair advantage to athletes who take them. In addition, the drugs can cause significant and dangerous side effects. For example, anabolic steroid use can increase cholesterol levels, raise blood pressure, and damage the liver. Altered testosterone levels (both too low or too high) have been implicated in causing structural damage to the heart, and increasing the risk for cardiac arrhythmias, heart attacks, congestive heart failure, and sudden death. Paradoxically, steroids can cause shriveled testes and enlarged breast tissue in men. In females, their use can cause analogous effects such as an enlarged clitoris and growth of facial hair. In both sexes, their use can promote increased aggression (commonly known as “roid-rage”), depression, sleep disturbances, severe acne, and infertility.

Sexual Behavior as a Form of Motivation

Sex is an important part of most people's lives. From an evolutionary perspective, the reason is obvious—perpetuation of the species. Sexual behavior in humans, however, involves much more than reproduction. Sexual arousal is the drive state that results in thoughts and behaviors related to sexual activity. It is generated by a large range of internal and external mechanisms that are triggered either after the extended absence of sexual activity or by the immediate presence and possibility of sexual activity (or by cues commonly associated with such possibilities). This section provides an overview of some research that has been conducted on sexual behavior and motivation.

Sexual motivation, often referred to as **libido**, is a person's overall sexual drive or desire for sexual activity. This motivation is determined by biological, psychological, and social factors. In most mammalian species, sex hormones control the ability to engage in sexual behaviors. However, sex hormones do not directly regulate the ability to have sexual intercourse in primates (including humans); rather, they are only one influence on the motivation to engage in sexual behaviors. Social factors, such as work, family, and relationship issues also have an impact, as do internal psychological factors like personality and lifestyle stress. Sex drive may also be affected by medical conditions (including illness or injury), medications, and pregnancy.

Physiological Mechanisms of Sexual Motivation and Behavior

Much of what we know about the physiological mechanisms that underlie sexual motivation and behavior comes from animal research. Research on male rats suggests that limbic system structures such as the amygdala and nucleus accumbens are especially important for sexual motivation. Damage to these areas results in a decreased motivation to engage in sexual behavior, while leaving the ability to do so intact (Everett, 1990; Figure 3.3.11.2). Similar dissociations of sexual motivation and sexual ability have also been observed in the female rat (Becker, Rudick, & Jenkins, 2001; Jenkins & Becker, 2001).

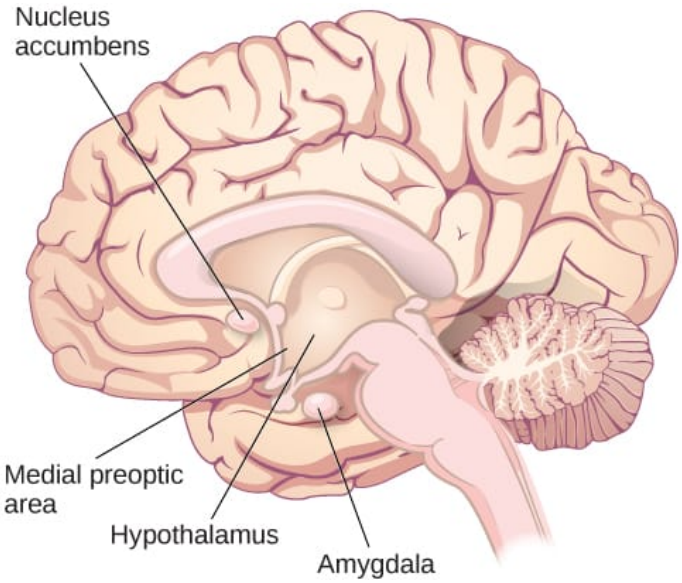

Figure 3.3.11.2: The medial preoptic area, an area of the hypothalamus, is involved in the ability to engage in sexual behavior, but it does not affect sexual motivation. In contrast, the amygdala and nucleus accumbens are involved in motivation for sexual behavior, but they do not affect the ability to engage in it.

The hypothalamus plays an important role in motivated behaviors, and sex is no exception. In fact, lesions to an area of

the hypothalamus called the medial preoptic area completely disrupt a male rat's ability to engage in sexual behavior, but, surprisingly, do not change how hard a male rat is willing to work to gain access to a sexually receptive female (Figure 3.3.11.3). This suggests that the ability to engage in sexual behavior and the motivation to do so may be mediated by neural systems distinct from one another.

Figure 3.3.11.3: A male rat that cannot engage in sexual behavior still seeks receptive females, suggesting that the ability to engage in sexual behavior and the motivation to do so are mediated by different systems in the brain.

Human Sexual Motivation and Behavior

Although human sexual behavior is much more complex than that seen in rats, some parallels between animals and humans can be drawn from this research. The worldwide popularity of drugs used to treat erectile dysfunction (Conrad, 2005) speaks to the fact that sexual motivation and the ability to engage in sexual behavior can also be dissociated in humans. Moreover, disorders that involve abnormal hypothalamic function are often associated with hypogonadism (reduced function of the gonads) and reduced sexual function (e.g., Prader-Willi syndrome). Given the hypothalamus's role in endocrine function, it is not surprising that hormones secreted by the endocrine system also play important roles in sexual motivation and behavior. For example, many animals show no sign of sexual motivation in the absence of the appropriate combination of sex hormones from their gonads. While this is not the case for humans, there is considerable evidence that sexual motivation for both men and women varies as a function of circulating testosterone levels (Bhasin, Enzlin, Coviello, & Basson, 2007; Carter, 1992; Sherwin, 1988). In other words, testosterone maintains libido (sex drive) in both males and females.

Vasopressin is also involved in the male arousal phase, and the increase of vasopressin during erectile response may be directly associated with increased motivation to engage in sexual behavior. The relationship between hormones and female sexual motivation is not as well understood, largely due to the overemphasis on male sexuality in Western research. Estrogen and progesterone typically regulate motivation to engage in sexual behavior for females, with estrogen increasing motivation and progesterone decreasing it. The levels of these hormones rise and fall throughout a woman's menstrual cycle. Research suggests that testosterone, oxytocin, and vasopressin are also implicated in female sexual motivation in similar ways as they are in males, but more research is needed to understand these relationships.

Sex and the Brain

The brain is the organ that translates the nerve impulses from the skin into pleasurable sensations. It controls nerves and muscles used during sexual behavior. The brain regulates the release of hormones, which are believed to be the physiological origin of sexual desire. The cerebral cortex (the outer layer of the brain that allows for thinking and reasoning) is believed to be the origin of sexual thoughts and fantasies. Deep to the cortex is the limbic system, a collection of structures believed to be the origin of emotions and feelings, also important for sexual behavior. The limbic system includes the amygdala, hippocampus, cingulate gyrus, and septal nucleus. The septal nucleus, an area that receives reciprocal connections from many other brain regions (including the hypothalamus and the amygdala), seems to play an important role in sexual pleasure. This region shows rhythmic spiking activity during sexual orgasm, and is also one of the brain regions that rats will most reliably voluntarily self-stimulate (Olds & Milner, 1954). In humans, placing a small amount of acetylcholine into this region, or stimulating it electrically, has been reported to produce a feeling of imminent orgasm (Heath, 1964; Heath, 1972).

Erogenous Zones

At first glance- or touch for that matter- the glans of the clitoris and penis are the parts of our anatomies that seem to bring the most pleasure. However, these two organs pale in comparison to our central nervous system's capacity for pleasure. Extensive regions of the brain and brainstem are activated when a person experiences pleasure, including the insula, temporal cortex, limbic system, nucleus accumbens, basal ganglia, superior parietal cortex, dorsolateral prefrontal cortex, and cerebellum (Ortigue et al., 2007; Figure 3.3.11.4). Neuroimaging techniques show that these regions of the brain are active when patients have spontaneous orgasms involving no direct stimulation of the skin (e.g., Fadul et al., 2005) and when experimental participants self-stimulate erogenous zones (e.g., Komisaruk et al., 2011). Erogenous zones are particularly sensitive areas of skin (which may be different across individuals), and (like all body areas with sensation) are connected (via the nervous system) to the somatosensory cortex in the brain (refer to the section on the central nervous system).

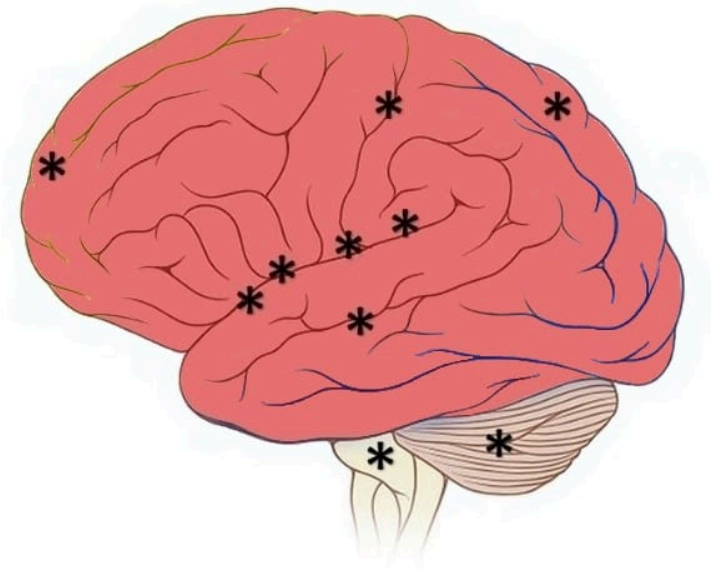

Figure 3.3.11.4: Some of the many regions of the brain and brainstem activated during pleasure experiences.

A study by Nummenmaa and his colleagues (2016) used a unique method to test the hypothesis that the more sensitive areas of our bodies have greater potential to evoke pleasure. The Nummenmaa research team showed experimental participants images of same- and opposite-sex bodies. They then asked the participants to color the regions of the body that, when touched, they or members of the opposite sex would experience as sexually arousing while masturbating or having sex with a partner. Nummenmaa found the expected "hotspot" erogenous zones around the external sex organs, breasts, and anus, but also reported areas of the skin beyond these hotspots: "[T]actile stimulation of practically all bodily regions trigger sexual arousal...." Moreover, he concluded, "[H]aving sex with a partner..."—beyond the hotspots—"...reflects the role of touching in the maintenance of...pair bonds." This also underlines the fact that individuals are different, and erogenous zones vary correspondingly.

The Role of the Hypothalamus and the Pituitary Gland

One brain structure that is particularly important for sexual functioning is the **hypothalamus** (Figure 3.3.11.5). This is a small area at the base of the brain consisting of several groups of neuron cell bodies that receive input from the limbic system. One of the reasons for the importance of the hypothalamus is that it controls the pituitary gland, which secretes hormones that control the other glands of the body.

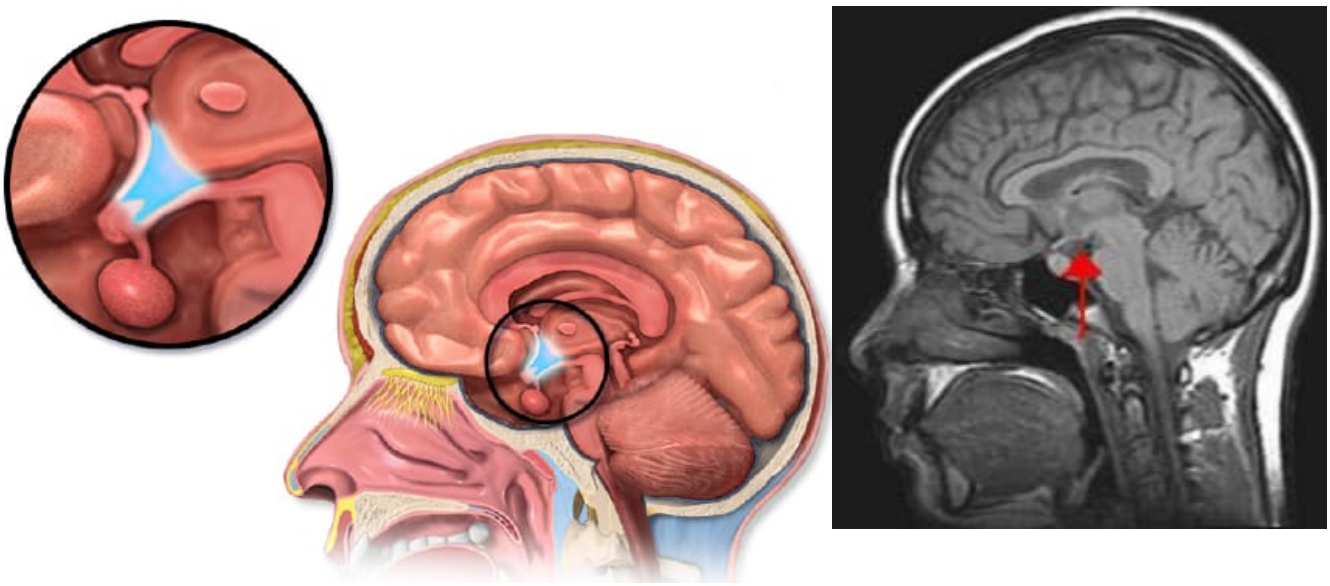

Figure 3.3.11.5: The hypothalamus controls the pituitary gland. Midsagittal views of the human brain: First, a drawing with the roughly triangular-shaped hypothalamus colored blue, and the small, oval-shaped pituitary gland visible attached below it (circle inset shows a magnified view). In the next image, an arrow points to the location of the hypothalamus on a brain scan.

Several important hormones related to sexual function are secreted by the pituitary gland, which is divided into anterior and posterior sections. The anterior pituitary secretes follicle-stimulating hormone (FSH), luteinizing hormone (LH), and prolactin. FSH and LH are responsible for ovulation in females and sperm production in males. Prolactin and oxytocin (which is released by the posterior pituitary) stimulate milk production in lactating females. Oxytocin is sometimes called the "love" hormone and is believed to be involved with maintaining close relationships. It is released with sexual activity during orgasm, causing rhythmic contractions in the uterus and penis. Oxytocin is also released in females during childbirth (causing the contractions of the uterus that push the baby out) and during breast-feeding (as part of the milk let-down reflex).

Parental Behavior

Parental behavior can be considered to be any behavior that contributes directly to the survival of fertilized eggs or offspring that have left the body of the female. There are many patterns of parental care in mammals. The developmental status of the newborn is an important factor driving the type and quality of parental care in a species- **altricial** young are born in an underdeveloped state and require extensive parental care to survive, whereas **precocial** young are born in a more advanced and mature state, already mobile and able to feed themselves. Maternal care is much more common than paternal care.

Hormones and Rodent Maternal Behavior

The vast majority of research on the hormonal correlates of mammalian parental behavior has been conducted on rats. Rats bear altricial young, and mothers perform a cluster of stereotyped maternal behaviors, including nest building, crouching over the pups to allow nursing and to provide warmth, pup retrieval, and increased aggression directed at intruders. If you expose nonpregnant female (or male) rats to pups, their most common reaction is to huddle far away from them in fear, since rats avoid new things (neophobia). However, if you expose adult female rats to pups every day, they soon begin to behave maternally.

Of course a new mother needs to act maternally as soon as her offspring arrive- not a week later. Hormones trigger the onset of maternal behavior in rats, and several methods of study (such as hormone removal and replacement therapy) have been used to investigate rat maternal behavior. A fast decline of blood concentrations of progesterone in late pregnancy (after sustained high concentrations of this hormone), in combination with high concentrations of estradiol (and probably prolactin and oxytocin), induces female rats to behave maternally almost immediately in the presence of pups. This pattern of hormones during the delivery of pups overrides the usual fear response of adult rats toward pups, and permits the onset of maternal behavior.

The medial preoptic area (of the hypothalamus) is critical for the expression of rat maternal behavior, and the amygdala appears to inhibit the expression of maternal behavior. The fearful response of adult rats towards pups is apparently mediated by chemosensory information, and lesions of the amygdala (or sensory pathways to the amygdala) allow the expression of maternal

behavior. Hormones or sensitization likely act to disinhibit the amygdala, thus permitting the occurrence of maternal behavior. Although correlations have been established, direct evidence of brain structural changes in human mothers remains unspecified (Fleming & Gonzalez, 2009).

Maternal Aggression

Laboratory rats are usually docile, but mothers can be quite aggressive toward animals that venture too close to their litter. Progesterone appears to be the primary hormone that induces this maternal aggression in rodents, but species differences exist. The role of maternal aggression in women's behavior has not been adequately described or tested.

Hormones and Human Maternal Behavior

A series of elegant experiments by Alison Fleming and her collaborators studied the endocrine correlates of human mothers' behavior and maternal attitudes, as expressed in self-report questionnaires. Responses such as patting, cuddling, or kissing the baby were called affectionate behaviors; talking, singing, or cooing to the baby were considered vocal behaviors. Both affectionate and vocal behaviors were considered approach behaviors. Basic caregiving activities, such as changing diapers and burping the infants, were also recorded. In these studies, no relationship between hormone concentrations and maternal responsiveness (as measured by attitude questionnaires) was found. For example, most women showed an increasing positive self-image during early pregnancy that dipped during the second half of pregnancy, but recovered after parturition (childbirth). A related dip in feelings of maternal engagement occurred during late pregnancy, but rebounded substantially after birth in most women

Figure 3.3.11.6: Although cortisol may not directly increase maternal behaviors, the next time your mom gives you a hug you know one hormone to thank.

However, when behavior (rather than questionnaire responses) was compared with hormone concentrations, a different story emerged. Blood plasma concentrations of cortisol were positively associated with approach behaviors. In other words, women who had high concentrations of blood cortisol (in samples obtained immediately before or after nursing) engaged in more physically affectionate behaviors (Figure 3.3.11.6) and talked more often to their babies than mothers with low cortisol concentrations. Additional analyses from this study revealed that the correlation was even greater for mothers who had reported positive maternal regard (feelings and attitudes) during gestation (pregnancy). Indeed, nearly half of the variation in maternal behavior among women could be accounted for by cortisol concentrations and positive maternal attitudes during pregnancy. Presumably, cortisol does not induce maternal behaviors directly, but it may act indirectly by increasing the mother's general level of arousal, thus increasing her responsiveness to infant-generated cues. New mothers with high cortisol concentrations were also more attracted to their infant's odors, were superior in identifying their infants, and generally found cues from infants highly appealing (Fleming, Steiner, & Corter, 1997).

Summary

Hormones are inextricably linked to the development and maturation of reproductive anatomy (both prenatally and during puberty), as well as the promotion and maintenance of adult reproductive functions. The effects of steroid sex hormones are typically characterized as organizational versus activational. Organizational effects result in permanent changes that usually occur early in development, such as the prenatal development of primary sex characteristics (differences in male and female bodies that are present at birth). Activational effects are usually temporary and occur throughout life, dependent on specific conditions.

The main categories of sex hormones are androgens (more prevalent in biological males, e.g. testosterone), and estrogens (more prevalent in biological females, e.g. estradiol). All individuals have both androgens and estrogens, but the relative proportion of the hormones present varies, usually correlated with biological sex. Testosterone is secreted by the testes in males and in small amounts by the ovaries in females. A small amount of testosterone is also secreted by the adrenal glands in both sexes. Estrogens are secreted by the ovaries in females and by fat cells in both sexes.

The interaction between hormones and behavior is bidirectional: hormones can influence behavior, and behavior can sometimes influence hormone concentrations. Hormones do not cause behavioral changes, but they influence the components that interact to produce behavior- sensory systems, the central nervous system, and muscles and glands. In this manner, specific stimuli are more likely to elicit certain responses in the appropriate behavioral or social context. For behavioral effects on hormones, in animal models, losing a fight results in decreased blood testosterone levels. Comparable results have been reported in humans.

Research on rats suggests that the motivation to engage in sexual behavior is separate from the ability to engage in sexual behavior. The hypothalamus plays an important role in motivated behaviors, including sex. In humans, testosterone maintains libido (sex drive) in both males and females.

Although the glans of the clitoris and penis are known to be associated with pleasure, extensive regions of the brain and brainstem are also activated when a person experiences pleasure. Erogenous zones are particularly sensitive areas of skin, which vary across individuals.

The hypothalamus is important for sexual functioning, particularly because it controls the pituitary gland. Hormones related to sexual function secreted by the pituitary gland include follicle-stimulating hormone (FSH), luteinizing hormone (LH), and prolactin from the anterior pituitary, and oxytocin from the posterior pituitary. FSH and LH are responsible for ovulation in females and sperm production in males. Prolactin and oxytocin stimulate lactation. Oxytocin causes rhythmic contractions in the uterus and penis (associated with orgasm), as well as uterine contractions during childbirth. Oxytocin is also believed to be involved in maintaining close relationships.

Hormones trigger the onset of maternal behavior in rats. A fast decline of progesterone in late pregnancy, combined with high concentrations of estradiol, induce female rats to behave maternally (overriding the usual fear response of adult rats toward pups). The medial preoptic area is critical for the expression of rat maternal behavior, and the amygdala appears to inhibit the expression of maternal behavior. Progesterone appears to be the primary hormone that induces maternal aggression (in rats) toward animals that venture too close to their litter.

In human studies, no relationship between hormone concentrations and maternal responsiveness (on attitude questionnaires) was found. However, women who had high concentrations of blood cortisol engaged in more physically affectionate behaviors and talked more often to their babies than mothers with low cortisol concentrations. The correlation was even greater for mothers who had reported positive maternal feelings and attitudes during pregnancy.

3.3.12: Sexual Development, Anatomy and Physiology

Learning Objectives

1. Describe the process of prenatal sexual differentiation in humans.
2. Identify male and female reproductive structures that originate from homologous embryonic tissues versus those that are formed from separate (Wolffian and Müllerian) duct systems.
3. Identify the functions of the main reproductive structures for both males and females.
4. Understand the basic events occurring in the ovaries and uterus during the human menstrual cycle.
5. Explain the four phases in the human sexual response cycle (Masters and Johnson).

Overview

This section covers development of the male and female reproductive systems (including prenatal sex differentiation, homologous structures and reproductive ducts, and sexual maturation during puberty), and adult sexual anatomy and physiology (including the male reproductive system, the female reproductive system, the menstrual cycle, and the sexual response cycle.

Development of the Reproductive Systems

The **reproductive system** is the human organ system responsible for the production of gametes (sperm or eggs), the meeting of gametes during fertilization, and the carrying of an embryo/fetus. The reproductive system is the only body system that differs substantially between individuals, typically divided into male and female forms (Figure 3.3.12.1), although there is actually a range of biological sex (see the differences of sexual development section). Many embryonic structures that will develop into the reproductive system start out the same in males and females, but by birth, the reproductive systems have differentiated. This section will describe how male and female reproductive structures typically form during development and the role of several hormones.

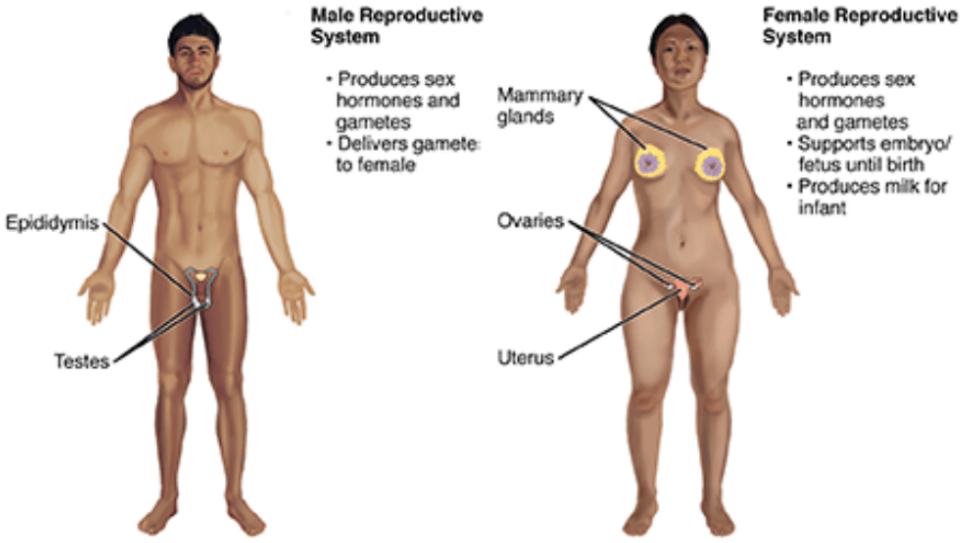

Figure 3.3.12.1: Reproductive Systems in the Human Male and Female. Both systems produce sex hormones and gametes. The male reproductive system additionally delivers gametes to the female; the epididymis and testes are labeled. The female reproductive system additionally supports an embryo/fetus until birth and produces milk for the infant; the mammary glands, ovaries, and uterus are labeled.

The **gonads** (the testes in males and the ovaries in females) produce gametes (sperm in males and eggs in females). A **gamete** is a haploid cell- a cell that contains one full set of chromosomes, or half the number needed to create a new individual. When two haploid gametes combine during fertilization, they form a single diploid cell, which now contains two full sets of chromosomes

(the necessary number to create a new individual) and is called a zygote (fertilized egg). In mammals, the ovum always contains an X chromosome, which can be fertilized by a sperm bearing either an X or a Y chromosome; this process is called sex determination. XX is the chromosomal sex of a female mammal and XY is the chromosomal sex of a male mammal.

Besides producing gametes, the gonads also produce sex hormones. **Sex hormones**, such as androgens and estrogens, are endocrine hormones that control the development of sex organs before birth, sexual maturation at puberty, and reproduction once sexual maturation has occurred. Other reproductive system organs have various functions, such as maturing gametes, delivering gametes to the site of fertilization, and providing an environment for the development and growth of offspring.

Prenatal Sex Differentiation

The process of becoming female or male is called sexual differentiation. Although both the X and the Y chromosomes are called sex chromosomes, only the Y chromosome contains genes that determine sex. A single gene on the Y chromosome, called SRY (for "sex-determining region Y gene"; Figure 3.3.12.2), triggers male development in the embryo. Without a Y chromosome, the embryo develops a female body plan, so you can think of a female as the default sex of the human species (as is the case for all mammals).

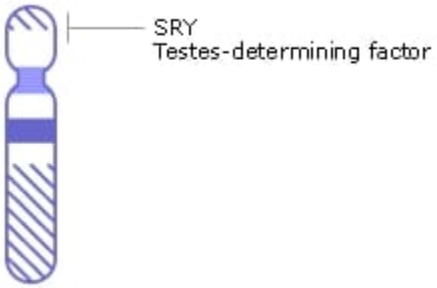

Figure 3.3.12.2: The SRY gene on the short arm of the Y chromosome causes the undifferentiated gonads of an embryo to develop into testes. Otherwise, the gonads develop into ovaries.

The gonads of the embryo are initially undifferentiated, meaning that they are indeterminate- identical in XX and XY embryos- and able to become either testes or ovaries. Starting around the sixth week after conception in genetically male (XY) embryos, the SRY gene initiates the production of a protein called testes determining factor. Testes determining factor causes the undifferentiated gonads to develop into testes. The testes secrete hormones — including testosterone — that trigger other changes in the developing offspring (now called a fetus), causing it to develop a complete male reproductive system. Without a Y chromosome, an embryo will develop ovaries that will then produce estrogens. Estrogens, in turn, enable the formation of the other organs of a female reproductive system.

Homologous Structures and Reproductive Ducts

Undifferentiated embryonic tissues develop into different structures in male and female fetuses. Structures that arise from the same tissues in males and females are called **homologous structures**. The testes and ovaries, for example, are homologous structures that develop from the undifferentiated gonads of the embryo. Likewise, the penis and clitoris are homologous structures that develop from the same embryonic tissues, as are the scrotum and the skin folds of the labia majora. The formation of typical male external anatomy (the penis and scrotum) requires the conversion of testosterone into a more potent androgen called dihydrotestosterone, whereas the formation of typical female external anatomy (the clitoris and the labia) does not require hormones. In this manner, the same embryonic tissue develops into one structure or another in a given individual, or occasionally forms a structure that is intermediate between the typical male or female form.

Not all tissues in the prenatal reproductive tract have the potential to develop into either male or female forms. The internal reproductive structures (for example the uterus, uterine tubes, and part of the vagina in females; and the epididymis, vas deferens, and seminal vesicles in males) form from one of two rudimentary duct systems in the embryo. For full reproductive function in the adult, one set of these ducts must develop properly, and the other must degrade. In males, cells in the testes secrete **Müllerian inhibiting substance**, which causes the **Müllerian duct** (the female duct) to degenerate. At the same time, testosterone secretion stimulates growth of the male tract, the **Wolffian duct**. Without Müllerian inhibiting substance, the Müllerian duct will develop; without testosterone, the Wolffian duct will degrade. Thus, the developing offspring will be female (Figure 3.3.12.3),

following the default female body form.

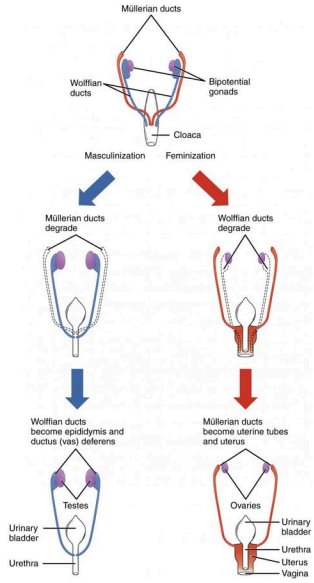

Figure 3.3.12.3: Differentiation of the male and female reproductive systems occurs during the fetal period of development. Initially, the cloaca, bipotential gonads, and both Wolffian and Mullerian ducts are present. In both sexes, the cloaca becomes the urinary bladder and urethra.With masculinization (shown on the left), the Mullerian ducts degrade and the Wolffian ducts become the epididymis and the ductus (vas) deferens. The bipotential gonads become testes. With feminization (shown on the right), the Wolffian ducts degrade and the Mullerian ducts become the uterine tubes and the uterus. The bipotential gonads become ovaries.

Sexual Maturation during Puberty

Puberty is a *period of rapid growth and sexual maturation*. These changes typically begin sometime between the ages of eight and fourteen, and start with an overall physical growth spurt, often most noticeable in the adolescent's increased height. Generally, girls begin puberty at around ten years of age and boys begin approximately two years later. Pubertal changes usually take around three to four years to complete.

Typically, the physical growth spurt is followed by the development of sexual maturity. Changes in the primary sexual characteristics (reproductive organs) in males includes growth of the testes, penis, and scrotum, and in females the growth and maturation of the ovaries, uterus and external genitalia (vulva). Important signals of sexual maturity include **spermarche** *or first ejaculation of semen* in males, and **menarche** *or the first menstrual period* in females. Stress and higher percentage of body fat are correlated with menstruation at younger ages.

Secondary sexual characteristics *are visible physical changes not directly linked to reproduction, but that signal sexual maturity*. For males this includes broader shoulders and a lower voice as the larynx grows. Body hair becomes coarser and darker, and hair growth occurs in the pubic area, under the arms and on the face. For females breast development occurs around age 10, although full development takes several years. Hips broaden and pubic and underarm hair develops and also becomes darker and coarser.

Adult Sexual Anatomy and Physiology

The Male Reproductive System

The main structures of the male reproductive system are external to the body (Figure 3.3.12.4). The two testes (singular, testis) hang between the thighs in a sac of skin called the scrotum. The testes produce both sperm and testosterone. Testosterone production is under the control of luteinizing hormone (LH) from the pituitary gland, which stimulates cells in the testes to secrete testosterone. Both follicle stimulating hormone (FSH) from the pituitary gland and testosterone are needed for normal spermatogenesis to be maintained in the testes. Additionally, testosterone maintains libido (sex drive) and plays a role in erection, allowing sperm to be deposited within the female reproductive tract. Testosterone is necessary for the proper functioning of the prostate gland, and is also important for muscle development and bone growth.

Resting atop each testis is a coiled structure called the epididymis (plural, epididymes). The function of the epididymes is to mature and store sperm. The penis is a tubular organ that contains the urethra and has the ability to stiffen during sexual arousal. Sperm passes out of the body through the urethra during a sexual climax (orgasm). This release of sperm is called ejaculation.

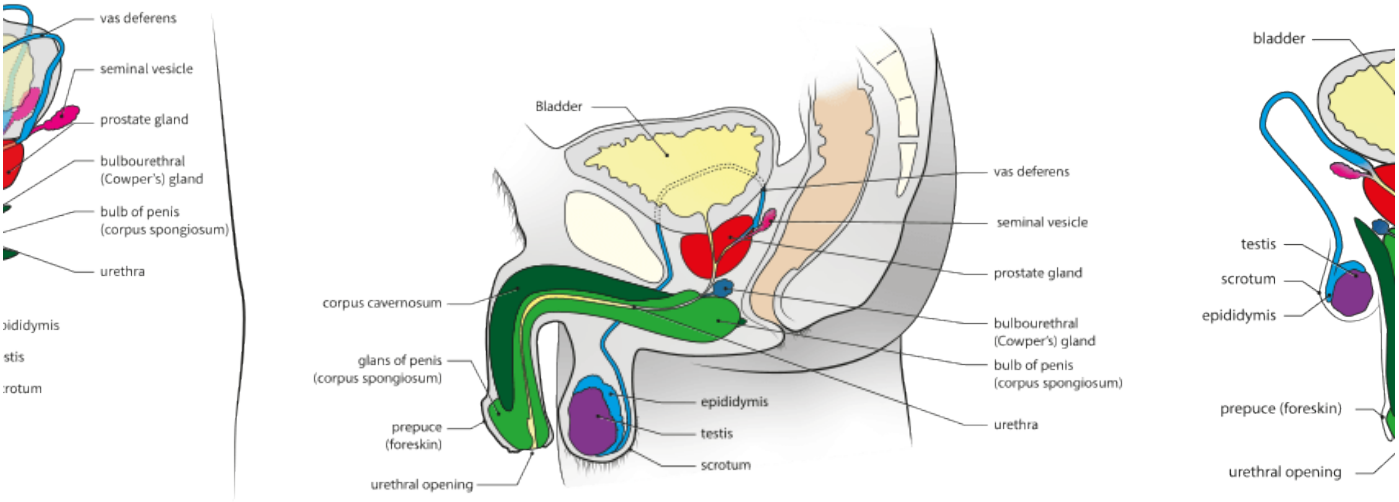

Figure 3.3.12.4: The main structures of the male reproductive system in 3D view, sagittal view, and frontal view. Note that structures that are homologous to female structures (originating from the same embryonic tissue, such as the testes) are color-coded to match the female reproductive system diagrams in Figure 3.3.12.5.

In addition to these external organs, there are several ducts and glands that are internal to the body. The ducts, which include the vas deferens (also called the ductus deferens), transport sperm from the epididymis to the urethra. The glands, which include the prostate gland and seminal vesicles, produce fluids that become part of semen. Semen is the fluid that carries sperm through the urethra and out of the body. It contains substances that control pH and provide sperm with nutrients for energy.

The Female Reproductive System

The main structures of the female reproductive system are internal to the body (Figure 3.3.12.5). They include the paired ovaries, which are small, oval structures that produce eggs and secrete estrogens. The two uterine tubes (also known as Fallopian tubes or oviducts) start near the ovaries and end at the uterus. Their function is to transport eggs from the ovaries to the uterus. If fertilization of an egg occurs, it usually happens while it is traveling through the Fallopian tube. The uterus is a pear-shaped muscular organ that functions to carry a fetus until birth. It can expand greatly to accommodate a growing fetus, and its muscular walls can contract forcefully during labor to push the baby into the vagina. The vagina is a tubular tract connecting the uterus to the outside of the body. The vagina is where sperm are usually deposited during sexual intercourse (via ejaculation). The vagina is also called the birth canal because a baby travels through the vagina to leave the body during birth.

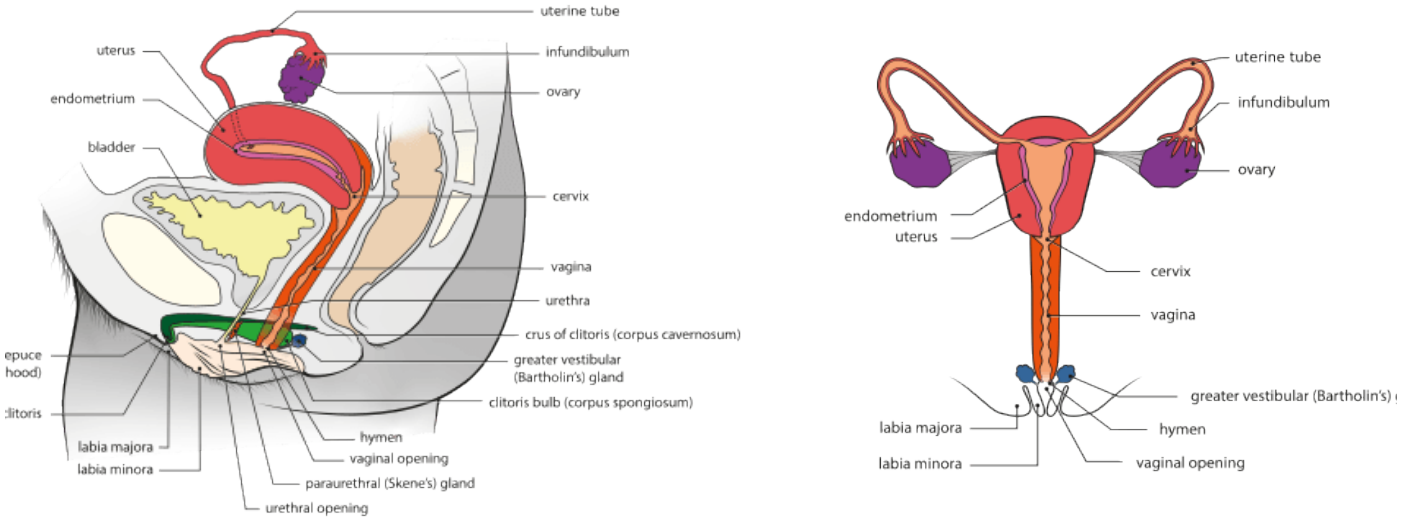

Figure 3.3.12.5: The main structures of the female reproductive system in 3D view, sagittal view, frontal view, and inferior view (between the legs). Note that structures that are homologous to male structures (originating from the same embryonic tissue, such as the ovaries) are color-coded to match the male reproductive system diagrams in Figure 3.3.12.4.

The external structures of the female reproductive system are referred to collectively as the vulva. The vulva includes the clitoris, which is homologous to the male penis (the erectile tissues of the penis and clitoris are colored dark green and light green in Figure 3.3.12.4 and Figure 3.3.12.5), and the two pairs of labia (singular, labium), which surround and protect the openings of the urethra and vagina.

The Menstrual Cycle

The **menstrual cycle** refers to natural changes that occur in the female reproductive system each month during the reproductive years. The cycle is necessary for the production of eggs and the preparation of the uterus for pregnancy. It involves changes in both the ovaries and the uterus and is controlled by pituitary and ovarian hormones. Day 1 of the cycle is the first day of the menstrual period**,** when bleeding from the uterus begins as the built-up endometrium lining the uterus is shed. The endometrium builds up again during the remainder of the cycle, only to be shed again during the beginning of the next cycle if pregnancy does not occur. In the ovaries, the menstrual cycle includes the development of a follicle, ovulation of a secondary oocyte (the name given to an egg before maturation), and the degeneration of the follicle if pregnancy does not occur. Both uterine and ovarian changes during the menstrual cycle are generally divided into three phases, although the phases are not the same in the two organs.

Ovarian Cycle

The events of the menstrual cycle that take place in the ovaries make up the ovarian cycle. It consists of changes that occur in the follicles of one of the ovaries. The ovarian cycle is divided into the following three phases: 1) the follicular phase (several follicles begin maturing, but only one is selected to mature completely), 2) ovulation (the mature egg is released), and 3) the luteal phase (progesterone maintains the lining of the uterus for potential implantation of the fertilized egg).

Follicle-stimulating hormone (FSH), secreted by the pituitary gland, rises and causes several follicles to begin to mature. One maturing follicle becomes dominant and starts releasing estrogen. The resulting rising levels of estrogen prevent multiple follicles from fully developing; non-dominant follicles undergo atresia, or degeneration. The continued rise in estrogen triggers a luteinizing hormone (LH) surge from the pituitary gland, which in turn stimulates ovulation. During the luteal phase, progesterone is secreted by the corpus luteum (a structure formed from the remnants of the follicle that released the egg) until the end of the cycle, when the corpus luteum either degenerates (if the egg was not fertilized) or is maintained by the new pregnancy.

Uterine Cycle

The events of the menstrual cycle that take place in the uterus make up the uterine cycle. This cycle consists of changes that occur mainly in the endometrium, which is the layer of tissue that lines the uterus. The uterine cycle is divided into the following three phases: 1) menstruation (shedding of the unfertilized egg and the endometrium lining that has built up), 2) the proliferative phase (the lining of the uterus grows again), and 3) the secretory phase (endometrium is prepared to receive a fertilized egg).

The ovarian cycle, the uterine cycle, and the changes in hormone levels that occur during the menstrual cycle are illustrated in Figure 3.3.12.6. Note that the changes in the lining of the endometrium are illustrated in the part showing the uterine cycle phases.

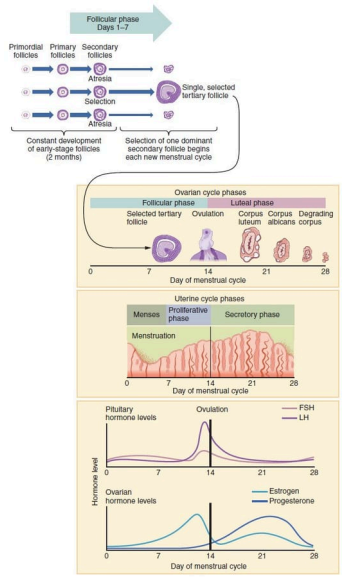

Figure 3.3.12.6:

The correlation of the hormone levels and their effects on the female reproductive system is shown in this timeline of the ovarian and menstrual cycles. The menstrual cycle begins at day one with the start of menses. Ovulation occurs around day 14 of a 28-day cycle, triggered by the LH surge.

The Sexual Response Cycle

In 1966, William Masters and Virginia Johnson published a book detailing the results of their observations of nearly 700 people who agreed to participate in their study of physiological responses during sexual behavior. Masters and Johnson observed people having intercourse in a variety of positions, as well as people masturbating, manually or with the aid of a device. Measurements of physiological variables, such as blood pressure and respiration rate, as well as measurements of sexual arousal, such as vaginal lubrication and penile tumescence (swelling associated with an erection) were recorded. In total, Masters and Johnson observed nearly 10,000 sexual acts as a part of their research (Hock, 2008).

Based on these observations, Masters and Johnson divided the sexual response cycle (Masters & Johnson, 1966) into four phases that are fairly similar in men and women:

1. Excitement: Activation of the sympathetic branch of the autonomic nervous system defines the *excitement phase*; heart rate and breathing accelerates, along with increased blood flow to the penis, vaginal walls, clitoris, and nipples. Involuntary muscular movements (**myotonia**), such as facial grimaces, also occur during this phase.
2. Plateau: Blood flow, heart rate, and breathing intensify during the *plateau phase*. During this phase females experience an **orgasmic platform**—the outer third of the vaginal walls tightening—and males often exhibit a release of pre-ejaculatory fluid.
3. Orgasm: The shortest but most pleasurable phase is the *orgasm phase*. After reaching its climax, neuromuscular tension is released and the hormone **oxytocin** floods the bloodstream—facilitating emotional bonding. Although the rhythmic muscular contractions of an orgasm are temporally associated with ejaculation in males, orgasm and ejaculation are actually two separate physiological processes (and can thus occur independently).
4. Resolution: The body returns to a pre-aroused state in the *resolution phase*.

The final phase, resolution, is where the main differences between males and females occur. Males enter a **refractory period**

of being unresponsive to sexual stimuli. The length of this period depends on age, frequency of recent sexual behavior, level of intimacy with a partner, and novelty. Because females do not have a refractory period, they have a greater potential—physiologically—of having multiple orgasms. Ironically, females are also more likely to "fake" having orgasms (Opperman et al., 2014). As such, whereas the graph for the male sexual response cycle shows only the most common progression through the four phases including orgasm (with a potential partial second cycle starting after the refractory period ends), the graph for the female sexual response cycle shows three alternative patterns- A. progression through all four stages with multiple orgasms, B. prolonged time in the plateau phase with no orgasm, and C. progression through all four stages with a single orgasm (Figure 3.3.12.7).

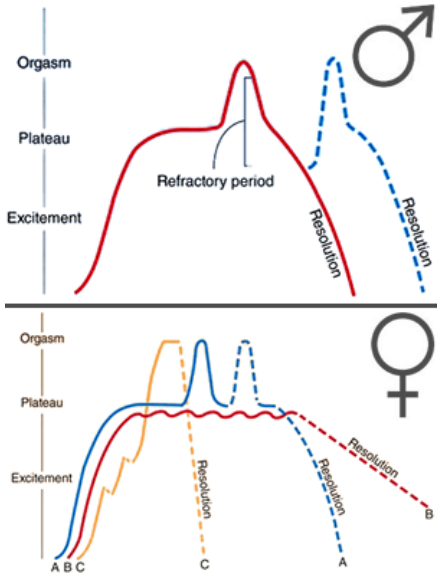

Figure 3.3.12.7:

Diagram of the common human sexual response cycles as described by Masters and Johnson

Of interest to note, the sexual response cycle is a universal response to sexual stimuli, and occurs regardless of the type of sexual behavior—whether the behavior is masturbation; romantic kissing; or oral, vaginal, or anal sex (Masters & Johnson, 1966). Further, a partner (of any sex/gender) or environmental object is sufficient, but not necessary, for the sexual response cycle to occur.

Feature: Human Biology in the News

Lung, heart, kidney, and other organ transplants have become relatively commonplace, so when they occur, they are unlikely to make the news. However, when America's first penis transplant took place, it was considered very newsworthy.

In 2016, Massachusetts General Hospital in Boston announced that a team of its surgeons had performed the first penis transplant in the United States. The patient who received the donated penis was a 64-year-old cancer patient. During the 15-hour procedure, the intricate network of nerves and blood vessels of the donor penis were connected with those of the penis recipient. The surgery went well, but doctors reported it would be a few weeks until they would know if normal urination would be possible, and even longer before they would know if sexual functioning would be possible. At the time that news of the surgery was reported in the media, the patient had not shown any signs of rejecting the donated organ. The surgeons also reported they were hopeful that such transplants would become relatively common, and that patient populations would expand to include wounded warriors and transgender males seeking to transition.

The 2016 Massachusetts operation was not the first penis transplant ever undertaken. The world's first successful penis transplant was actually performed in 2014 in Cape Town, South Africa. A young man who had lost his penis from complications of a botched circumcision at age 18 was given a donor penis three years later. That surgery lasted nine hours and was highly successful. The young man made a full recovery and regained both urinary and sexual functions in the transplanted organ.

> In 2005, a man in China also received a donated penis in a technically successful operation. However, the patient asked doctors to reverse the procedure just two weeks later, because of psychological problems associated with the transplanted organ for both himself and his wife.

Summary

The reproductive system is responsible for the production of gametes (sperm or eggs), the meeting of gametes during fertilization, and the carrying of an embryo/fetus. The gonads (the testes in males and the ovaries in females) produce gametes and sex hormones. Sex hormones (androgens and estrogens) control the development of sex organs before birth, sexual maturation at puberty, and reproduction once sexual maturation has occurred.

Sexual differentiation is the process of becoming male or female. A gene on the Y chromosome called SRY is critical for stimulating testis development and subsequently the development of male reproductive structures. Without a Y chromosome, the embryo develops a female body plan.

Undifferentiated embryonic tissues develop into different homologous structures in male and female fetuses, such as the testes and ovaries, or the penis and clitoris. However, the tissue that forms the internal reproductive structures stems from ducts that will develop into only male (Wolffian) or only female (Müllerian) structures. To be able to reproduce as an adult, one of these systems must develop properly and the other must degrade.

Further development of the reproductive systems occurs at puberty. The increase in sex steroid hormones leads to maturation of the gonads and other reproductive organs. Important signals of sexual maturity include spermarche (first ejaculation of semen) in males, and menarche (first menstrual period) in females. Increases in sex steroid hormones also lead to the development of secondary sex characteristics such as breast development in girls and facial hair and larynx growth in boys.

The main male reproductive structures are external to the body: the penis and the paired testes. The penis contains the urethra and is able to stiffen during sexual arousal. Sperm passes out of the body through the urethra during orgasm, called ejaculation. The testes produce sperm and testosterone, and are located in the scrotum. Luteinizing hormone (LH) stimulates cells in the testes to secrete testosterone. Both follicle stimulating hormone (FSH) and testosterone are needed for spermatogenesis. Additionally, testosterone maintains libido (sex drive), plays a role in erection, is necessary for prostate gland function, and is important for muscle development and bone growth. Internal ducts and glands include the vas deferens (which transports sperm from the epididymis to the urethra), the prostate gland and the seminal vesicles (which produce fluids that become part of semen).

The external structures of the female reproductive system are referred to as the vulva: the clitoris and the two pairs of labia surrounding and protecting the openings of the urethra and vagina. The main female reproductive structures are internal to the body and include the paired ovaries (which produce eggs and secrete estrogens), the two Fallopian tubes (which transport eggs from the ovaries to the uterus), the uterus (a muscular organ that carries a fetus until birth), and the vagina. The vagina is a tubular tract connecting the uterus to the outside of the body. Sperm are usually deposited in the vagina during sexual intercourse (via ejaculation), and a baby travels through the vagina (also called the birth canal) to leave the body.

The menstrual cycle in females is necessary for the production of eggs and the preparation of the uterus for pregnancy. It involves changes in both the ovaries and the uterus and is controlled by pituitary and ovarian hormones. The ovarian cycle is divided into the follicular phase (several follicles begin maturing, but only one is selected to mature completely), ovulation (the mature egg is released), and the luteal phase (progesterone maintains the lining of the uterus for potential implantation of the fertilized egg). The uterine cycle is divided into menstruation (shedding of the unfertilized egg and the endometrium lining that has built up), the proliferative phase (the lining of the uterus grows again), and the secretory phase (endometrium is prepared to receive a fertilized egg).

Masters and Johnson (1966) divided the sexual response cycle into four phases that are fairly similar in men and women: excitement (heart rate and breathing accelerates, increased blood flow to the penis, vaginal walls, clitoris, and nipples), plateau (blood flow, heart rate, and breathing intensify; females experience an orgasmic platform—the outer third of the vaginal walls tightening—and males often exhibit a release of pre-ejaculatory fluid), orgasm (shortest but most pleasurable phase), and resolution (the body returns to a pre-aroused state). The main differences between males and females occur during resolution. Males enter a refractory period of being unresponsive to sexual stimuli. Females do not have a refractory period, so they have a greater potential for having multiple orgasms.

3.3.13: Differences of Sexual Development

Learning Objectives

1. Identify the basic characteristics of the most common sex chromosome abnormalities (Turner Syndrome and Klinefelter Syndrome).
2. Understand the term intersex and the various conditions it encompasses.
3. Explain the role of hormones in the development of anomalous sexual differentiation for XX individuals with congenital adrenal hyperplasia (CAH) and XY individuals with androgen insensitivity syndrome (AIS).
4. Explain how David Reimer's case challenged Dr. John Money's theory of psychosexual neutrality.

Overview

This section discusses some of the many ways in which sexual development can differ from typical XX/male and XY/female formats. Note that while the scientific literature on this topic typically labels these conditions "Disorders of Sexual Development (DSD)", we prefer to refer to them as "Differences of Sexual Development". Chromosomal abnormalities (such as Triple X syndrome, Turner syndrome, and Klinefelter syndrome), intersex conditions, anomalous female differentiation (such as congenital adrenal hyperplasia) and anomalous male sexual differentiation (such as 5α-reductase deficiency and androgen insensitivity syndrome) demonstrate some of the diverse variations of biological sex found in humans. The case of David Reimer illustrates that raising a typically-developed biological male (who lost his penis in infancy due to a circumcision accident) as a girl can fail catastrophically.

Chromosomal Abnormalities

Aneuploidy

As discussed in the chapter on genetics, a typical human individual has 22 pairs of autosomes ("self" chromosomes) and one pair of sex chromosomes (either XX for females or XY for males), resulting in a total of 46 chromosomes (Figure 3.3.13.1).

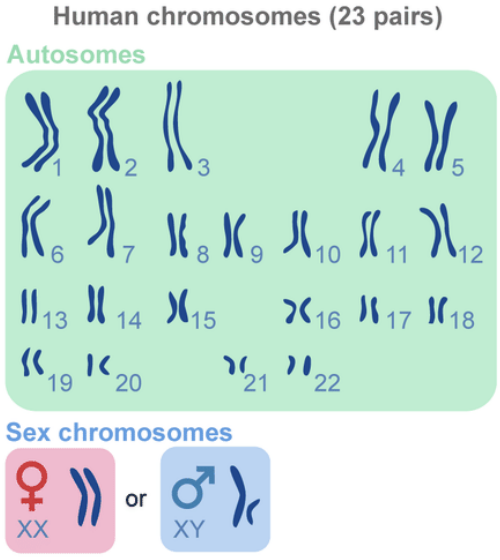

Figure 3.3.13.1
:Humans have 23 pairs of chromosomes. Pairs 1-22 are autosomes. Females have two X chromosomes, and males have an X and a Y chromoso

Sometimes errors occur during the formation of the gametes (eggs in females and sperm in males), resulting in missing

chromosomes or extra chromosomes. When an individual inherits too many or two few chromosomes, it is called a **chromosomal abnormality**. (Or, more specifically, **aneuploidy**- the presence of an abnormal number of chromosomes in a cell.) The most common cause of chromosomal abnormalities is older age of the mother. As a female ages, the immature eggs in her ovaries (which have been present since before birth, unlike the sperm cells in males) are more likely to suffer damage due to longer term exposure to environmental factors. Consequently, some gametes do not divide evenly when they are forming, and some eggs have more (or less) than 23 chromosomes. Often when the error includes one of the autosomes, the resulting zygote (fertilized egg) is not viable. In fact, it is believed that close to half of all zygotes have an abnormal number of chromosomes. Most of these zygotes fail to develop and are spontaneously aborted by the body of the mother (often without her knowledge that conception ever occurred).

One of the few chromosomal abnormalities that more commonly survives (to birth and decades beyond) is Down syndrome (trisomy 21- three copies of chromosome number 21). In addition to some degree of intellectual disability and characteristic facial features, affected individuals often have heart defects and other health problems. The overall occurrence of Down Syndrome is one in every 691 births, but it increases to one in every 300 births for women aged 35 and older.

Interestingly, chromosomal errors involving the sex chromosomes (the 23rd pair), called **sex chromosome aneuploidy**, are less lethal. The exception is having only a single Y chromosome- there are many important genes on the X chromosome, so a zygote with only one Y chromosome (and no X chromosome) will not survive. At least 1 in every 1,000 conceptions results in a variation of chromosomal sex beyond the typical XX or XY sets. Some of these variations include XXX (Figure 3.3.13.2), XYY, XXY, or even a single X (Dreger, 1998).

Figure 3.3.13.2: 9 year old girl with Triple X Syndrome.

Some individuals with atypical sex chromosomes may have unusual physical characteristics, such as being taller than average, having a thick neck, or being sterile (unable to reproduce); but in many cases, these individuals have no cognitive, physical, or sexual issues (Wisniewski et al., 2000). These sex-linked chromosomal disorders are briefly described in Table 3.3.13.1. It is even possible to have four or more sex chromosomes (XXXX, XXYY, XXXYY, etc.).

Table 3.3.13.1: Sex-Linked Chromosomal Disorders

Disorder	Sex Appearance & Fertility	Characteristics
Turner Syndrome (XO)	Female, but immature (infertile)	Affects cognitive functioning and sexual maturation; short stature may be noted.
Klinefelter Syndrome (XXY)	Male, may have some breast development (often infertile)	The Y chromosome stimulates the growth of male genitalia, but the additional X chromosome inhibits this development (may have low levels of testosterone).

Disorder	Sex Appearance & Fertility	Characteristics
Supermale Syndrome (XYY)	Male (usually normal fertility)	Few symptoms, which may include being taller than average, acne, and an increased risk of learning problems. Generally otherwise normal.
Triple X Syndrome (XXX)	Female (usually normal fertility)	May result in being taller than average, having learning difficulties, decreased muscle tone, seizures, and kidney problems.

The more common of these sex chromosome disorders are Turner Syndrome and Klinefelter Syndrome. **Turner Syndrome** occurs when one of the X chromosomes is missing or damaged and the resulting zygote has XO sex chromosomes. This occurs in 1 of every 2,500 live female births (Carroll, 2007) and affects the individual's cognitive functioning and sexual maturation. The external genitalia appear normal, but breasts and ovaries do not develop fully and the woman does not menstruate. Turner's syndrome also results in short stature and other physical characteristics, such as a webbed neck, shield-shaped thorax, and cardiac defects. Figure 3.3.13.3 illustrates the symptoms of Turner's syndrome and Figure 3.3.13.4 shows pictures of 18 individuals of Asian descent with Turner's syndrome.

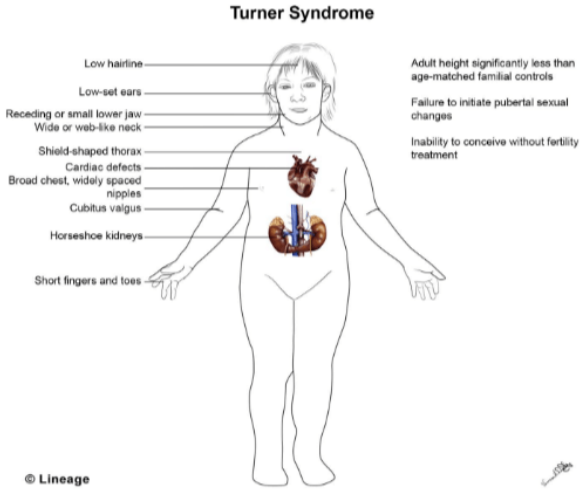

Figure 3.3.13.3: Symptoms of Turner's syndrome.

Figure 3.3.13.4: Eighteen Asian girls and women with Turner's syndrome.

Klinefelter Syndrome (XXY) *results when an extra X chromosome is present in the cells of a male* and occurs in 1 out of 700 live male births. The Y chromosome stimulates the growth of male genitalia, but the additional X chromosome inhibits this development. An individual with Klinefelter Syndrome often has some breast development, wide hips, infertility (this is the most common cause of infertility in males), small testicular size, and low levels of testosterone (National Institutes of Health, 2019). Figure 3.3.13.5 illustrates the symptoms of Klinefelter's syndrome on the left and a 29 year old male with Klinefelter`s syndrome who is undergoing testosterone treatment on the right. Regular testosterone injections can promote strength and facial hair growth, build a more muscular body type, increase sexual desire, and enlarge the testes.

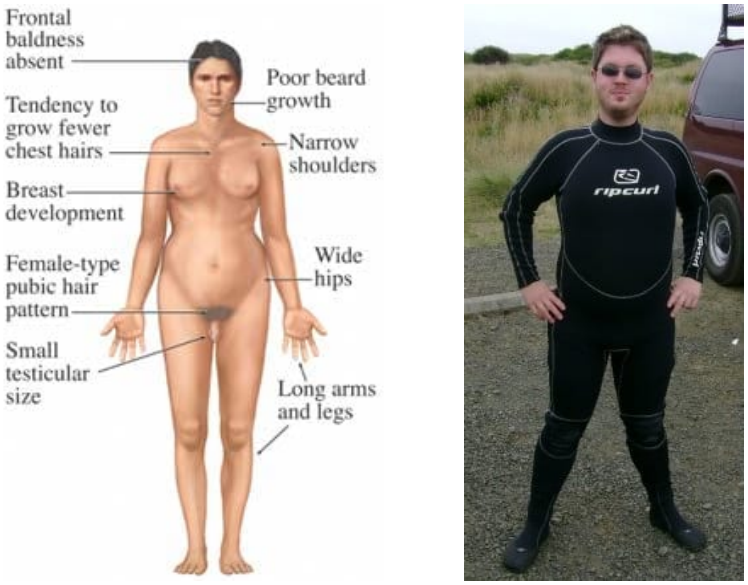

Figure 3.3.13.5: Symptoms of Klinefelter's syndrome [left] and 29 year old male undergoing testosterone treatment [right].

Other Chromosomal Alterations

As mentioned in Section 13.2, the SRY gene on the Y chromosome is the gene that directs development of the testes (typically leading to male reproductive structure development). Occasionally during sperm formation the SRY gene can cross over from the Y chromosome to the X chromosome. (Gene cross over regularly occurs between the 22 autosomes during the formation of gametes, but usually does *not* occur between the X and Y chromosomes, since they do not have the same genes.) If a sperm carrying a Y chromosome that has lost its SRY gene fertilizes an egg, although chromosomally genetically male (XY), the resulting embryo will not form testes and consequently will not develop male reproductive structures. (For mammals, female development is the "default" in the absence of hormones.) Likewise, if a sperm carrying an X chromosome that has an SRY gene attached to it fertilizes an egg, although chromosomally genetically female (XX), the resulting embryo will develop testes (which will then produce testosterone) and reproductive structures will develop in a male pattern. The individual will be infertile, however, since other genes on the Y chromosome are necessary for viable sperm production. This is another way in which abnormalities on the X or Y chromosomes (rather than having entire chromosomes that are extra or missing) produce variations in human sex characteristics.

Variations in Reproductive Structures

Intersex Conditions

In cases where hormones are not produced (or responded to) following the two most common patterns, a fetus may develop biological characteristics in between typical male and typical female structures. These people are considered to have intersex conditions. According to the Intersex Society of North America, intersex is a general term used for a variety of conditions in which a person is born with a reproductive or sexual anatomy that doesn't fit the typical definitions of male or female. For example, a person might be born appearing to be male on the outside, but having mostly female-typical anatomy on the inside. Or a person may be born with genitals that seem to be intermediate between the usual male and female types—for example, a girl

may be born with a notably large clitoris, or lacking a vaginal opening, or a boy may be born with a micropenis, or with a scrotum that is divided so that it has formed more like labia. Some people have mosaic genetics, meaning that two separate sets of chromosomes merged into one individual early in embryonic development. Any given body cell will contain one set or the other, and if all cells have either XX chromosomes or XY chromosomes, the condition may never even be detected. However, if some of their cells have XX chromosomes and some of them have XY chromosomes, separate areas of the body may have developed differently as a result. For example, a person may have an ovary on one side of the body and a testis on the other side. This is the true meaning of the word "hermaphrodite"- having both male and female gonadal tissue in the same body. (It is also possible to have a mixture of ovarian and testicular tissue in the gonads.) The intersex conditions discussed below are sometimes called "pseudohermaphrodites"- having something similar to both male and female anatomical structures in the same body (Figure 3.3.13.6).

Figure 3.3.13.6: Wax figure of human intersex genitalia from the Panoptikum House of Wax, Hamburg.

Though intersex is commonly thought of as an inborn condition, intersex anatomy isn't always apparent at birth. Some intersex traits are not recognizable until puberty or later in life (interACT 2021), or never even realized at all. Sometimes a person isn't found to have intersex anatomy until they reach the age of puberty, or find themselves to be infertile as an adult, or die of old age and are autopsied. Some people live and die with intersex anatomy without anyone (including themselves) ever knowing. Which variations of sexual anatomy count as intersex? In practice, different people have different answers to that question. That's not surprising, because intersex isn't a discrete category. Nature presents us with a spectrum of sexual anatomy. Breasts, penises, clitorises, scrotums, labia, gonads—all of these vary in size and shape and morphology. However, in human cultures, sex categories generally get simplified into male or female, sometimes with "intersex", "third sex" or "two spirit" included as an "other" option.

So nature doesn't determine where the category of "male" ends and the category of "intersex" begins, or where the category of "intersex" ends and the category of "female" begins. Humans decide. Humans (typically doctors today, at least in Western cultures) decide how small a penis has to be, or how unusual a combination of parts has to be, before it counts as intersex. Humans decide whether a person with XXY chromosomes or XY chromosomes and androgen insensitivity will count as intersex. Doctors' opinions about what should count as intersex vary substantially. Some think you have to have "ambiguous genitalia" to count as intersex, even if your inside is mostly of one sex and your outside is mostly of another. Some think your brain has to be exposed to an unusual mix of hormones prenatally to count as intersex—so that even if you're born with atypical genitalia, you're not intersex unless your brain experienced atypical development. And some think you have to have both ovarian and testicular tissue (be a true hermaphrodite- very rare!) to count as intersex. Intersex and transgender (having a gender identity that does not match your assigned birth sex) are not interchangeable terms; many transgender people have no intersex traits, and many intersex people do not consider themselves transgender.

According to the Intersex Society of North America, it is up to the individual to decide if they "count" as intersex. However, since some forms of intersex signal underlying metabolic concerns, a person who thinks they might be intersex should seek a diagnosis and find out if they need professional healthcare. Everyone, regardless of their sexual anatomy, should be free of shame, secrecy, and unwanted genital surgeries, even if someone else believes they have non-standard sexual anatomy. It used to be standard practice to surgically alter any newborn who didn't quite fit to the typical "male" or "female" body pattern, which often meant attempting to make the child look more like a typical girl (Figure 3.3.13.7). Although that is much easier surgically, gender identity

confusion, loss of sexual sensation, and possibly unsatisfactory future sexual relationships are unfortunate possible outcomes. Current recommendations are to simply leave the child alone and see where development takes them, being prepared for any possible combinations of gender expression and sexual orientation. If desired, the individual can choose genital reconstruction surgery for themselves when they are old enough to understand and consent to the procedure.

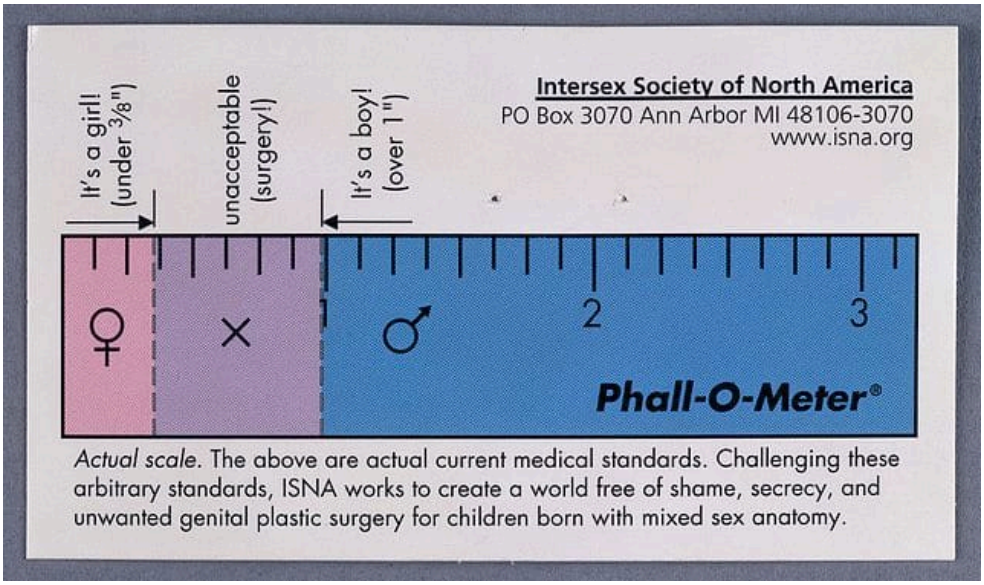

Figure 3.3.13.7: Phall-O-Meter, a ruler used to determine when to perform genital surgery on a newborn baby.

Anomalous Female Sexual Differentiation

By studying individuals who do not neatly fall into the dichotic boxes of female or male and for whom the process of sexual differentiation is atypical, behavioral endocrinologists glean hints about the process of typical sexual differentiation. Prenatal exposure to androgens is the most common cause of anomalous sexual differentiation among females. The source of androgen may be internal (e.g., secreted by the adrenal glands- endocrine glands located on top of the kidneys) or external (e.g., exposure to environmental estrogens). One case of prenatal exposure to internal androgens is congenital adrenal hyperplasia (CAH). CAH develops when an enzyme needed to produce cortisol is defective or missing, resulting in abnormal hormonal feedback which leads to excessive production of androgens by the adrenal cortex. In a female (XX) fetus, the elevated androgen levels caused by CAH result in varying degrees of masculinization of the external genitalia. As a result, the baby's sex may appear ambiguous or may even be mistaken as male. CAH is the most common cause of intersex conditions.

Although the effects of CAH on anatomical development are more noticeable in biological females, males can also inherit CAH. If a male (XY) fetus has CAH, his prenatal body development is similar to other males. However, he is likely to show precocious (early) sexual development as a result of the excessive androgens, such as enlargement of the penis and facial hair as a toddler (Jones & Lopez, 2006).

Anomalous Male Sexual Differentiation

Female mammals are considered the “neutral” sex; additional physiological steps are required for male differentiation, and more steps bring more possibilities for errors in differentiation. One example of male anomalous sexual differentiation (seen in Dominican Republic populations) is Guevedoces syndrome ("eggs at twelve") or 5α-reductase deficiency. Individuals with 5α-reductase deficiency are genetic males (XY) with testes that produce testosterone and cells that respond to androgens. However, because they lack the enzyme 5α-reductase, which converts testosterone to dihydrotestosterone, they are born with ambiguous genitalia and are raised as females. As mentioned in Section 13.2, dihydrotestosterone is required for typical prenatal development of the penis and scrotum. The high levels of testosterone occurring during puberty result in recognizable masculinization of the body. The "girls" become boys in dress and behavior and generally have heterosexual orientations (Jones & Lopez, 2006). In other words, these individuals readily transition to a masculine gender identity and are attracted to women.

Another example of male anomalous sexual differentiation is androgen insensitivity syndrome (AIS). Individuals with AIS lack receptors for androgens and develop as females. Androgen insensitivity syndrome is an example of an endocrine disorder where

an endocrine gland secretes a typical amount of hormone, but target cells do not respond normally to it. Individuals with AIS are genetically male and have an X and a Y chromosome, but they develop and are raised as females. This is due to a mutation in the androgen receptor gene which is located on the X chromosome. The androgen hormone testosterone normally causes the testes to descend and typical male characteristics to develop.

People with AIS have the external sex characteristics of females; they are typically raised as females and have a female gender identity. Affected individuals have male gonads (testes) that are undescended, which means they are located in the pelvis or abdomen (instead of inside a scrotum hanging between the legs). However, these individuals have neither female nor male internal reproductive structures. During prenatal development, the testes produced Mullerian inhibiting substance, which caused the duct system that would form female internal sex organs to degenerate. Thus, these individuals do not have a uterus and do not menstruate. Without ovaries, Fallopian tubes, or a uterus, they are infertile and thus unable to conceive a child. Since the Wolffian ducts (that form male internal sex organs) require testosterone to develop, they also degenerate prenatally. The testes did (and do) produce testosterone, but since the body cells lack receptors for androgens, male development does not occur.

Conclusion: Variations in Biological Sex

"Although male and female are the most typical biologically ordained poles of sexual identity, a vast number of gradations can be produced by normally occurring variations in the underlying hormonal control mechanisms that guide gender differentiation" (Panksepp, 2004, page 234). In humans, intersex individuals make up about two percent—more than 150 million people—of the world's population (Blackless et al., 2000). There are dozens of conditions that can lead to intersex anatomical variations, such as Androgen Insensitivity Syndrome and Turner's Syndrome (Lee et al., 2006). The term "syndrome" can be misleading; although intersex individuals may have physical limitations (e.g., about a third of Turner's individuals have heart defects; Matura et al., 2007), they otherwise lead relatively normal intellectual, personal, and social lives. In any case, intersex individuals demonstrate the diverse variations of biological sex.

The Case of David Reimer

In August of 1965, Janet and Ronald Reimer of Winnipeg, Canada, welcomed the birth of their twin sons, Bruce and Brian. Within a few months, the twins were experiencing urinary problems; doctors recommended the problems could be alleviated by having the boys circumcised. A malfunction of the medical equipment used to perform the circumcision resulted in Bruce's penis being irreparably damaged. Distraught, Janet and Ronald looked to expert advice on what to do with their baby boy. By happenstance, the couple became aware of Dr. John Money at Johns Hopkins University and his theory of psychosexual neutrality (Colapinto, 2000).

Dr. Money had spent a considerable amount of time researching transgendered individuals and individuals born with ambiguous genitalia. As a result of this work, he developed a theory of psychosexual neutrality. His theory asserted that we are essentially neutral at birth with regard to our gender identity and that we don't assume a concrete gender identity until we begin to master language. Furthermore, Dr. Money believed that the way in which we are socialized in early life is ultimately much more important than our biology in determining our gender identity (Money, 1962).

Dr. Money encouraged Janet and Ronald to bring the twins to Johns Hopkins University, and he convinced them that they should raise Bruce as a girl. Left with few other options at the time, Janet and Ronald agreed to have Bruce's testicles removed and to raise him as a girl. When they returned home to Canada, they brought with them Brian and his "sister," Brenda, along with specific instructions to never reveal to Brenda that she had been born a boy (Colapinto, 2000).

Early on, Dr. Money shared with the scientific community the great success of this natural experiment that seemed to fully support his theory of psychosexual neutrality (Money, 1975). Indeed, in early interviews with the children it appeared that Brenda was a typical little girl who liked to play with "girly" toys and do "girly" things.

However, Dr. Money was less than forthcoming with information that seemed to argue against the success of the case. In reality, Brenda's parents were constantly concerned that their "daughter" wasn't really behaving as most girls did, and by the time Brenda was nearing adolescence, it was painfully obvious to the family that Brenda was really having a hard time identifying as a female. In addition, Brenda was becoming increasingly reluctant to continue the visits with Dr. Money to the point that Brenda threatened suicide if she ever saw him again.

At that point, Janet and Ronald disclosed the true nature of Brenda's early childhood to their children. While initially shocked, Brenda reported that things made more sense now, and ultimately, decided to identify as a male, choosing the name David

Reimer (after the biblical story of David and Goliath, the small boy who defeated a giant). Brian did not take the news as well and distanced himself from his twin brother.

David was quite comfortable in his masculine role. He made new friends and began to think about his future. Although his castration had left him infertile, he still wanted to be a father. In 1990, David married a single mother and loved his new role as a husband and father. In 1997, David was made aware that Dr. Money was continuing to publicize his case as a success supporting his theory of psychosexual neutrality. This prompted David and his brother Brian to go public with their experiences in an attempt to discredit the doctor's publications. While this revelation created a firestorm in the scientific community for Dr. Money, it also triggered a series of unfortunate events that ultimately led to David committing suicide in 2004 (O'Connell, 2004).

This sad story speaks to the complexities involved in gender identity. While the Reimer case had earlier been paraded as a hallmark of how socialization trumped biology in terms of gender identity, the truth of the story made the scientific and medical communities more cautious in dealing with cases that involve intersex children and how to deal with their unique circumstances. In fact, stories like this one have prompted measures to prevent unnecessary harm and suffering to children who might have issues with gender identity. For example, in 2013, a law took effect in Germany allowing parents of intersex children to classify their children as indeterminate so that children can self-assign the appropriate gender once they have fully developed their own gender identities (Paramaguru, 2013). In 2017, California became the first US State to add a non-binary option to birth certificates and several other states have followed in recent years.

Summary

Although the scientific literature regarding sexual development that differs from typical XX/male and XY/female formats refers to these conditions as "Disorders of Sexual Development (DSD)", we use "Differences of Sexual Development" in this chapter. It is called a chromosomal abnormality (or aneuploidy) when an individual inherits too many or two few chromosomes, typically as a result of an error during gamete (egg or sperm) formation in one (or both) of the parents. The most common aneuploidies of the sex chromosomes (X and Y) include Triple X syndrome (XXX), Supermale syndrome (XYY), Klinefelter syndrome (XXY), and Turner syndrome (XO). (A zygote that inherits only one Y chromosome and no X chromosome is spontaneously aborted.) While individuals with Klinefelter syndrome and Turner syndrome usually have visible anatomical differences and are often infertile, individuals with Triple X syndrome and Supermale syndrome may have no noticeable symptoms and usually have normal fertility. Another chromosomal alteration that affects sexual development is the transfer of the SRY gene from the Y chromosome to the X chromosome. A zygote with a Y chromosome that has lost its SRY gene will develop in the "default" female pattern (since the gonads will not develop as testes without an SRY gene), and a zygote with an X chromosome that has the SRY gene attached to it will develop in a male pattern, but will not be fertile.

When an individual develops biological characteristics that are in between typical male and typical female structures during prenatal development, they are said to have an intersex condition. There are many anatomical and physiological variations which fit under this umbrella term, and there is no current consensus on what "counts" as intersex and what does not. The Intersex Society of North America states that it is up to the individual to decide if they "count" as intersex, and that everyone, regardless of their sexual anatomy, should be free of shame, secrecy, and unwanted genital surgeries. While immediate surgery to try to create a more typical (usually female) appearance used to be common practice, current recommendations are to simply leave the intersex child alone and see where development takes them, being prepared for any possible combinations of gender expression and sexual orientation. Although intersex individuals may have physical limitations, they otherwise lead relatively normal intellectual, personal, and social lives.

Prenatal exposure to androgens is the most common cause of anomalous sexual differentiation among females. Congenital adrenal hyperplasia (CAH) develops when excessive production of androgens by the adrenal cortex occurs due to a missing enzyme. In a female (XX) fetus, the elevated androgen levels result in varying degrees of masculinization of the external genitalia. As a result, the baby's sex may appear ambiguous or may even be mistaken as male. CAH is the most common cause of intersex conditions.

Androgen insensitivity syndrome (AIS) and 5α-reductase deficiency are the most common causes of anomalous male (XY) sexual differentiation. People with AIS have the external sex characteristics of females and they are typically raised as females and have a female gender identity. However, they are infertile because they do not have female internal structures and their gonads are testes rather than ovaries. Although their testes produce testosterone, their body cells lack testosterone receptors and thus do not respond accordingly. Individuals with 5α-reductase deficiency are born with ambiguous genitalia and are raised as females. During puberty, high levels of testosterone result in recognizable masculinization of the body, and these individuals usually transition to male gender identities and are generally attracted to women.

David Reimer was one of a pair of identical twin boys born in Canada in August 1965 (birth name Bruce). As a result of a tragic circumcision accident in infancy, his penis was destroyed, and he was raised as "Brenda" under the advice of Dr. John Money, who erroneously believed that gender identity was exclusively determined by experiences during childhood development. By early adolescence, it was clear that Brenda was having difficulties identifying as a girl, and the truth was revealed to Brenda and "her" twin brother Brian by their parents. Brenda returned to a masculine gender identity, choosing the name David, and initially his life was going well. In the early 2000s, after discovering that Dr. Money was still touting the "experiment" as a success, the Reimer family went public with their story. Ultimately a number of unfortunate events (including the death of Brian due to a drug overdose) led to David's suicide in 2004. The truth of this story (which had originally been used to support decisions to reassign the gender of intersex children at birth) made the scientific and medical communities more cautious in dealing with cases that involve intersex children and how to deal with their unique circumstances.

3.3.14: Gender

Learning Objectives

1. Distinguish between sex, gender, and sexual orientation
2. Describe gender variations recognized in some cultures

Overview

This section begins by explaining the difference between sex, gender, and sexual orientation. The terms cisgender and transgender are introduced, and gender variations across cultures are explored. Finally, the role of hormones in transgender treatment and the scientific and societal understanding of gender variations is addressed.

Sex, Gender, and Sexual Orientation: Three Different Aspects of You

Applying for a credit card or filling out a job application requires your name, address, and often birth-date. Additionally, applications usually ask for your sex or gender. The terms “sex” and “gender” are commonly used interchangeably. However, these terms are distinct from one another. Sex describes means of biological reproduction. Sex includes sexual organs, such as ovaries- defining biological reproduction as a female- or testes- defining biological reproduction as a male. As detailed in the section on differences of sexual development, biological sex is not as easily defined or determined as you might expect.

By contrast, the term gender describes psychological (gender identity) and sociological (gender role) representations of biological sex. Sex and gender are important aspects of a person’s identity. However, they do not inform us about a person’s sexual orientation (Rule & Ambady, 2008). Sexual orientation refers to a person’s sexual attraction (or lack thereof) to others. Within the context of sexual orientation, sexual attraction refers to a person’s capacity to arouse the sexual interest of another, or, conversely, the sexual interest one person feels toward another.

We live in an era when sex, gender, and sexual orientation are controversial religious and political issues. Some nations have laws against homosexuality, while others have laws protecting same-sex marriages. At a time when there seems to be little agreement among religious and political groups, it makes sense to wonder, “What is normal?” and, “Who decides?”

The international scientific and medical communities (e.g., World Health Organization, World Medical Association, World Psychiatric Association, Association for Psychological Science) view variations of sex, gender, and sexual orientation as normal. Furthermore, variations of sex and the orientation of sexual behavior occur naturally throughout the animal kingdom. More than 65,000 animal species have intersex individuals (Figure 3.3.14.1), born with either an absence or some combination of male and female reproductive organs, sex hormones, or sex chromosomes (Jarne & Auld, 2006). More than 500 animal species engage in homosexual or bisexual behaviors (Lehrer, 2006), such as the Mallard ducks shown in Figure 3.3.14.2.

Figure 3.3.14.1: A rare intersexed two-spotted bumble bee.

Figure 3.3.14.2: A male Mallard duck couple.

Gender

At an early age, we begin learning cultural norms for what is considered masculine and feminine. For example, American children may associate long hair or dresses with femininity. Later in life, as adults, we often conform to these norms by behaving in gender-specific ways: as men, we build houses; as women, we bake cookies (Marshall, 1989; Money et al., 1955; Weinraub et al., 1984).

Because cultures change over time, so too do ideas about gender. For example, European and American cultures today associate pink with femininity and blue with masculinity. However, less than a century ago, these same cultures were swaddling baby boys in pink, because of its masculine associations with "blood and war," and dressing little girls in blue, because of its feminine associations with the Virgin Mary (Kimmel, 1996).

Variations in Gender

Just as biological sex varies more widely than is commonly thought, so too does gender. Cisgender individuals' gender identities correspond with their birth (biological) sexes- biological males with masculine gender identities and biological females with feminine gender identities. In contrast, transgender individuals' gender identities do not correspond with their birth (biological)

sexes. The Latin prefix "cis" means "on the same side"; the prefix "trans" means "across". Many cisgender people do not self-identify as such. As with transgender people, the term or usage of cisgender does not indicate a person's sexual orientation or gender role expression (TSER, 2022). As mentioned in the section on intersex conditions (people whose sex characteristics or anatomy differ from typical development), intersex and transgender are not interchangeable terms; many transgender people have no intersex traits, and many intersex people do not consider themselves transgender. Because gender is so deeply ingrained culturally, rates of transgender individuals vary widely around the world (Table 3.3.14.1).

Nation	Transgender people per 100,000
Sweden	.17
Poland	.26
Ireland	1.4
Japan	1.4
India	167
Thailand	333
United States	476
Malaysia	1,333

Table 3.3.14.1: Nations vary in the number of transgender people found in their populations (De Gascun et al., 2006; Dulko & Imielinskia, 2004; Landen et al., 1996; Okabe et al., 2008, Conron et al., 2012; Winter, 2009).

Cultural Recognition of Gender Variations

Some cultures formally recognize the presence of people who do not conform to an expectation of biological sex matching gender identity. For example, "[some Native American tribes] believed that in addition to the prevailing variants of *man within man* and *woman within woman*, nature sometimes created a *man*'s *mind within the body of a woman* and a *woman*'s *mind within the body of a man*" (Panksepp, 2004, page 232). Transgender women are referred to as *fa'afafine* in the Samoan population (prevalence of five percent, Tan, 2016); *muxes* in Oaxaca, Mexico (as many as six percent of biological males, Stephen, 2002); *kathoey* (Figure 3.3.14.3) in Thailand; and *hijras* (Figure 3.3.14.3) in Pakistan, India, Nepal, and Bangladesh. Hijiras are recognized by their governments as a third gender (Pasquesoone, 2014).

Figure 3.3.14.3: Hjira dancer in Nepal and kathoey performers at a cabaret in Pattaya, Thailand.

Although incidence rates of transgender individuals differ significantly between cultures, transgender women (TGW)- whose birth sex was male- are by far the most frequent type of transgender individuals worldwide. Of the 18 countries studied by Meier and Labuski (2013), 16 of them had higher rates of TGW than transgender men (TGM)- whose birth sex was female- and the 18 country TGW to TGM ratio was 3 to 1.

However, the ratio of TGW to TGM individuals may be changing. A 2015 meta-analysis found that the overall incidence of transgender was 4.6 per 100,000 individuals, comprised of 6.8 TGW and 2.6 TGM, numbers that corroborate earlier reports of significantly higher rates of TGW than TGM individuals. A time analysis of the studies included revealed that the overall prevalence of transgender individuals had increased over the past 50 years (Arcelus et al., 2015). Echoing this trend, Leinung and Joseph (2020) reported an increase in individuals seeking hormone therapy in the past 25 years, and also indicated that the number of people requesting hormone therapy specifically for TGM transitions had increased steadily since 1990, resulting in equivalent numbers of TGW and TGM individuals being treated by 2017. It is unclear whether or how much this change reflects greater acceptance, destigmatization, and decreasing barriers to care specifically for TGM individuals (as the authors suggest), or if it may also represent a true increase in the number of TGM individuals in contemporary populations.

Role of Sex Hormones in Transgender Treatment

Feminizing or masculinizing hormone therapy is the administration of exogenous endocrine agents to induce changes in physical appearance. Hormone therapy is inexpensive relative to surgery, and highly effective in the development of some secondary sex characteristics, such as facial and body hair in transgender men (TGM, sometimes called female-to-male [FTM] individuals) or breast development in transgender women (TGW, sometimes called male-to-female [MTF] individuals). Thus, hormone therapy is often the first (and sometimes only) medical gender affirmation intervention accessed by transgender individuals looking to develop masculine or feminine characteristics consistent with their gender identity. In some cases, hormone therapy may be required before surgical interventions can be conducted. Transgender women are prescribed estrogen and anti-testosterone medication (such as cyproterone acetate and spironolactone). Transgender men are prescribed testosterone.

Scientific and Societal Understanding of Gender Variations

Hormones that masculinize the brain in chromosomally male (XY) individuals are distinct from those that lead to the development of a typically male body form. "Due to this branching of control factors for brain and body organization, it is quite possible for a male-type body to contain a female-type brain, and for a female-type body to contain a male-type brain" (Panksepp, 2004, page 225). These developmental deviations could influence an individual's ultimate sexual orientation and/or gender identity. An example of conflicting brain and body organization comes from a study which found that the bed nucleus of the stria terminalis (BNST, an area located near the hypothalamus that is known to be important for sexual behavior) was "female-like" in size (smaller than cisgender males and similar to cisgender females) in the brains of six male-to-female transsexuals. This difference was not correlated with either adult hormone levels or sexual orientation (Zhou et al., 1995). Given that studies requiring post-mortem

brain tissue to examine tiny brain areas are very difficult to conduct, this type of information is scarce.

Nonetheless, our scientific knowledge and general understanding of gender identity continue to evolve, and young people today have more opportunity to explore and openly express different ideas about what gender means than previous generations. Recent studies indicate that a majority of Millennials (birth years 1981-1996) regard gender as a spectrum instead of a strict male/female binary, and that 12% identify as transgender or gender non-conforming. Additionally, more people know others who use gender-neutral pronouns, such as they/them (Kennedy, 2017). This change in language may indicate that Millennials and Generation Z people (birth years 1997-2012) understand the experience of gender itself differently. As young people lead this change, other changes are emerging in a range of spheres, from public bathroom policies to retail organizations. For example, some retailers are starting to change traditional gender-based marketing of products, such as removing “pink and blue” clothing and toy aisles. Despite these changes, those who exist outside of traditional gender norms face difficult challenges. Even people who vary slightly from traditional norms can be the target of discrimination and sometimes even violence.

Summary

Although often used interchangeably, the terms sex and gender refer to distinct concepts, and sexual orientation is a third aspect of an individual's characteristics. Sex refers to the structures relevant for biological reproduction (such as ovaries in females and testes in males), whereas gender refers to an individual's sense of being masculine, feminine, neither or both. Gender identity is the psychological representation of biological sex, and gender role is the sociological representation. Sexual orientation describes a person's sexual attraction (or lack thereof) to others. Variations in each of these (sex, gender, and sexual orientation) is considered normal by international scientific and medical communities.

Children begin to learn cultural norms for masculine and feminine behaviors very early, but cultures vary widely and even the same culture changes over time- thus, ideas about gender also change. Cisgender individuals’ gender identities correspond with their birth (biological) sexes, while transgender individuals’ gender identities do not correspond with their birth (biological) sexes. Intersex (people whose sex characteristics or anatomy differ from typical development) and transgender are not interchangeable terms; many transgender people have no intersex traits, and many intersex people do not consider themselves transgender. Rates of transgender individuals vary widely around the world. Some cultures formally recognize the presence of people who do not conform to an expectation of biological sex matching gender identity, such as some Native American tribes. Transgender women specifically are referred to as *fa'afafine* in Samoa; *muxes in* Oaxaca, Mexico; *kathoey* in Thailand; and *hijras* in Pakistan, India, Nepal, and Bangladesh.

Worldwide, transgender women (whose birth sex was male) have been by far the most frequent type of transgender individuals, with a ratio of about three transgender women to one transgender man. However, recent trends (at least in people requesting hormone therapy) have progressively changed since the 1990s, such that by 2017, an equivalent number of transgender women and transgender men were being treated. Hormone therapy is used to induce changes in physical appearance. It is inexpensive relative to surgery, and highly effective in the development of some secondary sex characteristics, such as facial and body hair in transgender men, and breast development in transgender women. Hormone therapy is often the first (and sometimes only) medical gender affirmation intervention accessed by transgender individuals.

During prenatal development, hormones that masculinize the brain are distinct from those that lead to the development of a typically male body form. Developmental deviations can occur (such that the body is masculinized but the brain is not, for example), and could in turn influence an individual's ultimate sexual orientation and/or gender identity. Our scientific knowledge and general understanding of gender identity continue to evolve. Recent studies indicate that a majority of Millennials (birth years 1981-1996) regard gender as a spectrum instead of a strict male/female binary, and that 12% identify as transgender or gender non-conforming. Nonetheless, individuals who exist outside of traditional gender norms face difficult challenges, and may be the target of discrimination and even violence.

People's sense of gender identity does not always match their anatomy. Some people do not identify as either male or female, and instead, they identify as non-binary, or genderqueer. Others may identify as a gender that is the opposite of what is typically associated with their chromosomes or reproductive organs. These people are called transgender, and they may choose to transition to the opposite gender, a process that may or may not involve physical modifications. Watch the video below to learn about the use of hormones in gender transitioning.

3.3.15: Sexual Orientation

Learning Objectives

1. Understand Kinsey's continuum of sexual orientation and the range of sexual orientation labels used now
2. Explain the evidence for at least two nonsocial causes of sexual orientation

Overview

This section discusses sexual orientation, a person's emotional and sexual attraction to other individuals of a particular sex or gender. Kinsey's continuum of sexual orientation (a range from exclusively heterosexual through equally bisexual to exclusively homosexual) is introduced, as well as some additional terms that are in contemporary use (polysexual, pansexual, and asexual). The development and origins of sexual orientation are addressed, including research exploring genetics, prenatal hormone exposure, the fraternal-birth-order effect, and childhood development. Regardless of the root cause(s) for a person's sexual orientation (and/or gender identity), it is not a conscious choice and cannot be easily changed.

Sexual Orientation

A person's **sexual orientation** is their emotional and sexual attraction to a particular sex or gender, including a continuing pattern of romantic or sexual attraction (or a combination of these) to persons of a given sex or gender. According to the American Psychological Association (APA) (2016), sexual orientation also refers to a person's sense of identity based on those attractions, related behaviors, and membership in a community of others who share those attractions. Although a person's intimate behavior may have sexual fluidity- changing due to circumstances (Diamond, 2009)- sexual orientations are relatively stable over one's lifespan, and are influenced by genetics (Frankowski, 2004). Sexual orientation is distinct and independent from both biological sex and gender, as discussed in Section 13.4.

While some argue that sexual attraction is primarily driven by reproduction (e.g., Geary, 1998), empirical studies point to pleasure as the primary force behind our sex drive. For example, in a survey of college students who were asked, "Why do people have sex?" respondents gave more than 230 unique responses, most of which were related to pleasure rather than reproduction (Meston & Buss, 2007). Here's a thought-experiment to further demonstrate how reproduction has relatively little to do with driving sexual attraction: Add the number of times you've had and/or hope to have sex during your lifetime. With this number in mind, consider how many times the goal was (or will be) for reproduction versus how many it was (or will be) for pleasure. Which number is greater?

Figure 3.3.15.1: First photo: "Victory!" - This lesbian couple has been waiting 31 years to be able to marry (Sacramento, CA). Second photo: Two men holding hands, Gay Pride Project (Baltimore, MD).

A Continuum of Sexual Orientation

Instead of thinking of sexual orientation as being two dichotomous categories- homosexual (attracted to the same sex, Figure 3.3.15.1) and heterosexual (attracted to the opposite sex)- sexuality researcher Alfred Kinsey and colleagues argued that it is a continuum (Kinsey, Pomeroy, & Martin, 1948). They measured sexual orientation using a seven-point scale called the Heterosexual-Homosexual Rating Scale (Figure 3.3.15.2), in which zero is exclusively heterosexual, three is bisexual (with equal attractions to the same and opposite sexes), and six is exclusively homosexual. Research done over several decades has supported this idea that sexual orientation ranges along a continuum, from exclusive attraction to the opposite sex/gender to exclusive attraction to the same sex/gender (Carroll, 2016).

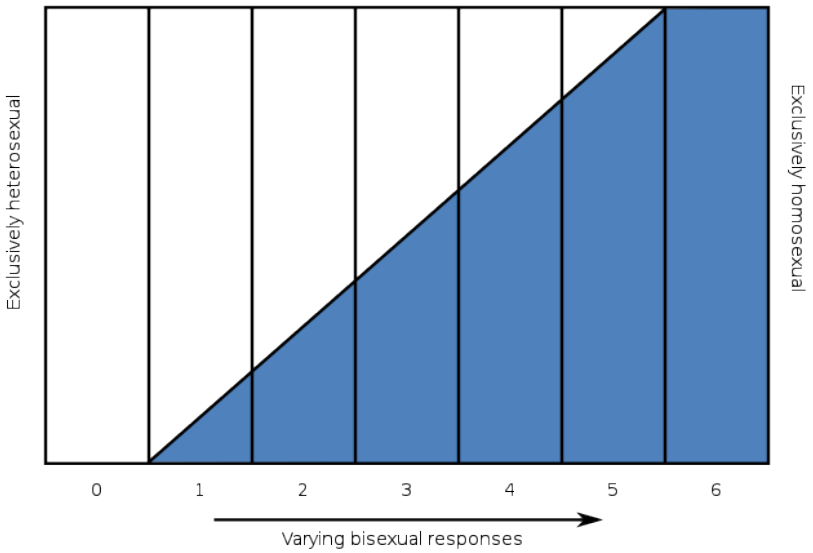

Figure 3.3.15.2: The Kinsey scale, a tool which enables an individual to select a response on a scale between heterosexual and homosexual. 0= exclusively heterosexual, 1= predominantly heterosexual, only incidentally homosexual, 2= predominantly heterosexual, more than incidentally homosexual, 3= equally heterosexual and homosexual, 4= predominantly homosexual, more than incidentally heterosexual, 5= predominantly homosexual, only incidentally heterosexual, and 6= exclusively homosexual.

The commonly stated notion that “10% of people are homosexual” originates (erroneously) from Kinsey’s 1948 study, which found that 10% of men reported being exclusively homosexual for at least three years during adulthood. In addition to the likelihood

that Kinsey's sample overestimated the actual occurrence of homosexuality in the population, only 4% of the male respondents in his study reported being homosexual their entire lifetime. This figure is much closer to the 3.5% prevalence of non-heterosexual (gay/lesbian/bisexual) orientation found in more recent and representative studies of US and other Western populations (Bailey et al., 2016). However, it is important to note that how a respondent is asked to report their sexual orientation produces very different results. Researchers using the Kinsey Scale have found 18% to 39% of Europeans and Americans identifying as somewhere between heterosexual and homosexual (Lucas et al., 2017; YouGov.com, 2015). These percentages drop dramatically to only 0.5% to 1.9% non-heterosexual when researchers force individuals to respond using only two categories (Copen, Chandra, & Febo-Vazquez, 2016; Gates, 2011).

Although the percentage of US adults identifying as LGBT (lesbian/gay/bisexual/transgender) remained relatively stable through the early 2010s (and still remains stable in older-aged cohorts), there is evidence that younger people are more likely to identify as LGBT than previous generations, which is in turn increasing the overall prevalence in the population. Gates (2017, page 1221) reports that "the percentage of older age cohorts identifying as LGBT has remained stable or declined despite large increases among Millennials, who are now three times more likely than Baby Boomers to identify as LGBT (7.3% vs 2.4%)." (Millennials are people born during the years 1981 through 1996 and Baby Boomers are people born during the years 1946 through 1964 (Dimock, 2019).)

Indeed, even beyond a continuum from heterosexual to homosexual, sexual orientation is as diverse as gender identity. Some examples of sexual orientation include **heterosexuality** (attraction to the opposite sex/gender), **homosexuality** (attraction to the same sex/gender, also referred to as **same-sex attraction**- some people find the term homosexuality offensive since it was previously classified as a mental illness), **bisexuality** (attraction to two sexes/genders), **polysexuality** (attraction to multiple sexes/genders), **pansexuality** (attraction to all sexes/genders), and **asexuality** (no sexual attraction to any sex/gender).

Development and Origins of Sexual Orientation

According to current scientific understanding, individuals are usually aware of their sexual orientation between middle childhood and early adolescence. However, this is not always the case, and some do not become aware of their sexual orientation until much later in life. It is not necessary to participate in sexual activity to be aware of these emotional, romantic, and physical attractions; people can be celibate (not participating in any type of sexual activity) and still recognize their sexual orientation. Some researchers argue that sexual orientation is not static and inborn, but is instead fluid and changeable throughout the lifespan. Regardless of when sexual orientation is recognized or how it is expressed, it is clearly not a conscious "choice" for either heterosexual or non-heterosexual individuals.

There is no scientific consensus regarding the exact reasons why an individual holds a particular sexual orientation. Research has examined possible biological, developmental, social, and cultural influences on sexual orientation, but there is no conclusive evidence that links sexual orientation to one specific factor (APA, 2016). In an extensive review of evidence for the causal mechanisms of human sexual orientation, Bailey et al. (2016, page 46) state that "no causal theory of sexual orientation has yet gained widespread support", further pointing out that the most probable scientific hypotheses are difficult to test. The most commonly suggested social causes of homosexuality, "sexual recruitment by homosexual adults, patterns of disordered parenting, or the influence of homosexual parents", generally have only weak support and are compromised by many confounding factors (Bailey et al., 2016, page 46). They conclude that "there is considerably more evidence supporting nonsocial causes of sexual orientation than social causes". Some of the prominent nonsocial causes that have been examined include genetics, prenatal hormone exposure, the fraternal-birth-order effect, and behavior differences during childhood development.

Genetics

One method of measuring the genetic roots of sexual orientation is concordance rates, which is the probability that a pair of individuals has the same sexual orientation. If both twins have the same sexual orientation, they are "concordant" for this trait. Concordance rates are calculated and compared between people who share the same genetics (monozygotic twins, 99%), some of the same genetics (dizygotic twins, 50%, and siblings, 50%), and non-related people (randomly selected from the population). Researchers find that concordance for sexual orientation is highest for monozygotic twins; and concordance rates for dizygotic twins, siblings, and randomly-selected pairs are not significantly different (Bailey et al. 2016; Kendler et al., 2000). Since concordance rates are most similar for monozygotic twins, this indicates that "nature" (genetics) influences the expression of sexual orientation. However, monozygotic twins do not always have the same sexual orientation, so "nurture" (the environment and individual experiences) also plays a role in determining sexual orientation. Nonetheless, because sexual orientation is a hotly debated issue, an appreciation of the genetic aspects of attraction can be an important piece of this dialogue.

Prenatal Hormone Exposure

Excess or deficient exposure to hormones during prenatal development has also been theorized as an explanation for non-heterosexual orientation. One-third of females exposed to abnormal amounts of prenatal androgens due to congenital adrenal hyperplasia (CAH, see the section on differences of sexual development) identify as bisexual or lesbian (Cohen-Bendahan, van de Beek, & Berenbaum, 2005). In contrast, too little exposure to prenatal androgens may affect male sexual orientation (Carlson, 2011).

Fraternal-Birth-Order Effect

The "fraternal-birth-order effect" is the well-documented (and cross-culturally robust) finding that homosexual males tend to have more older brothers than heterosexual males (Bailey et al., 2016). Interestingly, this effect is particular to right-handed homosexual males (Blanchard et al., 2006; Bogaert, 2007). This effect is also specific to biological brothers (Figure 3.3.15.3), meaning that the number of sons that have been gestated by the man's mother is the important factor, whether or not the man was raised with those brothers. "The effect is almost certainly causal, with each additional older brother causing an increase in the chances of a man's being homosexual. ... Assuming that a man without any older brothers has a 2% chance of being homosexual, a man with one older brother has a 2.6% chance; with two, three, and four older brothers, the chances are 3.5%, 4.6%, and 6.0%, respectively" (Bailey et al., 2016, page 79). One proposed mechanism for this is that the mother creates antibodies against proteins on her developing son's Y chromosome (a possibility which increases with each pregnancy of a son), and that those antibodies may prevent the normal functioning of subsequent sons' Y chromosomes (Bailey et al., 2016; O'Hanlan et al., 2018).

Figure 3.3.15.3: Four of the Marx Brothers in "I'll Say She Is!"—caricatures by John Decker (1924). Every biological older brother increases the likelihood of a man being homosexual. Groucho (the brother with the mustache) was the fourth brother (of six- the eldest died in infancy, https://en.Wikipedia.org/wiki/Marx_Brothers) and called himself "straight but curved around the edges" (http://everydayheterosexism.blogspot.com/2012/11/the-marx-brothers.html).

Childhood Development

Two other forms of evidence supporting non-social causes of sexual orientation, particularly for males, are related to childhood development and behavior: gender nonconformity and outcomes from attempts to alter gender identity. Children who display gender nonconformity by not following the roles that society expects (Figure 3.3.15.4) are more likely to be homosexual as adults. This is a robust finding across cultures, but applies much more strongly to boys than girls. Additionally, "when infant boys are surgically and socially "changed" into girls, their eventual sexual orientation is unchanged (i.e., they remain sexually attracted to females)" (Bailey et al., 2016, page 46). This "natural experiment" is most commonly the result of irreparable damage to the penis, as was the case with David Reimer (see the section on differences of sexual development).

Figure 3.3.15.4: A two-year-old boy plays nursing his doll. Gender nonconformity in childhood is associated with homosexuality in adulthood.

In Closing: Gender and Sexual Orientation

Although gender (discussed in Section 13.4) and sexual orientation are distinct, some research addresses both concepts concurrently. A review of biological origins for both sexual orientation and gender identity concludes that "multidisciplinary evidence reveals that ... sexual orientation and gender identity are conferred ... during the first half of pregnancy" and that "multiple layers of evidence confirm that sexual orientation and gender identity are as biological, innate and immutable as the other traits conferred during that critical time in gestation" (O'Hanlan et al., 2018). In other words, you cannot change an individual's sexual orientation and/or gender identity any more easily than you can change whether or not they developed a standard human body form with two arms and legs, two eyes and ears, a nose, mouth and typical internal organs.

Summary

Sexual orientation is an individual's emotional and sexual attraction to a particular sex or gender, including their sense of identity based on those attractions and related behaviors. A person may exhibit sexual fluidity (with attractions and behaviors changing due to circumstances), but sexual orientations tend to be relatively stable over the lifespan. Some argue that sexual attraction is primarily driven by reproduction, but empirical studies suggest that pleasure is the primary force behind our sex drive, and that reproduction has relatively little to do with it.

Arguing that dividing people into homosexual and heterosexual did not capture the breadth of human sexual orientation, Kinsey created a continuum with a seven-point scale called the Heterosexual-Homosexual Rating Scale. Zero is exclusively heterosexual, three is bisexual (with equal attractions to the same and opposite sexes), and six is exclusively homosexual. Subsequent research has supported this idea that sexual orientation ranges along a continuum. Representative studies of US and other Western populations report a 3.5% prevalence of non-heterosexual (gay/lesbian/bisexual) orientation. However, how a respondent is asked to report their sexual orientation produces very different results: using the Kinsey Scale, 18% to 39% of Europeans and Americans identify as somewhere between heterosexual and homosexual, whereas only 0.5% to 1.9% of respondents identify as non-heterosexual when researchers force individuals to respond using only two categories. While the percentage of US adults identifying as LGBT (lesbian/gay/bisexual/transgender) remains stable in older-aged cohorts, younger people are more likely to identify as LGBT than previous generations. Examples of terms currently used to identify sexual orientation include heterosexuality (attraction to the opposite sex/gender), homosexuality or same-sex attraction (attraction to the same sex/gender), bisexuality (attraction to two sexes/genders), polysexuality (attraction to multiple sexes/genders), pansexuality (attraction to all sexes/genders), and asexuality (no sexual attraction to any sex/gender).

Individuals are usually aware of their sexual orientation between middle childhood and early adolescence, and sexual activity is not necessary for this recognition. There is no scientific consensus regarding the root cause(s) of sexual orientation, but it is clearly not a conscious "choice" for either heterosexual or non-heterosexual individuals. Research has examined many possible biological, developmental, social, and cultural influences on sexual orientation. Social causes (such as having homosexual parents,

recruitment by homosexual adults, and experiencing disordered parenting) have only weak support and many confounding factors. Nonsocial causes (such as genetics, prenatal hormone exposure, the fraternal-birth-order effect, and behavior differences during childhood development) have much more supporting evidence.

Genetic influence on sexual orientation is explored using twin studies. Concordance for sexual orientation is highest for monozygotic twins; and concordance rates for dizygotic twins, siblings, and randomly-selected pairs do not differ. Since concordance rates are most similar for monozygotic twins, this indicates that "nature" (genetics) influences the expression of sexual orientation. However, since monozygotic twins are not 100% concordant, "nurture" (the environment and individual experiences) also plays a role. During prenatal development, excess exposure to androgens for females and deficient exposure to androgens for males has also been theorized as explaining non-heterosexual orientation. Homosexual males tend to have more older brothers than heterosexual males, termed the "fraternal-birth-order effect. One proposed mechanism for this is that the mother creates antibodies against proteins on her developing son's Y chromosome, and that those antibodies may prevent the normal functioning of subsequent sons' Y chromosomes.

Childhood gender nonconformity and outcomes from attempts to alter gender identity also support non-social causes of sexual orientation (particularly for males). Boys who do not follow expected societal roles are more likely to be homosexual as adults. Additionally, when boys are “changed” into girls during childhood (often as a result of irreparable damage to the penis), they remain sexually attracted to women in adulthood. Both sexual orientation and gender identity are determined, at least in part, during prenatal development, and as such are not easily altered.

3.3.16: Sex Differences and Evolutionary Interpretations

Learning Objectives

1. Explain sex differences that have been reported in the brain, sensory systems and cognitive functions, and the limitations of these findings
2. Describe how hormones may influence sex differences in behavior, such as childhood toy preferences and aggressive behaviors
3. Identify the core premises of sexual strategies theory

Overview

After noting that the dichotomy does not truly reflect the variations seen in both biological sex and gender identity, this section discusses sex differences that have been reported between human males and females. Sex differences in the brain, sex differences in sensory systems and cognition, and sex differences in behavior are covered, with the last topic including a review of hormonal influences on sex differences in behavior followed by discussions of childhood toy preferences and aggressive behaviors. Finally, evolutionary interpretations of reproductive behavior is addressed, including sexual strategies theory and error management theory (as it relates to reproductive behaviors).

Sex Differences

Preliminary Note

Earlier sections have emphasized the lack of a strict dichotomy between males and females, both in terms of biological sex and gender identity. Nonetheless, most research splits people into two categories- most commonly based on their biological sex assigned at birth- and often also assumes that the biological sex reported correlates with gender identity. While this is useful to a degree, hopefully future research will take a more nuanced approach to all three aspects of an individual's "sexual" self- sex, gender, and sexual orientation! You will note below that when we compare men and women on psychological traits and characteristics, there is actually only a slight difference (typically no more than 5%) between the two, and only at the group level. Think of it this way- adult men in the U.S. are about 9% taller than adult women, on average (McDowell et al., 2008), and about 15% larger in body mass (Larsen, 2003). Yet everyone can think of examples of men who are shorter and/or smaller than many women, and women who are taller and/or larger than many men- and this physical difference is at least twice the size of any of the differences found in psychological domains!

Also, as you will learn in the section on sex differences in the brain, while differences between male and female brains have been reported at a group level, there is no way to reliably classify an individual brain as either male or female, due to both the large overlap between males and females and the fact that each brain has its own unique mosaic of both "male" and "female" traits in differing (and unpredictable) ways.

Introduction to Sex Differences

Hens and roosters are different (Figure 3.3.16.1). Cows and bulls are different. Men and women are different. Even girls and boys are different. Humans, like many animals, are sexually dimorphic (*di*, “two”; *morph*, “type”) in the size and shape of their bodies, their physiology, and for our purposes, their behavior.

Figure 3.3.16.1: Sex differences in appearance are often more pronounced in nonhuman animals than in humans. Male birds particularly, for example roosters, tend to have physical features that differ from the females and also differ significantly in size.

Interestingly, the physical differences in size and appearance (for many individuals, we can readily determine biological sex from visible traits) between human males and females is related to some of the differences we see in human reproductive behaviors. In the animal kingdom, many animals whose mating strategy is to form monogamous pairs have virtually indistinguishable males and females, whereas polygamous species (where one male typically mates with many females, and some males completely miss out on mating) are conspicuously different, often in both physical features and in size. While apparent in some bird species, such as the obviously different polygamous rooster and hen mentioned above (versus monogamous swans, with nearly identical males and females), these differences are particularly evident in (non-human) primate species (and many other mammals). Examples in primate species include the similarly-appearing monogamous gibbons (Jaffe, 2019, page 210-211), versus the polygamous gorillas (Jaffe, 2019, page 209), where adult males are much larger than females and gain the characteristic "silverback" coloring as they mature (Figure 3.3.16.2). A difference of around ten percent- precisely where the human species falls on this size-difference continuum- is the dividing line between "monogamous" and "polygamous"; in other words, species that have less than ten-percent difference in physical appearance and size between males and females are usually monogamous and species that have greater than ten-percent difference tend to be polygamous. For humans, "...the sexes differ more in human beings than in monogamous mammals, but much less than in extremely polygamous mammals..." (Daly & Wilson, 1996, page 13). Thus, it is not really surprising, from an evolutionary standpoint, that some humans adopt a monogamous strategy for mating and reproduction, and others follow a polygamous strategy.

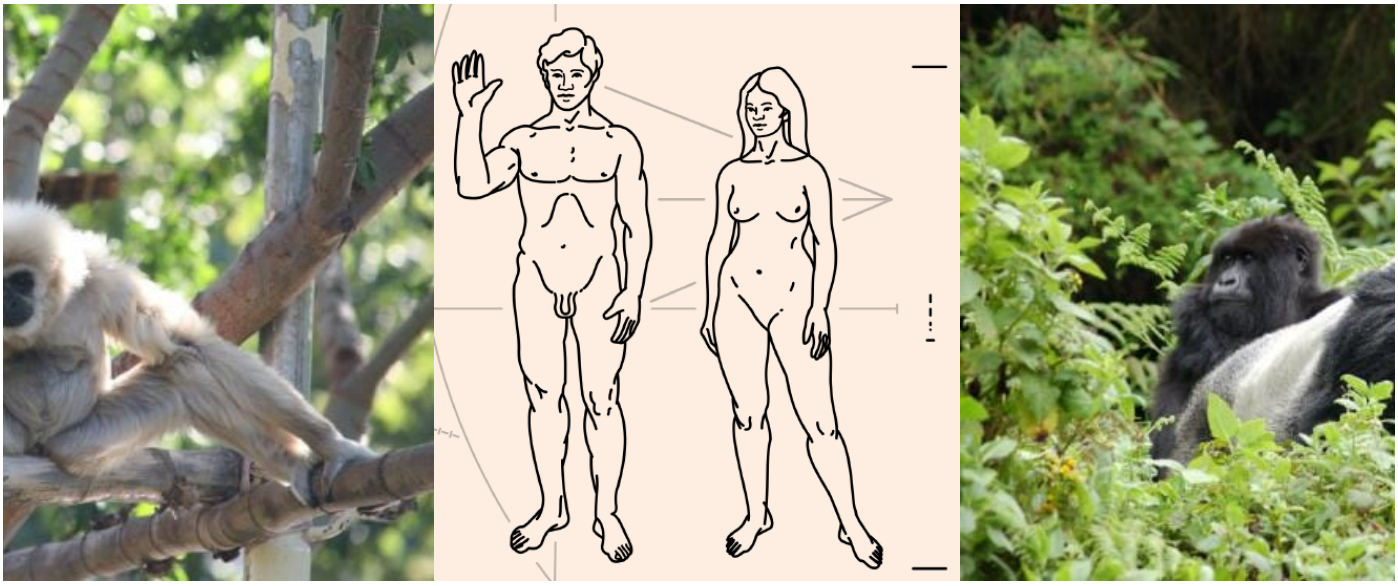

Figure 3.3.16.2: In humans (middle picture), males and females differ more than monogamous species, like White-handed Gibbons (left picture), but much less than polygamous species, like Mountain Gorillas (right picture).

Returning to human behavior, the behavior of boys and girls differs in many ways. Girls generally excel in verbal abilities relative to boys; boys are nearly twice as likely as girls to suffer from dyslexia (reading difficulties) and stuttering, and nearly four times more likely to suffer from autism. Boys are generally better than girls at tasks that require visuospatial abilities. Girls engage in nurturing behaviors more frequently than boys. More than 90% of all anorexia nervosa cases involve young women. Young men are twice as likely as young women to suffer from schizophrenia. Boys are much more physically aggressive and generally engage in more rough-and-tumble play than girls (Berenbaum, Martin, Hanish, Briggs, & Fabes, 2008). Many behavioral sex differences, such as the difference in physical aggressiveness, persist throughout adulthood. For example, there are many more men than women serving prison sentences for violent behavior. Below, this section addresses sex differences in the brain, in sensory systems and cognition, and in behavior, where sex differences in toy preferences and the previously mentioned aggressive behavior are discussed in greater detail.

Sex Differences in the Brain

Sex differences in overall human brain size have been reported for years (although the true significance of this finding is debatable). More recently, sex differences in specific brain structures have been discovered. For example, in rats, the sexually dimorphic nucleus (SDN-POA) of the preoptic area of the hypothalamus is much larger in males than females. This is a result of the organizing effects of gonadal steroid hormones upon brain and behavior, which is relatively constrained to the early stages of development. In rats, exposure to testosterone (which is converted to estradiol) or estradiol causes masculinization of the brain. (The same mechanism of a "female" hormone masculinizing the fetal brain is not present in primates, and thus presumably not in humans. Alpha-fetoprotein binds to estradiol in female rats to prevent masculinization of their brains.) Figure 3.3.16.3 depicts cross-sections through the brains of rats that show a male (A, left), a female (B, center), and a female treated with testosterone as a newborn (C, right). Note that the SDN-POA (the dark cell bodies) of the male are substantially larger than those of the untreated female but are equal in size to those of the testosterone-treated female. The extent that these sex differences in brain structure account for sex differences in behavior remain unspecified in mammals.

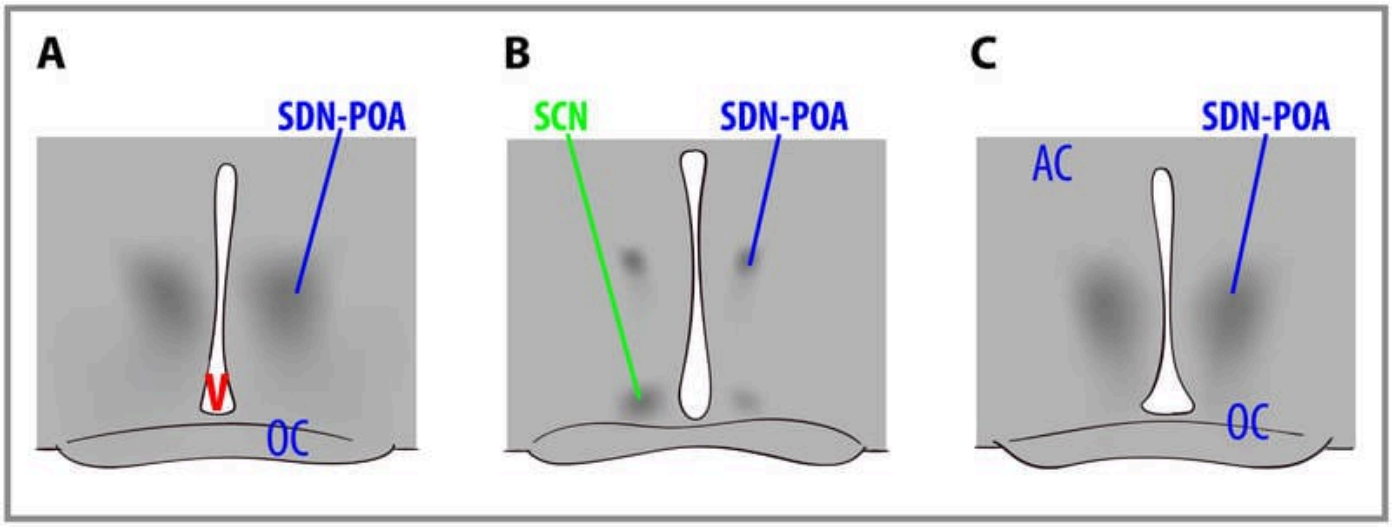

Figure 3.3.16.3: The sexually dimorphic nucleus of the preoptic area (SDN-POA). Rat brain cross-sections from a A) male (left), B) female (center), and C) female treated with testosterone as a newborn (right). OC = optic chiasm; SCN = suprachiasmatic nucleus; V = third ventricle.

In an area similar to the rat's SDN-POA, Simon LeVay (1991) reported a comparable difference in the human hypothalamus-INAH-3, the third interstitial nucleus of the anterior hypothalamus. Specifically, heterosexual men had INAH-3 nuclei that were more than twice as large (by volume) as homosexual men, whose INAH-3 nuclei volumes were similar to those of women. Although LeVay was able to replicate the result, attempts by another researcher lead to only a trend-level difference between heterosexual and homosexual men in the volume of INAH-3 (Byne 2000 & 2001, as cited by Bailey et al., 2016). Regardless of the true status of the possible differences in the human male's INAH-3 nucleus (it could be intermediate between the two researchers' findings, for example), "it would be unlikely that the INAH-3 size would be a key factor regulating sexual orientation. This is because there would be too many exceptions—homosexual men with a large INAH-3 and heterosexual men with a small INAH-3—to believe that INAH-3 size is crucial" (Bailey et al., 2016, page 72). The INAH-3 is a tiny structure- about the size of a grain of sand- and studying it requires post-mortem tissue. As such, it is unlikely that it will be studied further in the near future (Bailey et al., 2016).

For larger brain features, which can be studied in living people using imaging techniques, many brain differences between adult men and women have been reported, both in cortical regions and subcortical structures. An example of this includes magnetic resonance imaging (MRI) data suggesting that women have larger volumes of frontal and medial paralimbic cortices and men have larger volumes in the frontomedial cortex, amygdala and hypothalamus (Goldstein et al., 2001). However, closer scrutiny sometimes renders these sex differences unimportant. For example, the corpus callosum was widely believed to differ between males and females- the purported increased size in women was touted to result in greater connectivity between the right and left hemispheres of the brain- but has been found to not differ at all when men and women were matched for brain size (Luders et al., 2014). Another study underlining the importance of taking brain size into consideration was a twin study that found that a weak correlation between sex differences in the brain and behavioral sex differences turned out to be mainly driven by brain size. The authors warned that caution should therefore be used when inferring causality (van Eijk et al., 2021).

Additionally, Joel et al. (2015) conducted an extensive study of over 1400 MRIs of human brains and found that when taking the entire brain into account (and not just looking at one specific area versus another, where sex differences have been reported at a group level), it is impossible to categorize brains into male and female forms. Instead, there was extensive overlap of “male” and “female” features in human brains and it was very rare to have internal consistency (only “male” or only “female” features) in a specific brain. Thus, while we can often categorize biological sex by looking at anatomical structures- there are often distinct differences between male and female bodies, and a given body usually has only male or only female structures- we cannot determine if a specific brain came from a male or female body, nor can we predict by knowing the sex/gender of a particular individual what form their brain has taken. The authors state that “each brain is a unique mosaic of features, some of which may be more common in females compared with males, others may be more common in males compared with females, and still others may be common in both males and females” (Joel et al., 2015, page 15472). Additionally, their findings support the notion that masculinization and feminization of brain areas are two separate processes that progress independently, allowing variations of differentiation in a “male” or “female” pattern to occur within the same brain.

Sex Differences in Sensory Systems and Cognition

Sex differences in a number of sensory and cognitive functions have also been reported. Females are generally more sensitive to

auditory information, whereas males are more sensitive to visual information. Females are also typically more sensitive than males to taste and olfactory input. Women display less lateralization of cognitive functions than men. On average, females generally excel in verbal, perceptual, and fine motor skills, whereas males outperform females on quantitative and visuospatial tasks, including map reading and direction finding. Interestingly, women with Turner syndrome (whose ovaries are not functional) often have impaired spatial memory.

Although reliable sex differences can be documented, these differences in ability are slight. It is important to note that there is more variation *within* each sex than *between* the sexes for most cognitive abilities (Figure 3.3.16.4).

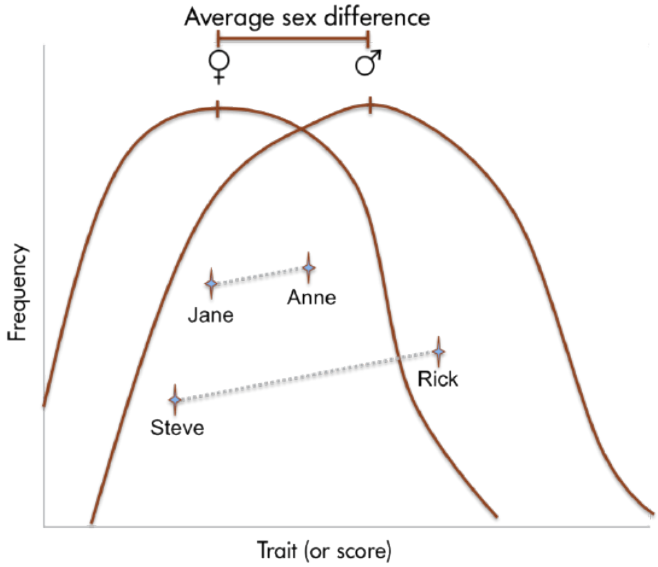

Figure 3.3.16.4: The average sex differences in human performance often reflect significant overlap between the sexes There are often greater differences in performance between individuals of the same sex (for example, between Steve and Rick in the figure) than between individuals of the opposite sex (for example, between Steve and Jane in the figure).

To emphasize the importance of recognizing the vast variation of personality traits and behavioral expressions found within all humans, regardless of their sex/gender, consider the following study results. Joel et al. (2015) conducted an analysis of the personality traits, attitudes, interests, and behaviors of more than 5,500 individuals. Their findings mirrored their MRI findings (great overlap between males and females and little internal consistency within the same individual). They report: "In accordance with the brain data, our analyses of gender-related data revealed extensive overlap between females and males in personality traits, attitudes, interests, and behaviors. Moreover, we found that substantial variability of gender characteristics is highly prevalent, whereas internal consistency is extremely rare, even for highly gender-stereotyped activities... Thus, most humans possess a mosaic of personality traits, attitudes, interests and behaviors, some more common in males compared with females, others more common in females compared with males, and still others common in both males and females" (Joel et al., 2015, page 15472). It is reasonable to conclude that overall, human males and females are more similar than they are different, both with regards to brain features and psychological traits.

Sex Differences in Behavior

Review of Hormonal Influences on Sex Differences in Behavior

The hormonal differences between men and women may account for adult sex differences that develop during puberty, but what accounts for behavioral sex differences among children *prior* to puberty and activation of their gonads? As discussed in section 13.2, the presence (or absence) of androgens determine whether the fetus develops a male or female body form. Androgens from the fetal testes steer the development of the body, central nervous system, and subsequent behavior in a male direction. In contrast, fetal ovaries do not secrete high concentrations of hormones, so the body, central nervous system, and later, behavior, follow a female pathway.

As discussed in section 13.1, gonadal steroid hormones have organizational (or programming) effects upon brain and behavior (Phoenix, Goy, Gerall, & Young, 1959). These organizing effects are relatively constrained to the early stages of development. In rats, early steroid hormone treatment causes relatively irreversible and permanent masculinization of later adult behavior (mating

and aggressive). In contrast, activational effects of hormones (provided in adulthood to influence behaviors) are temporary and reversible. Thus, typical male behavior requires exposure to androgens during gestation (in humans) or immediately after birth (in rats) to somewhat masculinize the brain and also requires androgens during or after puberty to activate these neural circuits. Typical female behavior requires a lack of exposure to androgens early in life which leads to feminization of the brain and also requires estrogens to activate these neural circuits in adulthood. But this simple dichotomy, which works well with animals with very distinct sexual dimorphism in behavior, has many caveats when applied to people.

Childhood Toy Preferences

If you walk through any major toy store, then you will likely observe a couple of aisles filled with pink boxes and the complete absence of pink packaging of toys in adjacent aisles. Remarkably, you will also see a strong self-segregation of boys and girls in these aisles. It is rare to see boys in the "pink" aisles and vice versa. The toy manufacturers are often accused of making toys that are gender biased, but it seems more likely that boys and girls enjoy playing with specific types and colors of toys. Indeed, toy manufacturers would immediately double their sales if they could sell toys to both sexes. Boys generally prefer toys such as trucks and balls and girls generally prefer toys such as dolls. Although it is doubtful that there are genes that encode preferences for toy cars and trucks on the Y chromosome, it is possible that hormones might shape the development of a child's brain to prefer certain types of toys or styles of play behavior. It is also reasonable to believe that children learn which types of toys and which styles of play are appropriate to their gender (Figure 3.3.16.5). How can we separate the contribution of learning from underlying physiological mechanisms to understand sex differences in human behaviors? To untangle these issues, animal models are often used. Unlike the situation in humans, where sex differences are usually only a matter of degree (often slight), in some animals, members of only one sex may display a particular behavior. For example, often only male songbirds sing. Studies of such strongly sex-biased behaviors are particularly valuable for understanding the interaction among behavior, hormones, and the nervous system.

Figure 3.3.16.5: If you think back to the toys you played with and clothing you wore in your youth, do you think they were more a result of your hormonal activity or the choices that society and your parents made for you?

A study of vervet monkeys calls into question the primacy of learning in the establishment of toy preferences (Alexander & Hines, 2002). Female vervet monkeys preferred girl-typical toys, such as dolls or cooking pots, whereas male vervet monkeys preferred boy-typical toys, such as cars or balls. There were no sex differences in preference for gender-neutral toys, such as picture books or stuffed animals. Presumably, monkeys have no prior concept of "boy" or "girl" toys. Young rhesus monkeys also show similar toy preferences.

What then underlies the sex difference in toy preference? It is possible that certain attributes of toys (or objects) appeal to either boys or girls. Toys that appeal to boys or male vervet or rhesus monkeys, in this case, a ball or toy car, are objects that can be moved actively through space, toys that can be incorporated into active, rough and tumble play. The appeal of toys that girls or female vervet monkeys prefer appears to be based on color. Pink and red (the colors of the doll and pot) may provoke attention to infants.

Society may reinforce such stereotypical responses to gender-typical toys. The sex differences in toy preferences emerge by 12 or 24 months of age and seem fixed by 36 months of age, but are sex differences in toy preference present during the first year of life? It is difficult to ask pre-verbal infants what they prefer, but in studies where the investigators examined the amount of time that babies looked at different toys, eye-tracking data indicate that infants as young as three months showed sex differences in toy preferences; girls preferred dolls, whereas boys preferred trucks. Another result that suggests, but does not prove, that hormones are involved in toy preferences is the observation that girls diagnosed with congenital adrenal hyperplasia (CAH), whose adrenal glands produce varying amounts of androgens early in life, played with masculine toys more often than girls without CAH. Further, a dose-response relationship between the extent of the disorder (i.e., degree of fetal androgen exposure) and degree of masculinization of play behavior was observed. Are the sex differences in toy preferences or play activity, for example, the inevitable consequences of the differential hormonal environments of boys and girls, or are these differences imposed by cultural practices and beliefs? Are these differences the result of receiving gender-specific toys from an early age, or are these differences some combination of hormonal and cultural factors? Again, these are difficult questions to unravel in people.

Aggressive Behaviors

Note that in this section "aggressive behavior" is referring specifically to the expression of physical aggression (arguably the only type of aggression that can be studied in animals as well as humans). When aggression is defined more broadly to include relational aggression (such as non-physical bullying, gossiping, and humiliation), human males and females show much more similar overall levels of aggression (Swearer Napolitano, 2008).

The possibility for aggressive behavior exists whenever the interests of two or more individuals are in conflict (Nelson, 2006). Conflicts are most likely to arise over limited resources such as territories, food, and mates. A social interaction decides which animal gains access to the contested resource. In many cases, a submissive posture or gesture on the part of one animal avoids the necessity of actual combat over a resource. Animals may also participate in threat displays or ritualized combat in which dominance is determined but no physical damage is inflicted.

There is overwhelming circumstantial evidence that androgens mediate aggressive behavior across many species. First, seasonal variations in blood plasma concentrations of testosterone and seasonal variations in aggression coincide. For instance, the incidence of aggressive behavior peaks for male deer in autumn, when they are secreting high levels of testosterone. Second, aggressive behaviors increase at the time of puberty, when the testes become active and blood concentrations of androgens rise. Juvenile deer do not participate in the fighting during the mating season. Third, in any given species, males are generally more aggressive than females. This is certainly true of deer; relative to stags, female deer rarely display aggressive behavior, and their rare aggressive acts are qualitatively different from the aggressive behavior of males. Finally, castration (removal of the testes) typically reduces aggression in males, and testosterone replacement therapy restores aggression to pre-castration levels. There are some interesting exceptions to these general observations that are outside the scope of this section.

As mentioned, males are generally more aggressive than females. Certainly, human males are much more physically aggressive than females. Many more men than women are convicted of violent crimes in North America. The sex differences in human aggressiveness appear very early. At every age throughout the school years, many more boys than girls initiate physical assaults. Almost everyone will acknowledge the existence of this sex difference, but assigning a cause to behavioral sex differences in humans always elicits much debate. It is possible that boys are more aggressive than girls because androgens promote aggressive behavior and boys have higher blood concentrations of androgens than girls. It is possible that boys and girls differ in their aggressiveness because the brains of boys are exposed to androgens prenatally and the “wiring” of their brains is thus organized in a way that facilitates the expression of aggression (Figure 3.3.16.6). It is also possible that boys are encouraged and girls are discouraged by family, peers, or others from acting in an aggressive manner. These three hypotheses are not mutually exclusive, but it is extremely difficult to discriminate among them to account for sex differences in human aggressiveness.

Figure 3.3.16.6: Researchers have electrically stimulated particular regions in people's brains, and these individuals have burst into aggressive, violent behavior, helping demonstrate that such responses are hardwired into us.

What kinds of studies would be necessary to assess these hypotheses? It is usually difficult to separate out the influences of environment and physiology on the development of behavior in humans. For example, boys and girls differ in their rough-and-tumble play at a very young age, which suggests an early physiological influence on aggression. This pattern of more physical play behavior is seen in a number of other species including nonhuman primates, rats, and dogs. Is the difference in the frequency of rough-and-tumble play between boys and girls due to biological factors associated with being male or female, or is it due to cultural expectations and learning? Parents interact with their male and female offspring differently; they usually play more roughly with male infants than with females, which suggests that the sex difference in aggressiveness is partially learned. This difference in parental interaction style is evident by the first week of life. If there is a combination of biological and cultural influences mediating the frequency of rough-and-tumble play, then what proportion of the variation between the sexes is due to biological factors and what proportion is due to social influences? Importantly, is it appropriate to talk about "normal" sex differences when these traits virtually always arrange themselves along a continuum rather than in discrete categories? Because of these complexities in the factors influencing human behavior, the study of hormonal effects on sex-differentiated behavior has been pursued in nonhuman animals, where it is easier to hold environmental influences relatively constant.

With the appropriate animal model, we can address the questions posed above: Is the sex difference in aggression due to higher adult blood concentrations of androgens in males than in females, or are males more aggressive than females because their brains are organized differently by perinatal hormones? Are males usually more aggressive than females because of an interaction of early and current blood androgen concentrations? If male mice are castrated prior to their sixth day of life, then treated with testosterone in adulthood, they show low levels of aggression. Similarly, female mice ovariectomized prior to their sixth day but given androgens in adulthood do not express male-like levels of aggression. Treatment of perinatally gonadectomized males or females with testosterone prior to their sixth day life and also in adulthood results in a level of aggression similar to that observed in typical male mice. Thus, in mice, the proclivity for males to act more aggressively than females is organized perinatally by androgens but also requires the presence of androgens after puberty in order to be fully expressed. In other words, aggression in male mice is both organized and activated by androgens. Testosterone exposure in adulthood without prior organization of the brain by steroid hormones does not evoke typical male levels of aggression. The hormonal control of aggressive behavior in mice is thus similar to the hormonal mediation of heterosexual male mating behavior in other rodent species. Aggressive behavior is similarly both organized and activated by androgens in many species, including rats, hamsters, voles, dogs, and possibly some primate species.

Evolutionary Interpretations of Reproductive Behavior

Evolutionary psychology connects evolutionary principles with modern psychology and focuses primarily on psychological adaptations: changes in the way we think in order to improve our survival. (See Chapter 3 for more information on evolution.) This section describes one of the major evolutionary psychological theories that is relevant to reproductive behaviors- sexual strategies theory- which describes the psychology of human mating strategies and the ways in which women and men differ in those strategies. Additionally, an example from another evolutionary psychological theory- error management theory- that is

relevant to human mating is provided.

Sexual Strategies Theory

Sexual strategies theory is based on sexual selection theory- the evolution of characteristics due to mating advantage rather than survival advantage, such as traits that make an individual more attractive to the opposite sex, and competition between members of the same sex. It proposes that humans have evolved a list of different mating strategies, both short-term and long-term, that vary depending on culture, social context, parental influence, and personal mate value (desirability in the “mating market”). Initially the focus was on the differences between men and women in mating preferences and strategies (Buss & Schmitt, 1993), starting by looking at the minimum parental investment needed to produce a child. For women, even the minimum investment is significant: after becoming pregnant, they have to carry that child for nine months inside of them (Figure 3.3.16.7). For men, on the other hand, the minimum investment to produce the same child is considerably smaller—simply the act of sex.

Figure 3.3.16.7: Because women bear responsibility for pregnancy, they may use different mating strategies than men do.

These differences in parental investment have an enormous impact on sexual strategies. For a woman, the risks associated with making a poor mating choice is high. She might get pregnant by a man who will not help to support her and her children, or who might have poor-quality genes. And because the stakes are higher for a woman, *wise* mating decisions for her are much more valuable. While this discussion is not intended in any way to endorse "bad behavior", for men, biologically speaking, the need to focus on making wise mating decisions isn’t as important. That is, unlike women, men 1) don’t biologically have the child growing inside of them for nine months, and 2) do not have as high a cultural expectation to raise the child. This logic leads to a powerful set of predictions: In short-term mating, women will likely be choosier than men (because the costs of getting pregnant are so high), while men, on average, will likely engage in more casual sexual activities (because this cost is greatly lessened). Due to this, men will sometimes deceive women about their long-term intentions for the benefit of short-term sex, and men are more likely than women to lower their mating standards for short-term mating situations.

An extensive body of empirical evidence supports these and related predictions (Buss & Schmitt, 2011). Men express a desire for a larger number of sex partners than women do. They let less time elapse before seeking sex. They are more willing to consent to sex with strangers and are less likely to require emotional involvement with their sex partners. They have more frequent sexual fantasies and fantasize about a larger variety of sex partners. They are more likely to regret missed sexual opportunities. And they lower their standards in short-term mating, showing a willingness to mate with a larger variety of women as long as the costs and risks are low.

However, it is also important to note that in situations where both the man and woman are interested in long-term mating, both sexes tend to invest substantially in the relationship and in their children. In these cases, the theory predicts that both sexes will be extremely choosy when pursuing a long-term mating strategy. Much empirical research supports this prediction, as well. In fact, the qualities women and men generally look for when choosing long-term mates are very similar: both want mates who are intelligent, kind, understanding, healthy, dependable, honest, loyal, loving, and adaptable.

Nonetheless, women and men do differ in their preferences for a few key qualities in long-term mating, because of somewhat distinct adaptive problems. Modern women have inherited the evolutionary trait to desire mates who possess resources, have qualities linked with acquiring resources (e.g., ambition, wealth, industriousness), and are willing to share those resources with them. On the other hand, men more strongly desire youth and health in women, as both are cues to fertility. These male and female differences are universal in humans. They were first documented in 37 different cultures, from Australia to Zambia (Buss, 1989), and have been replicated by dozens of researchers in dozens of additional cultures (for summaries, see Buss, 2012).

As we know, though, just because we have these mating preferences (e.g., men with resources; fertile women), people don't always get what they want. There are countless other factors which influence who people ultimately select as their mate. For example, the sex ratio (the percentage of men to women in the mating pool), cultural practices (such as arranged marriages, which inhibit individuals' freedom to act on their preferred mating strategies), the strategies of others (e.g., if everyone else is pursuing short-term sex, it's more difficult to pursue a long-term mating strategy), and many others all influence who we select as our mates.

Sexual strategies theory—anchored in sexual selection theory— predicts specific similarities and differences in men and women's mating preferences and strategies. Whether we seek short-term or long-term relationships, many personality, social, cultural, and ecological factors will all influence who our partners will be.

Error Management Theory

How we think, make decisions, and evaluate uncertain situations (error management theory) has also been used to predict adaptive biases in the domain of mating. Consider something as simple as a smile. In one case, a smile from a potential mate could be a sign of sexual or romantic interest. On the other hand, it may just signal friendliness. Because of the costs to men of missing out on chances for reproduction, error management theory predicts that men have a *sexual overperception bias*: they often misread sexual interest from a woman, when really it's just a friendly smile or touch. In the mating domain, the sexual overperception bias is one of the best-documented phenomena. It's been shown in studies in which men and women rated the sexual interest between people in photographs and videotaped interactions. As well, it's been shown in the laboratory with participants engaging in actual "speed dating," where the men interpret sexual interest from the women more often than the women actually intended it (Perilloux, Easton, & Buss, 2012). In short, error management theory predicts that men, more than women, will over-infer sexual interest based on minimal cues, and empirical research confirms this adaptive mating bias.

Summary

Humans, like many animals, are sexually dimorphic in the size and shape of their bodies, their physiology, and for our purposes, their behavior. Girls generally excel in verbal abilities, whereas boys generally have better visuospatial abilities. Boys are more likely to suffer from dyslexia, stuttering, autism, and schizophrenia, while most anorexia nervosa cases involve young women. Girls engage in nurturing behaviors more frequently, and boys generally engage in more rough-and-tumble play. One behavioral sex difference that persists into adulthood is the higher levels of physical aggression exhibited by boys and men.

In rats, the sexually dimorphic nucleus of the preoptic area in the hypothalamus (SDN-POA) is much larger in males than females. A female rat treated with testosterone as a newborn develops an SDN-POA similar in size to a typical male rat. In humans, a similar brain area, the third interstitial nucleus of the anterior hypothalamus (INAH-3), was found to be larger in heterosexual men than homosexual men (whose INAH-3 was similar in size to those of women). However, replication outside of the initial lab did not reach statistical significance. Brain imaging studies have reported various differences in cortical regions and subcortical structures, but closer scrutiny sometimes renders these sex differences unimportant, and caution should be used when inferring causality. A study of over 1400 MRIs of human brains found that when taking the entire brain into account, it is impossible to categorize brains into male and female forms. There was extensive overlap of "male" and "female" features in human brains and it was very rare to have internal consistency in a specific brain. These findings also support the notion that masculinization and feminization of brain areas are two separate processes that progress independently, allowing for considerable variation across individuals.

Sex differences in a number of sensory and cognitive functions have also been reported, but these differences in ability are slight. Furthermore, there is more variation *within* each sex than *between* the sexes for most cognitive abilities. An analysis of personality traits, attitudes, interests, and behaviors of more than 5,500 individuals mirrored the MRI findings (great overlap between males and females and little internal consistency within the same individual). It is reasonable to conclude that overall, human males and females are more similar than they are different, both with regards to brain features and psychological traits.

Boys generally prefer toys such as trucks and balls and girls generally prefer toys such as dolls. It is possible that hormones

shape the development of a child's brain to prefer certain types of toys or styles of play behavior, but children also learn which types of toys and which styles of play are appropriate to their gender. Studies of vervet monkeys and rhesus monkeys find that females prefer girl-typical toys, and males prefer boy-typical toys, with no sex differences in preference for gender-neutral toys. While society likely reinforces stereotypical responses to gender-typical toys in human children, sex differences in toy preferences emerge by 12 or 24 months of age and seem fixed by 36 months of age. Studies using eye-tracking indicate that infants as young as three months show stereotypical sex differences in toy preferences. Additionally, in a dose-response relationship, girls diagnosed with congenital adrenal hyperplasia (CAH) played with masculine toys more often than girls without CAH, suggesting that prenatal hormones may affect later toy preferences.

Aggressive behavior may occur when two (or more) individuals are in conflict, typically over limited resources such as territories, food, and mates. Evidence strongly suggests that androgens mediate aggressive behavior across many species. Seasonal variations in testosterone levels and variations in aggression coincide; aggressive behaviors increase at puberty (when the testes become active and androgens rise); in any given species, males are generally more aggressive than females; and castration (removal of the testes) typically reduces aggression in males, while testosterone replacement therapy restores aggression. Human males are much more physically aggressive than females, and these sex differences appear very early. It is possible that boys are more aggressive than girls because androgens promote aggressive behavior, it could be due to exposure to androgens prenatally, or boys may be encouraged to act in aggressive ways. These three hypotheses are not mutually exclusive, but it is extremely difficult to discriminate among them to account for sex differences in human aggressiveness. In many animal species (mice, rats, hamsters, voles, dogs, and possibly some primates), aggressive behavior is both organized and activated by androgens.

Sexual strategies theory describes the psychology of human mating strategies and the ways in which women and men differ in those strategies. Because differences in parental investment are so large between males and females- men have little necessary investment and consequently don't need to make wise choices, whereas mating decisions for women are much more important (since a minimum of none months carrying the child is required)- women are predicted to be choosier than men in short-term mating. Thus, men will sometimes deceive women for the benefit of short-term sex, and men are more likely than women to lower their mating standards for short-term mating situations. However, when choosing long-term mates, the qualities women and men seek are very similar: mates who are intelligent, kind, understanding, healthy, dependable, honest, loyal, loving, and adaptable. There are nonetheless some universal differences in mate preference- women desire mates who possess resources (and are willing to share them), and men more strongly desire youth and health in women (as both are cues to fertility).

3.4.1: Evolution of Minds and Behavior

Learning Objectives

1. Discuss the claim that nothing in psychology makes sense except in the light of evolution.
2. Explain the process of natural selection and provide an example.
3. Describe what is meant by adaptation and explain what is meant by a psychological adaptation.
4. Explain how evolution can be nonrandom, yet still without purpose.
5. Describe what William James meant by the term "instincts" applied to humans, according to Cosmides and Tooby.
6. Discuss how evolutionary psychologists conceptualize human nature.
7. Discuss evolution as the unifying principle for psychology, given that evolution is the unifying principle for all of biology.
8. Discuss how two types of selection (hint: one of these is kin selection) may explain the duality of human moral nature and feelings of moral conflict.
9. Describe the primary features of evolutionary psychology as an approach to the study of the mind and brain.

Overview

Why do humans and other animals move, why do they have particular mental capabilities and not others, and what laws or principles govern the organization of behavior and mental processes? In this section, the concept of evolution will be introduced and the insights it can provide regarding mind and behavior considered. When we recognize that mental activities and behavior in humans and other animals are the product of a biological organ, the brain, we can then apply principles of biological science to an understanding of psychology. This approach focuses attention on the biological functions served by mental abilities and behavior and how they contribute to adaptation to environmental change.

Evolution, Natural Selection, and Psychological Adaptation

> “In the distant future I see open fields for far more important researches. Psychology will be based on a new foundation, that of the necessary acquirement of each mental power and capacity by gradation.” Charles Darwin, *On the Origin of Species* (1859/1996, p. 394)

> “Nothing in biology makes sense except in the light of evolution.” Theodosius Dobzhansky (1973, p. 125)

When looking at nature, it is important to ask why things in nature have the properties that they do. This is especially important when thinking about organisms. Why do organisms possess the traits that they do? Why do birds have feathers? Why do we have emotions and why are our emotions so similar to the emotions found in a wide range of other animal species? Why do we have the capacity to think, why does our thinking take the forms that it does, and why are many of our thinking processes fundamentally similar to the thinking processes found in many other animal species? Why do we see color, while many other species don't? Why do we have the capacity to form mental images of the past and of imagined futures?

Psychology is the scientific study of mental processes and behavior. These processes are, of course, all functions of a biological organ, the brain. Like other organs, the brain and its operations have evolutionary origins. Understanding evolution can give us fresh insights about our psychology and the psychology of other species. The characteristics of organisms, including mental and behavioral traits, perform biological functions that contribute to survival and reproduction.

The minds and behavior of organisms have been shaped by evolutionary forces over millions of years, just like their anatomical and physiological features. To the trained eye, the mark of evolution is still evident in the psychology of present-day humans and other animals. And, as Darwin's principle of the continuity of species predicts, human and animal species, although diverse, show fundamental similarities in mind and behavior just as they do in their anatomy and physiology. Although there are many factors that affect evolution, the key driving force in evolution is the process of natural selection (Dawkins, 1976, 1982).

Natural Selection

Darwin was not the first to propose that species evolve, that they change over time. Darwin's brilliant insight was the discovery of the primary process which guides evolutionary change--natural selection, the survival and reproduction of the "fittest". "Fit" in this context does not mean the healthiest or the strongest, rather it is a reference to the ability to pass one's genes on to the next generation. Natural selection is similar to artificial selection, a process used by animal breeders to enhance characteristics which they deem desirable. But in natural selection it is the environment that does the selection.

Natural selection acts on natural variation within populations. One important feature of life is that individual organisms within any sexually-reproducing species vary from one another in countless ways. Natural selection works because some individuals are better suited to the environment than others; those individuals better fit to the environment have a competitive advantage and naturally survive and reproduce in greater numbers and therefore pass on their heritable (genetic) traits to succeeding generations with greater frequency. This is the essence of evolution.

Evolution by natural selection is inevitable given three factors:

- genetic variation in heritable traits in a population of reproducing organisms due to mutation and the mixing of genes during sexual reproduction;
- competition among members of the population for limited environmental resources;
- those individuals who are better suited, better "fit," to the demands and opportunities of the environment have a competitive advantage and therefore survive and reproduce in greater numbers. The result is the proliferation of the genes and traits which provide superior fitness to the environment. Fitness is measured not simply in terms of survival, but more importantly by reproductive success, the number of living offspring that are produced.

In other words, some individuals, by chance, happen to have genetic characteristics that make them better prepared to survive and reproduce, leading their genes to be selected and to persist in future generations. By this process of selection, traits which give a competitive edge in solving problems of survival and reproduction and in exploiting environmental opportunities tend to be preserved over generations, while traits less well-suited are removed. For example, those better at predator avoidance, better at obtaining energy from food, better at successful mating, or better at inventing ways to use the environment for adaptive advantage survive and reproduce more offspring. By this process of natural selection, over countless generations, species of living things evolve characteristics (including mental and behavioral traits) that are well-adapted to solve problems and to exploit opportunities in their particular environments. Gradually, over long periods of time, organisms acquire adaptive "design" by completely natural and unintentional processes. Note that as the environment changes, new traits may evolve. In a sense, evolutionary change tracks changes in the environment, creating an improving match between organism and environment over evolutionary time.

Nevertheless, relatively rapid changes in the environment may outpace the rate of evolutionary change. This means that adaptations that evolved for an earlier environment may not necessarily be well suited to the current environment. This is important in understanding some of the psychological traits of humans that were once advantageous, but which have now become non-adaptive. For example, some experts have argued that humans have an innate disposition to be territorial and to be suspicious and wary of strangers, of outsiders, and perhaps even hostile to those outside of their own group. Although this may have been an adaptive psychological trait in our ancient Pleistocene past when humans lived in small groups of hunter-gatherers, in today's world these tendencies may dispose us toward prejudice and even dangerous and wasteful wars.

Environmental Selection and Sexual Selection

The type of natural selection discussed above is environmental selection--selection by the environment of which genetic variants in a population will survive long enough to have a chance to reproduce. Note that the environment "selects" who will survive and who won't by virtue of the fact that the environment presents challenges to survival such as disease, predators, and insufficient supplies of resources such as energy (in the form of sunlight for plants, or food for animals), territory, and water. The "selection" by the environment occurs when individuals that just happen to be better suited to meet the challenges presented by the environment naturally have a competitive advantage and survive and reproduce in greater numbers than those unlucky individuals who are less well fit to the environment.

In addition to environmental selection, in sexually reproducing species, there is a second layer of selection, sexual selection--selection based on the "attractiveness" of potential sexual partners. All other factors being equal, individuals with genes that make them more attractive to the opposite sex tend to have more reproductive opportunities and, at least in times past, tend to have more offspring than those perceived to be less attractive. This effect is in part due to the fact that bodily features associated

with health and likely reproductive success tend to be perceived as sexually attractive (presumably as a result of brain evolution).

Evolution is neither random nor purposeful

It is important to note, as described above, that although evolution depends on random variations (in traits and genes) among individuals within a population, evolution is not a random process--natural selection acts on the random variation, constraining it toward successful adaptation. As Buss and Hawley (2010, p. ix) state, “Individual differences are indispensable for natural selection. Without heritable variants, natural selection—the only known process capable of creating and maintaining functional adaptations—could not occur.” In this way, evolution is not random as some who don't understand the process are apt to claim--natural selection gives it direction.

Furthermore, it is important to note that evolution is not purposeful, even though it is not random. Evolution happens automatically, without purpose, simply as a result of differential rates of reproduction in a population occurring as a consequence of the fact that individuals in a population with traits (and genes) that are more successful in a particular environment end up surviving and producing more offspring than their competitors--that's natural selection. This results in changes in gene frequencies in populations of organisms, and that is evolution. As biologist, Theodosius Dobzhansky (1964, p.449), stated: "My genes are different sequences of the same four "letters" of the "genetic alphabet" which also compose the genes of a fish or of a corn plant. Genes reproduce themselves generally with an astonishing accuracy; the sequences of the four 'letters,' the nucleotide bases, are usually identical in hundreds of billions of cells of the bodies of the parents and of their progeny. Occasionally, there occur, however, changes, "misprints," mutations. Self-reproduction plus mutation make possible natural selection. Natural selection makes possible evolution." We might even say that given these conditions, natural selection and evolution are not only possible, but inevitable.

Adaptations

The heritable features which organisms use to solve problems of survival and reproduction are called **adaptations**. These evolved adaptations can be anatomical, such as having wings or fur; physiological, such as digestive processes or having an immune system; and behavioral and mental (i.e. psychological). The evolved behavioral and mental traits of an organism are its **psychological adaptations** (e.g. having a fear response to danger; feelings of sexual attraction which draw you toward desirable potential mates; having a "sweet tooth" that drives you to seek out and ingest high caloric foods; having tender feelings toward your offspring motivating care-giving; understanding cause-effect relations and making causal inferences; having the mental ability to imagine future actions and to mentally anticipate the probable outcomes of those actions; and so on). According to psychologists who favor an evolutionary perspective, the mind can be seen as a large collection of evolved psychological adaptations (not all psychologists agree with this view; see Panksepp and Panksepp, 2000). These psychological adaptations are built by evolution into the structure of the brain and its physical operations. These psychological adaptations can be quite specific and concrete, such as the innate emotions related to pair-bonding and mating (e.g. "falling in love") or inborn human taste preferences for sweets and fats (see Cosmides and Tooby, 1997), or they can be quite general and abstract *instincts of thought* such as the innate disposition to understand the world in terms of cause-effect, to be sensitive to predictability between events, and to form categories and inferences based on similarities among things. These and other instincts of thought make up much of what we call intelligence (Koenigshofer, 2017).

Figure 3.4.1.2: Cultural overlays on a set of psychological adaptations. Human mating involves a number innate "instinctive" emotions and psychological needs which have evolved to foster reproduction of genes. Genetic evolution of these psychological adaptations has been accompanied by cultural evolution (selection and cultural transmission of learned behaviors via tradition, modeling, and other mechanisms of cultural transmission) of traditional practices associated with the genetically evolved psychological adaptations, the "reproductive instincts." (Image from Wikimedia Commons; File:Long Wedding Dress for Couple with Flowers.jpg; https://commons.wikimedia.org/wiki/F...th_Flowers.jpg; by epSos.de; licensed under the Creative Commons Attribution 2.0 Generic license).

In humans, psychological adaptations such as the emotions involved in mate selection, pair bonding, and mating are often associated with learned ritual behaviors that are culturally transmitted over generations and become part of the culture of particular human groups (see Figure 3.1.2). Such cultural practices are often based on commonly held "myths" that unify and help identify large groups of humans as culturally distinct from one another while facilitating cooperative effort among the members of such large groups toward common goals. According to one author (Harari, 2014), this ability to form cultural myths that imbue large numbers of strangers with a common identity, permitting them to work toward common goals, is unique to humans and accounts, in large part, for the unprecedented success of our species compared to all others. However, it is important to realize that this ability to form unifying myths depends upon features of the human brain that don't exist in sufficient degree in other animal species. Myths associated with cultural practices ranging from marriage or child birth to religious ritual or imperialism require the ability to form abstract concepts. Although research shows that non-human animal species can form concepts (Smith et al., 2010; Zentall et al., 2008), human concepts are highly abstract, apparently uniquely so, and ability for high levels of abstraction may depend upon the unique complexity of the human cerebral cortex (Koenigshofer, 2017; see Chapter 14 on Intelligence and Cognition). However, in addition, to ability to form abstract concepts, ability to learn and to transmit learned knowledge and behaviors from one generation to the next (cultural transmission) was essential to human uniqueness, and this ability to transmit learned information from generation to generation, by tradition and other non-genetic means, also depended upon particular features of the human brain (see Chapters 14 and 15 and sections 18.5 and 18.13). Thus, the great accomplishments of human civilization, which set us so clearly apart from other species, ultimately depended upon human brain evolution setting the stage, with human cultural evolution superimposed and critically dependent on brain evolution. One specific example may help drive the point home. Many experts believe that human tool making and tool use were extremely important in human evolution and early human adaptive success (see sections 3.3 and 18.5). The manufacture of stone tools by early humans was a complex and sophisticated cognitive and manual task beyond the capability of all other primates. Orban and colleagues (2006) identified a set of regions in the dorsal intraparietal sulcus (IPS) of the human cerebral cortex which they believe perform the complex visual analysis needed for the precision with which humans manipulate tools; these brain areas are not found in monkeys. Thus, a key product of human cultures was only possible because of unique features evolved in the human brain. This is only one example of a general claim: human cultural achievements that make our species so unique depend upon unique features of human brain evolution.

Individual Selection, Kin Selection, and Human Moral Conflict

From an evolutionary perspective, the minds and behavior of humans and animals, just like their anatomy and physiology, have evolved in service of survival and reproduction, either through the reproduction of one's own genes, or indirectly through the survival and reproduction of close relatives and their genes (Dawkins, 1976). The former (individual selection) favors the self-interested side of human nature; the latter (kin selection) favors our altruistic side including prosocial behaviors such as caring, giving, sharing, and cooperation (some of the adaptive benefits of living in groups in social species such as humans, wolves, lions, chimpanzees, elephants, etc). In humans at least, self-interest and the interests of others often conflict, generating psychological tension experienced as moral dilemma. For humans, it is likely that there is an optimal balance between these two opposing behavioral dispositions; an extreme, maladaptive imbalance can lead to psychopathologies such as narcissistic and anti-social personality disorders. The duality of human moral nature may have roots in the duality of these two evolutionary processes, selection for survival and reproduction of one's own genes and kin selection, selection for survival and reproduction of the genes of close genetic relatives (Koenigshofer, 2010, 2016).

Evolutionary Psychology

Because psychological adaptations are located in the brain and its operations, these adaptations can be understood as information processing features of neural systems. On this view, the brain is a computational machine comprised of an enormous number of computational systems or modules, essentially mini-computers, made of circuits of neurons whose circuit configurations and operations have been shaped by evolutionary forces, developmental processes, and environmental experiences.

As noted in the opening quote above, Darwin recognized the relevance of evolution to psychology. Others have followed his lead. As Cosmides and Tooby (1997, p. 1) state, "In the final pages of the Origin of Species, after he had presented the theory of evolution by natural selection, Darwin made a bold prediction: 'In the distant future I see open fields for far more important researches. Psychology will be based on a new foundation, that of the necessary acquirement of each mental power and capacity by gradation.' Thirty years later, William James tried to do just that in his seminal book, Principles of Psychology, one of the founding works of experimental psychology (James, 1890). In Principles, James talked a lot of "instincts". This term was used to refer (roughly) to specialized neural circuits that are common to every member of a species and are the product of that species' evolutionary history. Taken together, such circuits constitute (in our own species) what one can think of as 'human nature.'"

Today, the influence of these early thinkers is expressed in evolutionary approaches to psychology. Cosmides and Tooby (1997, p. 1) state: "The goal of research in evolutionary psychology is to discover and understand the design of the human mind. Evolutionary psychology is an approach to psychology, in which knowledge and principles from evolutionary biology are put to use in research on the structure of the human mind. It is not an area of study, like vision, reasoning, or social behavior. It is a way of thinking about psychology that can be applied to any topic within it. In this view, the mind is a set of information-processing machines that were designed by natural selection to solve adaptive problems faced by our hunter-gatherer ancestors." Furthermore, they explain, "Psychology is that branch of biology that studies (1) brains, (2) how brains process information, and (3) how the brain's information-processing programs generate behavior. Once one realizes that psychology is a branch of biology, inferential tools developed in biology -- its theories, principles, and observations -- can be used to understand psychology" (Cosmides and Tooby, 1997 p. 3).

Evolutionary psychologists have applied this approach to emotion (Johnston, 1999; Ketelaar, 2015), intelligence and cognition (Bouchard, 2014; Koenigshofer, 2017; Pika, et al., 2020), personality (Buss and Hawley, 2010; Figueredo, et al., 2009), language (Corballis, 2010; Fitch, 2010; Pinker, 2003), social cognition (Fiddick, 2015; Vonk, et al., 2015), and a wide range of other psychological processes. Evolution by natural selection is gaining increasing acceptance among psychologists as "a strong candidate for central inclusion in a unifying meta-theory of psychology" (Marsh and Boag, 2013, p. 655; also see Goetz & Shackelford, 2006), just as evolution has become the unifying principle for all of biology. As you read about evolution and its mechanisms in the following sections, keep in mind that not only physical traits evolve, but mental and behavioral traits and capabilities (psychological traits) do as well.

In the remainder of this chapter we examine the processes of evolution in greater detail including primate and human evolution, and evolutionary theories in psychology. To emphasize the importance of evolution to an understanding of mind and behavior, recall the claim stated above: *Nothing in psychology "makes sense except in the light of evolution."*

Summary

Behavior and the information processing mechanisms that underlie behavior are biological processes (in their origin and functions), dependent upon a biological organ, the brain. Just as evolution by natural selection is the organizing principle for all of biology, it must be a key organizing principle for psychology as well. Natural selection is the primary driving force of evolution, although other processes (examined in other sections of this chapter) are also involved. Natural selection occurs automatically without purpose or goal simply as a mechanistic consequence of two facts of life: 1) that individuals of any species vary from one another in their heritable traits, and 2) that some individuals by chance, because of the traits they possess (and the genes that underlie those traits), have a competitive advantage that favors their rates of survival and reproduction in a particular environment compared to those variants that are less fit. Therefore, the individuals (and the underlying genes) that are best fit to the environment end up leaving more surviving offspring and therefore have a disproportionately greater impact on the genes and traits of future generations. As a consequence, evolution occurs over generations, causing species to accumulate traits that are a better fit to survival and reproduction in the particular environments they occupy. For biological psychology, it is important to recognize that in addition to anatomy and physiology, psychological traits are also shaped into adaptive form by these same processes. Thus, to understand human and animal behavior, an evolutionary approach provides a biological context within which we can examine origins, functions, and organizing principles of minds and behavior. This approach does not negate or deny the influence of learning and culture but views these processes as biological phenomenon with evolutionary and neurophysiological roots in the brain.

3.4.2: Evolution - Mechanisms and Evidence

Learning Objectives

1. Describe how the present-day theory of evolution was developed.
2. Explain natural selection and its role in evolution.
3. Explain convergent and divergent evolution.
4. Describe homologous and vestigial structures.
5. Discuss misconceptions about the theory of evolution.
6. Explain the categories of evidence for evolution.
7. Describe species and speciation.
8. Explain kin selection, inclusive fitness, and the evolution of altruistic behaviors such as helping, cooperation, and giving.

Overview

The theory of evolution is the unifying theory of biology, meaning it is the framework within which biologists ask questions about the living world. Its power is that it provides direction for predictions about living things that are borne out in experiment after experiment. Recall the claim by geneticist, Theodosius Dobzhansky, quoted in Section 3.1, that “nothing makes sense in biology except in the light of evolution." He meant that the tenet that all life has evolved and diversified from a common ancestor is the foundation from which we approach all questions in biology. It is important to keep this claim in mind when we think about brain evolution and psychology. The evolutionary links among animal species help explain the similarities in their brains and behavior.

Summary of Key Points:

1. Evolution: All species of living organisms, from bacteria to baboons to blueberries, evolved at some point from a different species. Although it may seem that living things today stay much the same, that is not the case—evolution is an ongoing process.
2. Understanding Evolution: Evolution by **natural selection** describes a mechanism for how species change over time. That species change had been suggested and debated well before Darwin began to explore this idea. The view that species were static and unchanging was grounded in the writings of Plato, yet there were also ancient Greeks who expressed evolutionary ideas. Darwin was the first to describe the primary mechanism of evolutionary change--natural selection.
3. When Darwin proposed his theory of evolution, the mechanisms of inheritance were unknown. Now, we know a great deal about those mechanisms. Here are some key definitions. **Chromosomes** are long strings of genes made of the molecule, deoxyribonucleic acid (DNA). A **gene** is a segment of a chromosome coding for synthesis of a specific protein. **Alleles** are alternative forms of a gene at the same location on the chromosome (for example a blue gene for eye color and a brown gene for eye color are alleles). **Genotype** is the genetic makeup of an individual. **Phenotype** is the actual anatomical, physiological, and behavioral/psychological characteristics of an individual.

Figure 3.4.2.1: All organisms are products of evolution adapted to their environment. (a) Saguaro (Carnegiea gigantea) can soak up 750 liters of water in a single rain storm, enabling these cacti to survive the dry conditions of the Sonora desert in Mexico and the Southwestern United States. (b) The Andean semiaquatic lizard (Potamites montanicola) discovered in Peru in 2010 lives between 1,570 to 2,100 meters in elevation, and, unlike most lizards, is nocturnal and swims. Scientists still do not know how these cold-blood animals are able to move in the cold (10 to 15°C) temperatures of the Andean night. Understanding Evolution

Darwin's evolution by natural selection describes a mechanism for how species change over time. Darwin described evolution as "descent with modification."

In the eighteenth century, James Hutton, a Scottish naturalist, proposed that geological change occurred gradually by the accumulation of small changes from processes operating like they are today over long periods of time. This contrasted with the predominant view that the geology of the planet was a consequence of catastrophic events occurring during a relatively brief past. Hutton's view was popularized in the nineteenth century by the geologist Charles Lyell who became a friend to Darwin. Lyell's ideas were influential on Darwin's thinking: Lyell's notion of the greater age of Earth gave more time for gradual change in species, and the process of change provided an analogy for gradual change in species. In the early nineteenth century, Jean-Baptiste Lamarck published a book that detailed a mechanism for evolutionary change. This mechanism is now referred to as an inheritance of acquired characteristics by which modifications in an individual that are caused by its environment, or the use or disuse of a structure during its lifetime, could be inherited by its offspring and thus bring about change in a species. A simple example or two will illustrate why this is wrong--the idea suggests that if you go to the gym and get buff, then you will have buff kids, or if you lose a finger in an accident, that you will have children missing a finger, and that such changes will eventually become characteristics of the species. Today we know that if the change in characteristics does not change genes, the change cannot be passed on to future generations. While this mechanism for evolutionary change was discredited, Lamarck's ideas were an important influence on evolutionary thought.

Charles Darwin and Natural Selection

In the mid-nineteenth century, the actual mechanism for evolution was independently conceived of and described by two naturalists: Charles Darwin and Alfred Russel Wallace. Importantly, each naturalist spent time exploring the natural world on expeditions to the tropics. From 1831 to 1836, Darwin traveled around the world on *H.M.S. Beagle*, including stops in South America, Australia, and the southern tip of Africa. Wallace traveled to Brazil to collect insects in the Amazon rainforest from 1848 to 1852 and to the Malay Archipelago from 1854 to 1862. Darwin's journey, like Wallace's later journeys to the Malay Archipelago, included stops at several island chains, the last being the Galápagos Islands, west of Ecuador. On these islands, Darwin observed species of organisms on different islands that were clearly similar, yet had distinct differences. For example, the ground finches inhabiting the Galápagos Islands comprised several species with a unique beak shape. The species on the islands had a graded series of beak sizes and shapes with very small differences between the most similar. He observed that these finches closely resembled another finch species on the mainland of South America. Darwin imagined that the island species might be species modified from one of the original mainland species. Upon further study, he realized that the varied beaks of each finch helped the birds acquire a specific type of food. For example, seed-eating finches had stronger, thicker beaks for breaking seeds, and insect-eating finches had spear-like beaks for stabbing their prey.

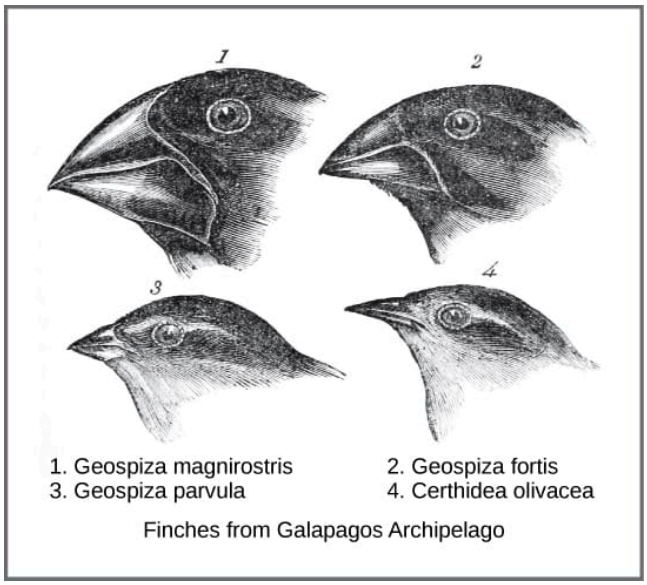

Figure 3.4.2.2: Darwin observed that beak shape varies among finch species. He postulated that the beak of an ancestral species had adapted over time to equip the finches to acquire different food sources.

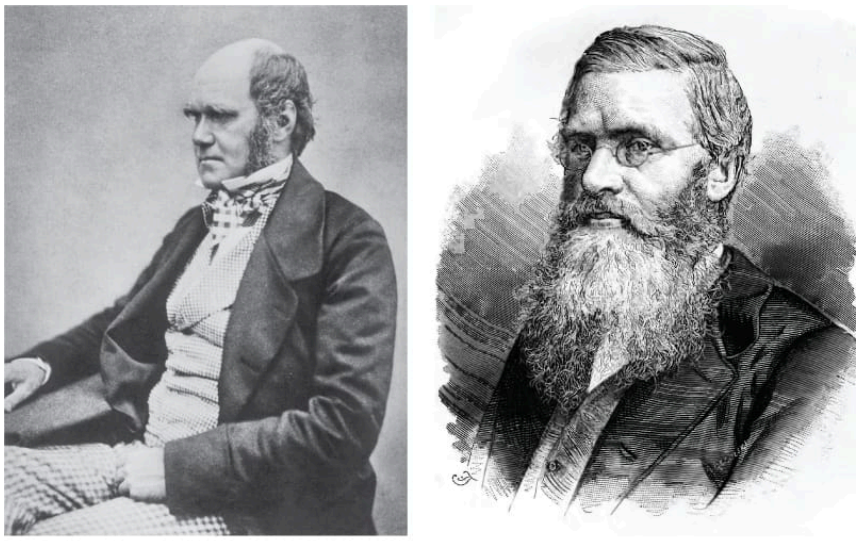
Wallace and Darwin both observed similar patterns in other organisms and they independently developed the same explanation for how and why such changes could take place. Darwin called this mechanism natural selection. Natural selection, also known as "survival of the fittest," is more accurately described as survival and *reproduction* of the fittest. Survival alone is insufficient. Evolution involves differential rates of reproduction. Survival alone without reproduction has no effect on the genetic evolution of a species. Natural selection results in the more prolific reproduction of individuals with traits that contribute to survival and reproduction in a changing environment; this increased rate of reproduction in individuals with traits better fit to the environment compared to individuals with traits less fit leads to evolutionary change.

For example, a population of giant tortoises found in the Galapagos Archipelago was observed by Darwin to have longer necks than those that lived on other islands with dry lowlands. These tortoises were "selected" because they could reach more leaves and access more food than those with short necks. In times of drought when fewer leaves would be available, those that could reach more leaves had a better chance to eat and survive than those that couldn't reach the food source. Consequently, long-necked tortoises would be more likely to be reproductively successful and pass the long-necked trait to their offspring. Over time, only long-necked tortoises would be present in the population, as short-necked animals failed to survive and reproduce.



Natural selection, Darwin argued, was an **inevitable outcome of three principles** that operated in nature.

First, **most characteristics of organisms are inherited**, or passed from parent to offspring. Although no one, including Darwin and Wallace, knew how this happened at the time, it was a common understanding.

Second, more offspring are produced than are able to survive, so resources for survival and reproduction are limited. The capacity for reproduction in all organisms outstrips the availability of resources to support their numbers. Thus, there is **competition for** those **resources in each generation**. Both Darwin and Wallace's understanding of this principle came from reading an essay by the economist Thomas Malthus who discussed this principle in relation to human populations.

Third, **offspring vary** among each other in regard to their characteristics **and those variations are inherited**. Darwin and Wallace reasoned that **offspring with inherited characteristics which allow them to best compete for limited resources will survive and have more offspring than those individuals with variations that are less able to compete**. Because characteristics are inherited, these traits will be better represented in the next generation. This will lead to change in populations over generations in a process that Darwin called **descent with modification**. Ultimately, natural selection leads to greater adaptation of the population to its local environment; it is the only mechanism known for adaptive evolution.

Papers by Darwin and Wallace presenting the idea of natural selection were read together in 1858 before the Linnean Society in London. The following year Darwin's book, *On the Origin of Species*, was published. His book outlined in considerable detail his arguments for evolution by natural selection.

(a) (b)

Figure 3.4.2.3: Both (a) Charles Darwin and (b) Alfred Wallace wrote scientific papers on natural selection that were presented together before the Linnean Society in 1858.

Demonstrations of evolution by natural selection are time consuming and difficult to obtain. As briefly discussed in Module 3.1, one of the best examples has been demonstrated in the very birds that helped to inspire Darwin's theory: the Galápagos finches. Peter and Rosemary Grant and their colleagues have studied Galápagos finch populations every year since 1976 and have provided important demonstrations of natural selection. The Grants found changes from one generation to the next in the distribution of beak shapes in the medium ground finch on the Galápagos island of Daphne Major. The birds have inherited variation in the bill shape with some birds having wide deep bills and others having thinner bills. During a period in which rainfall was higher than normal because of an El Niño (an unusual warming of the Pacific Ocean near the West coast of the Americas), the large hard seeds that large-billed birds ate were reduced in number; however, there was an abundance of the small soft seeds which the small-billed birds ate. Therefore, survival and reproduction were much better in the following years for the small-billed birds. In the years following this El Niño, the Grants measured beak sizes in the population and found that the average bill size was smaller. Since bill size is an inherited trait, parents with smaller bills had more offspring and the size of bills had evolved to be smaller. As conditions changed and a long period of drought ensued, larger seeds became more available. The trend toward smaller average bill size ceased and selection for larger beaks and body size resulted in a lasting increase in beak size.

As discussed in Section 3.1, another well known example of observable evolution is the peppered moth. Because of its importance as another example of natural selection in action, we review the details here. Prior to industrialization in England, the peppered moth had light colored wings that closely matched the color of the bark of the trees. This inherited trait provided camouflage for the moths helping to protect them from predator birds. Although most of the moths had light colored wings, a few each generation had darker wings, but without sufficient camouflage these darker colored moths had been easy prey and survived and reproduced with low frequency. As industrialization came to England, soot from factories began to slowly turn the bark of trees darker and darker. As this occurred, darker wings were now an advantage, helping to hide the darker moths from predators when they landed on trees, increasing their survival and reproductive rates over the lighter colored moths. As natural selection continued over decades, the light colored moths, once the predominant form, were increasingly replaced over generations by darker winged variants, until today, after no more than a hundred years of evolution, the peppered moth has dark wings (although as mentioned in Module 3.1 with cleaner air, numbers of the lighter variant are increasing as the tree bark continues to lighten). This transformation of the species as a consequence of natural selection, as the environment changed, is a good example of evolution rapid enough that it can be observed.

Process and Pattern of Evolution

Natural selection can only take place if there is variation, or differences, among individuals in a population. Importantly, these differences must have some genetic basis; otherwise, the selection will not lead to change in the next generation. This is critical because variation among individuals can be caused by non-genetic reasons, such as an individual being taller because of better nutrition rather than different genes.

Genetic diversity in a population comes from two main mechanisms: mutation and sexual reproduction. **Mutation**, a change in

DNA, is the ultimate source of new **alleles** (alternative forms of a gene located at the same place on a chromosome), or new genetic variation in any population. The genetic changes caused by mutation can have one of three outcomes on the phenotype. A mutation affects the phenotype of the organism in a way that gives it reduced fitness—lower likelihood of survival or fewer offspring. A mutation may produce a phenotype with a beneficial effect on fitness. And, many mutations will also have no effect on the fitness of the phenotype; these are called neutral mutations. Mutations may also have a whole range of effect sizes on the fitness of the organism that expresses them in their phenotype, from a small effect to a great effect. Sexual reproduction also leads to genetic diversity: when two parents reproduce, unique combinations of alleles assemble to produce the unique genotypes and thus phenotypes in each of the offspring.

A heritable trait that helps the survival and reproduction of an organism in its present environment is called an **adaptation**. Scientists describe groups of organisms becoming adapted to their environment when a change in the range of genetic variation occurs over time that increases or maintains the "fit" of the population to its environment. The webbed feet of platypuses are an adaptation for swimming. The snow leopards' thick fur is an adaptation for living in the cold. The cheetahs' fast speed is an adaptation for catching prey.

Whether or not a trait is favorable depends on the environmental conditions at the time. The same traits are not always selected because environmental conditions can change. For example, consider a species of plant that grew in a moist climate and did not need to conserve water. Large leaves were selected because they allowed the plant to obtain more energy from the sun. Large leaves require more water to maintain than small leaves, and the moist environment provided favorable conditions to support large leaves. After thousands of years, the climate changed, and the area no longer had excess water. The direction of natural selection shifted so that plants with small leaves were selected because those populations were able to conserve water to survive the new environmental conditions.

Formation of New Species: Although all life on earth shares various genetic similarities, only certain organisms combine genetic information by sexual reproduction and have offspring that can then successfully reproduce. Scientists call such organisms members of the same biological species. For example, a mule is a cross between a donkey and a horse. However, since the mule cannot reproduce (donkey and horse do not have the same number of chromosomes), donkeys and horses are considered separate species. However, a cross between a Dachshund and a Norwegian Elkhound can result in offspring that can reproduce with another domestic dog, and thus all domestic dogs are considered the same species (all have the same number of chromosomes). **Speciation** (the formation of new species) occurs over a span of evolutionary time, so when a new species arises, there is a transition period during which the closely related species continue to interact.

The evolution of species has resulted in enormous variation in form and function. Sometimes, evolution gives rise to groups of organisms that become tremendously different from each other. When two species evolve in diverse directions from a common point, it is called **divergent evolution**. Such divergent evolution can be seen in the forms of the reproductive organs of flowering plants which share the same basic anatomies; however, they can look very different as a result of selection in different physical environments and adaptation to different kinds of pollinators. As you will see in the section on human evolution, human and apes lines diverged from one another millions of years ago, yet evidence of a common ancestry comes from many sources, including similarities in DNA.

Figure 3.4.2.4: Flowering plants evolved from a common ancestor. Notice that the (a) dense blazing star (Liatrus spicata) and the (b) purple coneflower (Echinacea purpurea) vary in appearance, yet both share a similar basic morphology. (credit a: modification of work by Drew Avery; credit b: modification of work by Cory Zanker)

In other cases, similar phenotypes evolve independently in distantly related species. For example, flight has evolved in both bats and insects, and they both have structures we refer to as wings, which are adaptations to flight. However, the wings of bats and insects have evolved from very different original structures. This phenomenon is called **convergent evolution**, where similar traits evolve independently in species that do not share a recent common ancestry. The two species came to the same function, flying, but did so separately from each other.

Natural Selection and Adaptive Evolution

Natural selection only acts on the population's heritable traits: selecting for beneficial alleles and thus increasing their frequency in the population, while selecting against deleterious alleles and thereby decreasing their frequency—a process known as **adaptive evolution**. Natural selection does not act on individual alleles, however, but on entire organisms. An individual may carry a very beneficial genotype with a resulting phenotype that, for example, increases the ability to reproduce (fecundity), but if that same individual also carries an allele that results in a fatal childhood disease, that fecundity phenotype will not be passed on to the next generation because the individual will not live to reach reproductive age. Natural selection acts at the level of the individual; it selects for individuals with greater contributions to the gene pool of the next generation, known as an organism's evolutionary (Darwinian) fitness.

Fitness is often quantifiable and is measured by scientists in the field. However, it is not the absolute fitness of an individual that counts, but rather how it compares to the other organisms in the population. This concept, called relative fitness, allows researchers to determine which individuals are contributing additional offspring to the next generation, and thus, how the population might evolve.

Evidence of Evolution

The evidence for evolution is compelling and extensive. Looking at every level of organization in living systems, biologists see the signature of past and present evolution. Darwin dedicated a large portion of his book, On the Origin of Species, to identifying patterns in nature that were consistent with evolution, and since Darwin, our understanding has become clearer and broader.

Fossils

Fossils provide solid evidence that organisms from the past are not the same as those found today, and fossils show a progression of evolution. Scientists determine the age of fossils and categorize them from all over the world to determine when the organisms lived relative to each other. The resulting fossil record tells the story of the past and shows the evolution of form over millions of years. For example, scientists have recovered highly detailed records showing the evolution of humans and horses.

(a) (b)

Figure 3.4.2.5: In this (a) display, fossil hominids are arranged from oldest (bottom) to newest (top). As hominids evolved, the shape of the skull changed. An artist's rendition of (b) extinct species of the genus Equus reveals that these ancient species resembled the modern horse (Equus ferus) but varied in size.

Anatomy and Embryology

Another type of evidence for evolution is the presence of structures in organisms that share the same basic form. For example, the bones in the appendages of a human, dog, bird, and whale all share the same overall construction (Figure 18.1.618.1.6) resulting from their origin in the appendages of a common ancestor. Over time, evolution led to changes in the shapes and sizes of these bones in different species, but they have maintained the same overall layout. Scientists call these synonymous parts **homologous structures.**

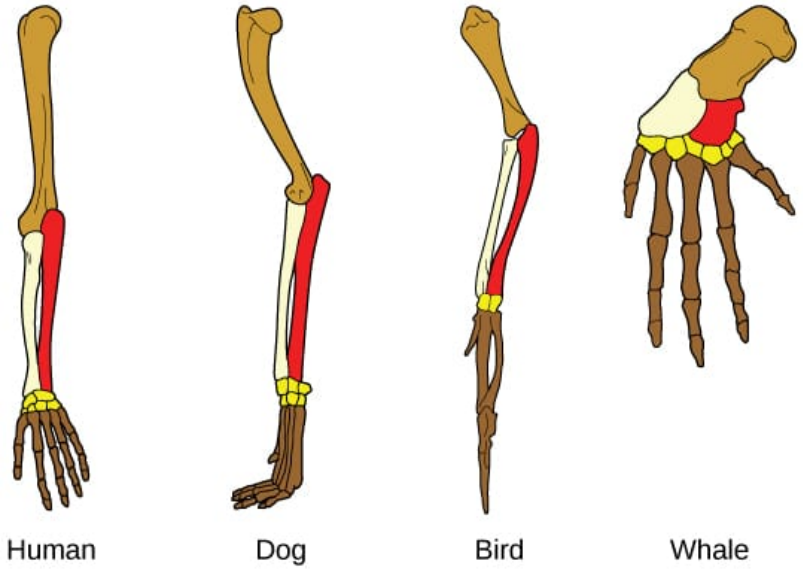


Figure 3.4.2.6: The similar construction of these appendages indicates that these organisms share a common ancestor.

Some structures exist in organisms that have no apparent function at all, and appear to be residual parts from a past common ancestor. These unused structures without function are called **vestigial structures**. Examples of vestigial structures are wings on flightless birds, leaves on some cacti, and hind leg bones in whales.

Link to Learning

Visit this interactive site to guess which bones structures are homologous and which are analogous, and see examples of evolutionary adaptations to illustrate these concepts.

Another evidence of evolution is the **convergence of form** in organisms that share similar environments. For example, species of unrelated animals, such as the arctic fox and ptarmigan, living in the arctic region have been selected for seasonal white phenotypes during winter to blend with the snow and ice. These similarities occur not because of common ancestry, but because of similar selection pressures—the benefits of not being seen, by prey or by predators, respectively.

(a) (b)

Figure 3.4.2.7: The white winter coat of the (a) arctic fox and the (b) ptarmigan's plumage are adaptations to their environments. (credit a: modification of work by Keith Morehouse)

Embryology, the study of the development of the anatomy of an organism to its adult form, also provides evidence of relatedness between now widely divergent groups of organisms. Mutational tweaking in the embryo can have such magnified consequences in the adult that embryo formation tends to be conserved. As a result, structures that are absent in some groups often appear in their embryonic forms and disappear by the time the adult or juvenile form is reached. For example, all vertebrate embryos, including humans, exhibit gill slits and tails at some point in their early development. These disappear in the adults of terrestrial groups but are maintained in adult forms of aquatic groups such as fish and some amphibians. Great ape embryos, including humans, have a tail structure during their development that is lost by the time of (their) birth.

Biogeography

The geographic distribution of organisms on the planet follows patterns that are best explained by evolution in conjunction with the movement of tectonic plates over geological time. Broad groups that evolved before the breakup of the supercontinent Pangaea (about 200 million years ago) are distributed worldwide. Groups that evolved since the breakup appear uniquely in regions of the planet, such as the unique flora and fauna of northern continents that formed from the supercontinent Laurasia and of the southern continents that formed from the supercontinent Gondwana. The presence of members of the plant family Proteaceae in Australia, southern Africa, and South America is best explained by their presence prior to the southern supercontinent Gondwana breaking up.

The great diversification of marsupials in Australia and the absence of other mammals reflect Australia's long isolation. Australia has an abundance of endemic species—species found nowhere else—which is typical of islands whose isolation by expanses of water prevents species to migrate. Over time, these species diverge evolutionarily into new species that look very different from their ancestors that may exist on the mainland. The marsupials of Australia, the finches on the Galápagos, and many species on the Hawaiian Islands are all unique to their one point of origin, yet they display distant relationships to ancestral species on mainlands.

Molecular Biology

Like anatomical structures, the structures of the molecules of life reflect Darwin's "descent with modification" (i.e. evolution). Evidence of a common ancestor for all of life is reflected in the universality of DNA as the genetic material and in the near universality of the genetic code and the machinery of DNA replication and expression. Fundamental divisions in life between the three domains (archaea--single celled organisms without a cell nucleus; bacteria; and eukaryote--including plants, animals, and fungi) are reflected in major structural differences in otherwise conservative structures such as the components of ribosomes and the structures of membranes. In general, the relatedness of groups of organisms is reflected in the similarity of their DNA sequences—exactly the pattern that would be expected from descent and diversification from a common ancestor.

DNA sequences have also shed light on some of the mechanisms of evolution. For example, it is clear that the evolution of new functions for proteins commonly occurs after gene duplication events that allow the free modification of one copy by mutation, selection, or drift (changes in a population's gene pool resulting from chance), while the second copy continues to produce a functional protein.

Misconceptions About Evolution

Although the theory of evolution generated some controversy when it was first proposed, it was almost universally accepted by biologists, particularly younger biologists, within 20 years after publication of *On the Origin of Species*. Nevertheless, the theory of evolution is a difficult concept and misconceptions about how it works abound.

Link to Learning

This site addresses some of the main misconceptions associated with the theory of evolution.

Evolution Is Just a Theory

Critics of the theory of evolution dismiss its importance by purposefully confounding the everyday usage of the word "theory" with the way scientists use the word. In science, a "theory" is understood to be a body of thoroughly tested and verified explanations for a set of observations of the natural world. Scientists have a theory of the atom, a theory of gravity, and the theory of relativity, each of which describes understood facts about the world. In the same way, the theory of evolution describes facts about the living world. As such, a theory in science has survived significant efforts to discredit it by scientists. In contrast, a "theory" in common vernacular is a word meaning a guess or suggested explanation; this meaning is more akin to the scientific concept of "hypothesis." When critics of evolution say evolution is "just a theory," they are implying that there is little evidence supporting it and that it is still in the process of being rigorously tested. This is a mischaracterization.

Individuals Evolve

Evolution is the change in genetic composition of a population over time, specifically over generations, resulting from differential reproduction of individuals with certain alleles. Individuals do change over their lifetime, obviously, but this is called development and involves changes programmed by the set of genes the individual acquired at birth in coordination with the individual's environment. When thinking about the evolution of a characteristic, it is probably best to think about the change of the average value of the characteristic in the population over time. For example, when natural selection leads to bill-size change in medium-ground finches in the Galápagos, this does not mean that individual bills on the finches are changing. If one measures the average bill size among all individuals in the population at one time and then measures the average bill size in the population several years later, this average value will be different as a result of evolution. Although some individuals may survive from the first time to the second, they will still have the same bill size; however, there will be many new individuals that contribute to the shift in average bill size.

Evolution Explains the Origin of Life

It is a common misunderstanding that evolution includes an explanation of life's origins. Conversely, some of the theory's critics believe that it cannot explain the origin of life. The theory does not try to explain the origin of life. The theory of evolution explains how populations change over time and how life diversifies the origin of species. It does not shed light on the beginnings of life

including the origins of the first cells, which is how life is defined. The mechanisms of the origin of life on Earth are a particularly difficult problem because it occurred a very long time ago, and presumably it just occurred once. Importantly, biologists believe that the presence of life on Earth precludes the possibility that the events that led to life on Earth can be repeated because the intermediate stages would immediately become food for existing living things.

However, once a mechanism of inheritance was in place in the form of a molecule like DNA, either within a cell or pre-cell, these entities would be subject to the principle of natural selection. More effective reproducers would increase in frequency at the expense of inefficient reproducers. So while evolution does not explain the origin of life, it may have something to say about some of the processes operating once pre-living entities acquired certain properties.

Organisms Evolve on Purpose

Statements such as “organisms evolve in response to a change in an environment” are quite common, but such statements can lead to two types of misunderstandings. First, the statement must not be understood to mean that individual organisms evolve. The statement is shorthand for “a population evolves in response to a changing environment.” However, a second misunderstanding may arise by interpreting the statement to mean that the evolution is somehow intentional. A changed environment results in some individuals in the population, those with particular phenotypes, benefiting and therefore producing proportionately more offspring than other phenotypes. This results in change in the population, if the characteristics are genetically determined.

It is also important to understand that the variation that natural selection works on is already in a population and does not arise in response to an environmental change. For example, applying antibiotics to a population of bacteria will, over time, select a population of bacteria that are resistant to antibiotics. The resistance, which is caused by a gene, did not arise by mutation because of the application of the antibiotic. The gene for resistance was already present in the gene pool of the bacteria, likely at a low frequency. The antibiotic, which kills the bacterial cells without the resistance gene, strongly selects individuals that are resistant, since these would be the only ones that survived and divided. Experiments have demonstrated that mutations for antibiotic resistance do not arise as a result of antibiotic.

In a larger sense, evolution is not goal directed. Species do not become “better” over time; they simply track their changing environment with adaptations that maximize their reproduction in a particular environment at a particular time. Evolution has no goal of making faster, bigger, more complex, or even smarter species, despite the commonness of this kind of language in popular discourse. What characteristics evolve in a species are a function of the variation present and the environment, both of which are constantly changing in a non-directional way. What trait is fit in one environment at one time may well be fatal at some point in the future. This holds equally well for a species of insect as it does the human species.

Population Evolution and the Modern Synthesis

The mechanisms of inheritance, or genetics, were not understood at the time Charles Darwin and Alfred Russel Wallace were developing their idea of natural selection. This lack of understanding was a stumbling block to understanding many aspects of evolution. In fact, the predominant (and incorrect) genetic theory of the time, blending inheritance, made it difficult to understand how natural selection might operate. Darwin and Wallace were unaware of the genetics work by Austrian monk Gregor Mendel, which was published in 1866, not long after publication of Darwin's book, *On the Origin of Species* (1859). Mendel’s work was rediscovered in the early twentieth century at which time geneticists were rapidly coming to an understanding of the basics of inheritance. Initially, the newly discovered particulate nature of genes made it difficult for biologists to understand how gradual evolution could occur. But over the next few decades, genetics and evolution were integrated in what became known as **the modern synthesis**—the coherent understanding of the relationship between natural selection and genetics that took shape by the 1940s and is generally accepted today. In sum, the modern synthesis describes how evolutionary processes, such as natural selection, can affect a population’s genetic makeup, and, in turn, how this can result in the gradual evolution of populations and species. The theory also connects this change of a population over time, called microevolution, with the processes of macroevolution that gave rise to new species and higher taxonomic groups with widely divergent characters.

Kin Selection

In the discussion of natural selection, the emphasis was on how natural selection works on individuals to favor the more fit and disfavor the less fit in a population. The emphasis was on the survival (mortality selection), mating success (sexual selection), or family size (fecundity selection) of **individuals**. But what of the worker honeybee who gives up her life when danger threatens

her hive? Or the mother bird who, feigning injury, flutters away from her nestful of young, thus risking death at the hands of a predator? How can evolution produce genes for such instinctive patterns of behavior when the owner of these genes risk failing the first test of fitness: survival?

A possible solution to this dilemma lies in the effect of such seemingly altruistic behavior on the overall ("inclusive") fitness of the family of the altruistic individual. Linked together by a similar genetic endowment, the altruistic member of the family enhances the chance that many of its own genes will be passed on to future generations by sacrificing itself for the welfare of its relatives. It is interesting to note that most altruistic behavior is observed where the individuals are linked by fairly close family ties. Natural selection working at the level of the family rather than the individual is called **kin selection**.

How good is the evidence for kin selection? Does the behavior of the mother bird really increase her chances of being killed? After all, it may be advantageous to take the initiative in an encounter with a predator that wanders near. But even if she does increase her risk, is this anything more than another example of maternal behavior? Her children are, indeed, her kin. But isn't natural selection simply operating in one of the ways Darwin described: to produce larger mature families?

Perhaps clearer examples of altruism and kin selection are to be found in those species of birds that employ "helpers". One example: Florida scrub jays (*Aphelocoma coerulescens coerulescens*). These birds occupy well-defined territories. When they reach maturity, many of the young birds remain for a time (one to four years) in the territory and help their parents with the raising of additional broods. How self-sacrificing! Should not natural selection have produced a genotype that leads its owners to seek mates and start raising their own families (to receive those genes)?

But the idea of kin selection suggests that the genes guiding their seemingly altruistic behavior have been selected for because they are more likely to be passed on to subsequent generations in the bodies of an increased number of younger brothers and sisters than in the bodies of their own children. To demonstrate that this is so, it is necessary to show that:

1. the "helping" behavior of these unmated birds is really a help and that
2. they have truly sacrificed opportunities to be successful parents themselves.

Thanks to the patient observations of Glen Woolfenden, the first point is established. He has shown that parents with helpers raise larger broods than those without. But the second point remains unresolved. Perhaps by waiting until they have gained experience with guarding nests and feeding young and until a suitable territory becomes available, these seemingly altruistic helpers are actually improving their chances of *eventually* raising larger families than they would have if they started right at it. If so, then once again we are simply seeing natural selection working through one of Darwin's criteria of individual fitness: ability to produce larger mature families.

The evolutionary advantage of helping ceases if the young are not actually siblings of the helper. It is well-established (e.g., by DNA analysis) that the females of many species of birds have "extramarital" affairs; that is, produce broods where the young have been sired by more than one male. Interestingly, it turns out that the more promiscuous the females of a given species, the less likely it is that they are assisted by helpers. Conversely, those species that employ helpers tend to be monogamous (however, there are a few exceptions.)

Kin Selection in Social Insects

The honeybee and other social insects provide the clearest example of kin selection. They are also particularly interesting examples because of the peculiar genetic relationships among the family members.

Male honeybees (drones) develop from the queen's unfertilized eggs and are haploid. Thus, all their sperm will contain exactly the same set of genes. This means that all their daughters will share exactly the same set of **paternal** genes, although they will share — on average — only one-half of their mother's genes. (Human sisters, in contrast, share one-half of their father's as well as one-half of their mother's genes.) So any behavior that favors honeybee sisters (75% of genes shared) will be more favorable to their genotype than behavior that favors their children (50% of genes shared).

Since that is the case, why bother with children at all? Why not have most of the sisters be sterile workers, caring for their mother as she produces more and more younger sisters, a few of whom will someday be queens? As for their brothers, worker bees share only 25% of their genes with them. Is it surprising, then, that as autumn draws near, the workers lose patience with the lazy demanding ways of their brothers and finally drive them from the hive?

No Perfect Organism

Natural selection is a driving force in evolution and can generate populations that are better adapted to survive and successfully reproduce in their environments. But natural selection cannot produce the perfect organism. Natural selection can only select on existing variation in the population; it does not create anything from scratch. Thus, it is limited by a population's existing genetic variance and whatever new alleles (genetic variants) arise through mutation and gene flow (when some organisms from one population migrate into another population).

Natural selection is also limited because it works at the level of individuals, not alleles, and some alleles are linked together due to their physical proximity in the genome, making them more likely to be passed on together (linkage disequilibrium). Any given individual may carry some beneficial alleles and some unfavorable alleles. It is the net effect of these alleles, or the organism's fitness, upon which natural selection can act. As a result, good alleles can be lost if they are carried by individuals that also have several overwhelmingly bad alleles; likewise, bad alleles can be kept if they are carried by individuals that have enough good alleles to result in an overall fitness benefit.

Finally, it is important to understand that not all evolution is adaptive. While natural selection selects the fittest individuals and often results in a more fit population overall, other forces of evolution, including genetic drift and gene flow, often do the opposite: introducing deleterious alleles to the population's gene pool. Evolution has no purpose—it is not changing a population into a preconceived ideal. It is simply the sum of the various forces described in this chapter and how they influence the genetic and phenotypic variance of a population.

Summary

Evolution is the process of adaptation through mutation and natural selection which allows better biologically fit (i.e. better adapted) characteristics to be passed to succeeding generations while less well adapted characteristics tend to be weeded out. Over time, organisms evolve characteristics that are beneficial to their survival and reproduction. For living organisms to adapt and change to environmental pressures, genetic variation must be present. With genetic variation, individuals have differences in form and function that allow some to survive environmental conditions better than others. These organisms pass their favorable traits to their offspring. Eventually, environments change, and what was once a desirable, advantageous trait may become an undesirable trait and organisms may further evolve. Evolution may be convergent with similar traits evolving in multiple species or divergent with diverse traits evolving in multiple species that came from a common ancestor. Evidence of evolution can be observed by means of DNA code and the fossil record, and also by the existence of homologous and vestigial structures.

The modern synthesis of evolutionary theory grew out of the combination of Darwin's and Wallace's formulations of evolution with Mendel's analysis of heredity, along with the more modern study of population genetics. The modern synthesis describes the evolution of populations and species, from small-scale changes among individuals to large-scale changes over paleontological time periods. To understand how organisms evolve, scientists can track populations' allele frequencies over time.

Kin selection and inclusive fitness involve selection for altruistic behaviors which benefit close genetic relatives.

3.4.3: Human Evolution

Learning Objectives

1. Explain the basic trends of human evolution including bipedalism and encephalization.
2. Describe hominins and what distinguishes hominins from other members of the Primate order.
3. Describe the category of features that distinguishes proto-hominins from hominins.
4. Describe, including approximate date ranges, the evolution of the genus *Homo,* including *e*arly *Homo* species and modern humans.
5. Explain how material culture helps inform us about the psychology of ancestral *Homo sapiens* and other hominin species.

Overview

Trends: There are a number of trends in the evolution of the proto-hominins (primitive ape-like species regarded as possibly ancestral to modern humans) to modern Homo sapiens. These traits do not occur all at once, but over millions of years.

Proto-Hominins and Hominins: In determining what fossil features a specimen must have in order to be classified as a hominin (the term used for humans and their ancestors after the split with chimpanzees and bonobos), many different characteristics are examined, including those related to bipedalism and dental features related to chewing. Apes have a space between biting teeth and grinding teeth where the upper canine fits when the jaws close. Other characteristics such as brain and body size are also considered.

Homo Genus: The emergence of the genus Homo (our genus) marks the advent of larger brains, the emergence of material culture (e.g. stone tools), and the eventual colonization of the world outside of Africa.

Material Culture: The earliest evidence of material culture is in the form of stone tools found on sites which dated back to 2.4 million years ago (see Supplementary Content, Chapter 18, Material Culture).

Figure 3.4.3.1: The original complete skull (without upper teeth and mandible) of a 2.1 million years old Australopithecus africanus specimen so-called "Mrs. Ples" (catalogue number STS 5, Sterkfontein cave, hominid fossil number 5), discovered in South Africa . Human and Ape Evolutionary Paths: Divergence from Common Ancestors

Before we begin our discussion of human evolution, it will be helpful to take a look at the big picture. The two figures below along with Figure 3.7.16, much further below, collectively depict 20 million years of evolution leading to our species, *Homo sapiens*. Figure 3.7.2 shows the last 10 million years of humanoid evolution. Figure 3.7.3 shows the last 20 million years of humanoid evolution and so is inclusive of Figure 3.7.2, which shows greater detail beginning with the Homininae (African hominids including humans) phylogeny, 10 Mya to present. Both of these figures show our genus Homo at the top left of each diagram. Figure 3.7.16 shows an enlarged and much more detailed depiction of the genus Homo including relationships between Homo sapiens and Neanderthals and the fact that these two species once co-existed at the same time outside of Africa about 30,000-40,000 years ago. In the first two figures immediately below, notice the great divergence into a surprisingly large number of species over millions of years. Also notice how small and how recent the genus Homo is by comparison, and how one very recent species that emerged during the Pleistocene, humans, has so quickly come to dominate the Earth, at least for now. It is hoped that by closely examining these figures, you will be better able to organize the details that follow in this section and that you will be able to understand them within the larger context of primate evolution.

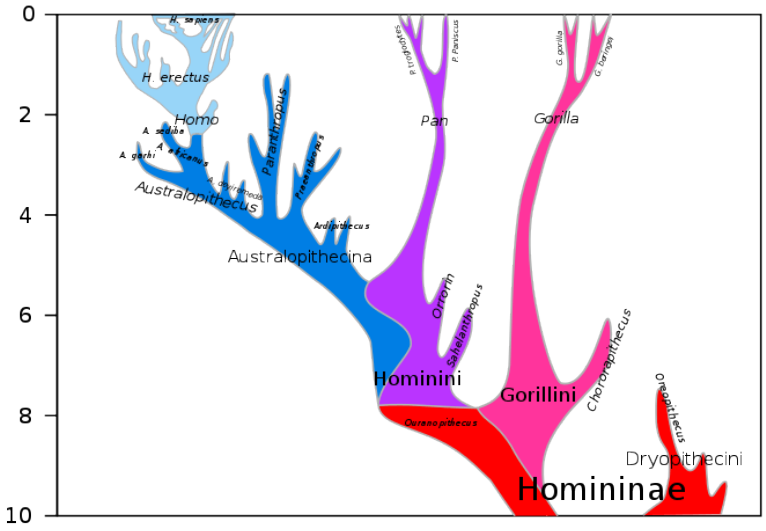

Figure 3.4.3.2: Hominini (includes Homo and Pan, but excludes gorillas) and Homininae (African hominids including humans) phylogeny, 10 Mya to present; the human branch beginning with Homo, top left, is enlarged and shown in greater detail in Figure 3.7.16 closer to the bottom of this page. The Hominin ancestral line (modern humans, extinct human species and all our immediate ancestors including members of the genera *Homo*, *Australopithecus*, *Paranthropus* and *Ardipithecus*) and the ape line, including gorillas, diverged from one another about 8 Mya (million years ago) and the Hominin and Pan (chimpanzee) lines diverge from one another about 6 Mya. Homo sapiens are shown at the very top left. To go back 20 Mya, see Figure 3.7.3 below. There you can see that Pongo (orangutans) diverged from the Hominin line much earlier, about 14 million years ago (Image from Wikimedia Commons; File:Hominini lineage.svg; https://commons.wikimedia.org/wiki/F...ni_lineage.svg; by Dbachmann; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

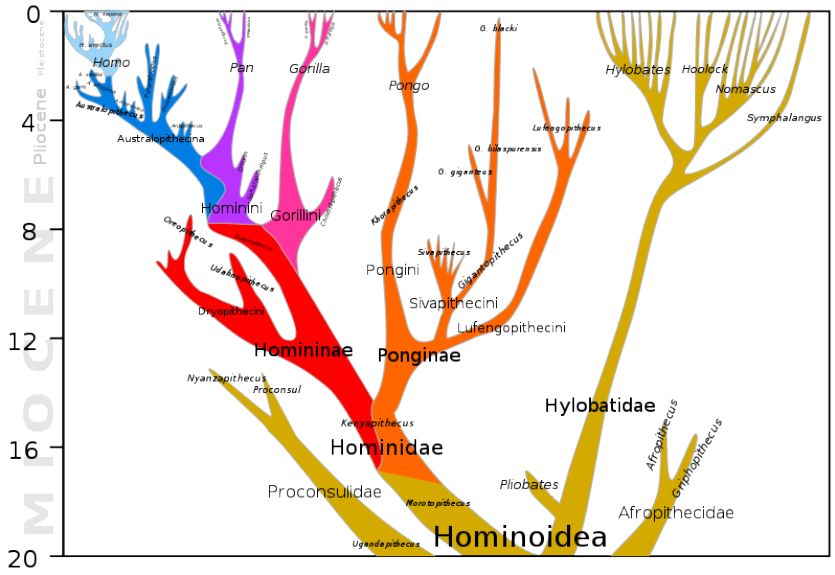

Figure 3.4.3.3: Hominoidea phylogeny, 20 Mya to present. A hominoid, sometimes called an ape, is a member of the superfamily Hominoidea: extant members are the gibbons (lesser apes, family Hylobatidae) and the hominids. A hominid is a member of the family Hominidae, the great apes: orangutans (Ponginae; Pongo), gorillas (Gorillini), chimpanzees (Pan) and humans. Note that the split between the Homo line, leading to humans, from the chimpanzee and gorilla lineages occurred about six million and eight million years ago, respectively. (Image from Wikimedia Commons; File:Hominoidea lineage.svg; https://commons.wikimedia.org/wiki/F...ea_lineage.svg; by Dbachmann; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

Trends in Human Evolution

A number of questions about human evolution are:

- Why did our earliest ancestors stand up?
- Why did some species become extinct until only one species, *Homo sapiens*, was left?
- When, where and why did modern humans evolve?
- What was the role of the Neanderthals?
- What makes us human?

While hypotheses suggest answers, research continues to refine our understanding of human evolution.

This section provides an overview of key finds and trends in **hominin** evolution. (For additional information, see the "For Further Exploration" at the end of this page).

Figure 3.4.3.4: A man contemplating his evolution.

Defining Hominins

It is through our study of our hominin ancestors and relatives that we are exposed to a world of “might have beens”--of other paths not taken by our species, of other ways of being human. But in order to better understand these different evolutionary trajectories, we must first define the terms we are using. If an imaginary line were drawn between ourselves and our closest relatives, the great apes, bipedalism (habitually walking upright on two feet) is where that line would be drawn. Hominin**,** then, means everyone on “our” side of that line defined by bipedalism. Thus, hominins are humans and all of our extinct bipedal ancestors and relatives since our divergence from the last common ancestor (LCA) that we shared with chimpanzees. As shown above in Figures 3.3.2 and 3.3.3, many scientists believe that this split between human and chimpanzee lineages took place about 6 million years ago. However, data from DNA using estimated mutation rates suggests that the split between the human and ape lineages may have occurred much earlier--divergence between human and chimpanzee lines taking place about 7 to 8 million and possibly as many as 13 million years ago, while the divergence between human and gorilla lines may have occurred as long ago as 8 to 19 million years ago (Gibbons, 2012). These different estimates may be confusing to students. However, this wide range of estimates serves as a good example of how our knowledge is incomplete and sometimes changing as new discoveries and methods arise. In this context, it is best to keep in mind that "[...] when all is said and done a taxonomy is just a hypothesis; it is not written on stone tablets" (Wood, 2010, p. 8908).

Morphological Trends in Human Evolution

There are a number of trends in the evolution of the human lineage from the proto-hominins (early human ancestral species) to modern *Homo sapiens*. These traits do not occur all at once, but over millions of years. In general, the trends include:

- the forward movement of the foramen magnum (the hole at the bottom of the skull where spinal cord enters skull to connect with brain): related to upright posture
- a reduction in the size of the canines
- an increase in the size of the molars
- an increase in cranial capacity
- flattening of the face
- rounding of the skull

Again, not all of these traits occur at the same time and there is variation among the various hominin species, but all of these morphological characteristics occur in the evolutionary line of *Homo sapiens*. Two other trends are especially important in the evolution of hominins:

- bipedalism, and

- encephalization of the brain.

These are discussed in more detail next.

Bipedalism

Bipedalism, or upright walking, was the first morphological trait on the road to humanity. Human bipedalism is the primary form of moving around (this is called habitual bipedalism). Other primates practice temporary or occasional bipedal locomotion, e.g., primates like chimpanzees may walk bipedally while they carry something in their hands. Few other animals are habitual bipeds like humans, e.g., birds and kangaroos.

Figure 3.4.3.5: Human skeleton walking.

There are numerous anatomical changes that evolved to make hominins efficient bipedal locomotors including changes in position of foramen magnum (see above), the vertebral column of the spine, the pelvis, femur and tibia bones, knee joint, and foot structure--many of these changes being related to improved balance and shock absorption (eLucy 2007).

The morphological changes associated with bipedalism take millions of years to evolve. They first appear 6.0-7.0 million years ago (mya), but are not fully in place until around 4.0 mya. These physical changes continue to refine until we see them as we do today in modern Homo sapiens (Jurmain et al. 2013).

Hypotheses about the Evolution of Bipedalism

Several hypotheses have been proposed over the last century or so to explain the evolution of hominins. As bipedalism is the first trait on the road to modern humans, these hypotheses focus on the emergence of habitual bipedalism. Many have been refuted as new data is discovered. The first hypothesis was the hunting hypothesis proposed by Charles Darwin. The hunting hypothesis claims that the key to human evolution was the shift from an arboreal life to a terrestrial one. He predicted that the earliest hominins would be found in Africa based on the similarities he saw between humans and African apes. He suggested that bipedalism gave the first hominins an advantage in that it freed up their hands to carry weapons used to hunt animals. Darwin also suggested that larger brains preceded bipedalism as intelligence was needed to make the tools. Now we know that habitual bipedalism predates large brains so Darwin's hypothesis is no longer considered an adequate explanation. With the discovery of new data, other hypotheses have been proposed including the patchy-forest and provisioning hypotheses.

The patchy forest hypothesis suggests that the emerging mosaic environment that began at the end of the Miocene made bipedalism advantageous. The phrase mosaic environment in this case refers to an environment that had patchy forest interspersed with grasslands that eventually became the African savannas of today. This caused food resources to become spread out over the landscape. For traveling long distances, bipedalism is more energy efficient than quadrupedalism (walking on "all fours"). Traveling bipedally freed up hands for carrying provisions and the early hominins could have easily fed from both terrestrial

and arboreal resources.

The provisioning hypothesis states that having hands free to carry food allowed males to provision females and offspring. Since much of the females energy went to child-rearing, the ability of a male to provision her and her offspring would have been an attractive quality. Those males who could walk more efficiently bipedally while carrying food would have been prime mate material, allowing both the male and female to reproduce successfully. However, species such as wolves provision their females and offspring even though they are quadrupeds by consuming meat and regurgitating it to the pups.

The truth of the matter is that the origins of bipedalism are still murky. Further research will hopefully help us come closer to a determination of why bipedalism, and hence our early ancestors, evolved. In the meantime, you can explore other hypotheses on the origins of bipedalism on the NOVA web site: http://www.pbs.org/wgbh/nova/evoluti...ipedalism.html [optional].

Dental Features

Apes have a chewing complex which is good for cutting and shredding food. Over time, hominins lose this dental feature, as the canine reduces in size, and the molars increase in size (Larsen 2014).

Brain Evolution

In relation to other mammals, primates have a more expanded and elaborate brain, including expansion of the cerebral cortex. Compare the complexity of the human brain on the left to the cat brain on the right (photos are not to scale).

Figure 3.4.3.6: Human Brain.

Figure 3.4.3.7: Cat Brain.

Clearly, significant anatomical changes have taken place during the evolution of the brain in primates, in other mammals, and in animals in general. Are there generalizations that can be made about the evolution of animal brains?

Striedter (2006) has identified a number of general principles of brain evolution applicable across a wide range of species (i.e. not just primates or mammals).

1) Embryonic brains across species are more similar than adult brains, because brains tend to diversify more as they grow toward adult form;

2) relative brain size to body size in the vertebrates (animals with backbones) has tended to increase more often than decrease over evolutionary time;

3) it appears that increases in relative brain size were generally accompanied by increases in social or food foraging complexity;

4) most increases in relative brain size were accompanied by increases in absolute body size;

5) increases in absolute brain size require changes in the brain's internal connections which imply greater modularity or specialization (specialized processing modules increasing the "division of labor" as opposed to the whole brain doing all kinds of processing equally) of brain anatomy and functioning;

6) evolution generally enlarges brains by extending the period of brain development before and after birth while conserving (keeping the same) the "birth order" of different brain regions, so that big-brained animals tend to have disproportionately larger late-"born" (late-developing) regions ("late equals large"), such as cerebral cortex, leading to disproportionately more cerebral cortex (increased corticalization) in big-brained mammals (non-mammals don't have cerebral cortex); however there are exceptions to this rule, for example, at any given absolute brain size, there is more cerebral cortex in simians than in prosimians, and in parrots there is an unusually large telencephalon (forebrain) which is not accounted for by the rule;

7) changes in size proportions of brain areas, although "automatic" within the scaling (allometric) rules above, can still be adaptive and undergo natural selection;

8) as brain regions increase in absolute or proportional size, they tend to become laminated--organized into sheets of neurons--allowing point for point corresponding connections between sensory and motor maps with minimal axonal and dendritic wiring, saving space and metabolic energy;

9) as brain size increases, more regional subdivisions occur from ancestral parts subdividing into new parts, as in the dorsal thalamus (located below the cortex near the center of the brain), or, as in the case of neocortex, a new part was added onto an ancestral set of conserved (retained over evolution) brain parts;

10) a principle known as Deacon's rule is that "large equals well connected," meaning that as the relative size of a brain structure increases it tends to receive more connections and to project (send) more outputs to other structures.

Striedter (2006) adds a number of additional generalizations about the mammal and primate brains, including human brains:

11) six-layered mammalian neocortex (found only in mammals like us) probably evolved from a 3-layered reptilian precursor called dorsal cortex (something like that found in turtles) by addition of several layers of cortex;

12) aside from neocortex, the mammalian brain is similar to the reptilian brain (which also has hippocampus, for example) but even with a "fundamental scheme" of brain regions and circuitry, many minor changes in wiring can drastically change how information flows through a brain and thus how it functions--thus, the mammal brain is not just an upscale version of the reptilian brain;

13) increasing corticalization in mammals cannot be explained in terms of the above scaling (allometric) rules and involved highly specialized changes in brain anatomy presumably due to natural selection which expanded precursor sensory and motor cortical regions;

14) bird forebrains evolved along a very different path with expansion of their dorsal ventricular ridge (DVR), the major sensorimotor region of the avian telencephalon, highly similar in function to mammalian neocortex, making "many birds at least as intelligent as most mammals."

Striedter adds a number of points about the **human brain** in an attempt to identify features that make it special compared to the brains of other mammals.

15) In the six million years since bipedal apes (hominins) diverged from other apes, absolute brain size increased radically (about fourfold), not gradually, but in bursts--**from when genus *Homo* first evolved, absolute brain size doubled from 400 to 800 cubic centimeters, then remained relatively steady in *Homo erectus* during the next 1.5 million years, but then exploded again in the transition to *Homo sapien* until about 100,000 years ago, at which time absolute brain size reached its current value of about 1,200 to 1,800 cubic centimeters.** The first jump in Homo brain size was likely related to change in diet involving transition to meat and later the cooking of meat. The second leap was perhaps stimulated by competition among humans for mates and other resources;

16) the principle of "late equals large" predicts large neocortex in humans (the human neocortex to medulla ratio is twice that of chimpanzees);

17) the principle of "large equals well connected" is consistent with known expanded numbers of projections from human neocortex to motor neurons in medulla (located just above spinal cord) and spinal cord permitting greater precision of control over muscles serving hands, lips, tongue, face, jaw, respiratory muscles, and vocal folds, required for the **development of human language about 50,000 to 100,000 years ago**;

18) once human language appeared, dramatic changes in human behavior became possible without further increases in brain size;

19) increase in brain size has some disadvantages: including increased metabolic costs because the brain utilizes so much metabolic energy (20% of human metabolic energy even though it is only 2% of human body weight; being so metabolically expensive increases in brain size must be paid for by improved diet or reduction of other metabolic energy demands); decreased connectivity perhaps making the two hemispheres more independent of one another, and perhaps explaining why the two cerebral hemispheres became functionally specialized (performing different cognitive functions); and size limits of neonatal brain due to constraints imposed by size of the human mother's pelvis and birth canal. According to Striedter, these costs may explain why human brain size plateaued about 100,000 years ago;

20) within neocortex (found only in mammals), the lateral prefrontal cortex (located forward of your temples) has become relatively enlarged in the human brain, likely increasing its role in behavior (see Chapter 14 for additional discussion of the the lateral prefrontal cortex and higher cognitive functions such as thought, planning, etc.);

21) some key evolutionary changes in brain structure were not caused by increases in absolute or relative brain size, such as evolution of the neocortex of mammals, but require additional explanation; comparing distantly related species on absolute brain size alone misses important factors, for example, brains of some large whales weight 5 times as much as the human brain but whale brains have poorly laminated and thin neocortex; in cases of distantly related species, comparisons of relative brain size are more useful, for example, human and some toothed whales (e.g. killer whales) have relative brain sizes significantly larger than average mammals of similar body size;

22) two general hypotheses about brain evolution are that individual brain systems evolve independently by natural selection (the mosaic hypothesis) or alternatively that components of such systems evolve together because of functional constraints (the concerted or constraint hypothesis), with a third view being that all brain evolution is simultaneously both mosaic and concerted.

One problem with Striedter's approach is that it doesn't explicate the forces of natural selection that may account for more specific features of brain evolution in specific species, including our own. He admits that evolution of the neocortex cannot be explained by evolution of bigger brains and that neocortex evolved independently of absolute brain size. However, aside from restating the theory that complex social life in ancestral humans, along with competition among humans for resources, stimulated the evolution of increases in the size and complexity of the neocortex, he offers little insight about what role natural selection played in the evolution of the neocortex of mammals, or in brain evolution in general. As Adkins-Regan (2006, p.12-13) states in her critique of Striedter's work, "There is relatively little discussion of tests of hypotheses about the selective pressures responsible for the origin and maintenance of traits . . . The author would seem to be experiencing symptoms of discomfort with the concept of adaptation. . .. Given that brain mechanisms are products of natural selection, a central strategy in neuroscience should be to use the methods of evolutionary biology, which have been so successful in helping us to understand the mechanisms and design of organisms generally." In Chapter 14 of this text, on Intelligence and Cognition, consistent with the critique of Adkins-Regan, you will find an extensive discussion of the role of natural selection in evolution of brain systems involved in intelligence and thinking.

Encephalization of the Brain

Encephalization of the brain refers to a couple of things: 1) the **increase in brain size** over time and 2) the **size of the brain in relation to total body mass**. The brain-size to body mass ratio does not change that much in the hominins in spite of presumed increases in intelligence, however increases in brain size becomes significant beginning with the early Homo species. Studies of living mammal species suggest that **increased number of neurons and increased density of neuron packing into the cranial cavity may be a key factor in the evolution of increased intelligence across species.** However, while there is gradual increase in brain size throughout the australopithecine lineage, it is not until early *Homo* that there is a significant increase in cranial capacity, approximately a 20% increase over australopithecines. More significant is the approximately 50% increase in brain size of *Homo erectus* and the earlier *Homo* species. It is not just the size of the brain that is important. During this process

of encephalization, it has been speculated, without fossil evidence, that there was also a rewiring of the brain that coincides with the emergence of material culture such as stone tools. It is not until this occurs that hominins leave Africa, enabled greatly by cultural advances.

Non-human primate brains are symmetrical as are the brains of early hominins. **With the emergence of *Homo* we see the lateralization of the brain**--it becomes asymmetrial (right brain, left brain). We know this from endocasts. Endocasts form when minerals replace brain matter inside the cranium during the fossilization process. These endocasts allow researchers to study the cortical folds of the brain and compare it to modern humans. Based on endocasts, researchers determined that three areas of the brain began to **change in *Homo*:** the **cerebellum**, which handles learned motor activities, the **limbic system**, which processes motivation, emotion and social communication, and the **cerebral cortex**, which is responsible for sensory experiences, memory, and complex mental functions such as language, cognition, planning, imagination, and intelligence (see chapters 14 and 15 on Cognition and Intelligence and Language). It is these changes that may have allowed the early members of our genus, *Homo*, to develop **cultural adaptations to environmental pressures**.

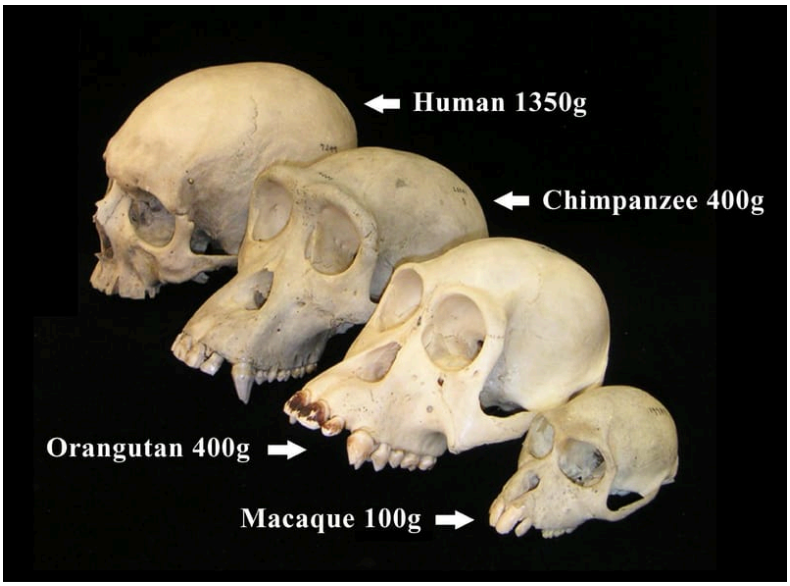

Figure 3.4.3.8: Comparison of cranial capacities of living primates. Primate skulls provided courtesy of the Museum of Comparative Zoology, Harvard University. (Image from Wikimedia Commons; File:Primate skull series with legend.png; https://commons.wikimedia.org/wiki/F...ith_legend.png; by Christopher Walsh, Harvard Medical School; licensed under the Creative Commons Attribution-Share Alike 2.5 Generic license).

Why did the brain change in early Homo?

The question that confronted researchers was why the brain changed. Big brains have some disadvantages:

- they require a lot of metabolic energy; approximately 25-30% of a human's metabolic energy is consumed by the brain although it comprises only 2% of total body weight
- big brains require infants to be born in an immature state with head and brain size small enough to permit birth through a relatively small birth canal, resulting in a longer period of infant dependency (the average infant brain at birth is only about 1/3 the size of an adult brain with much of brain development and behavioral and mental development occurring over a period of years after birth)
- longer infant dependency is an increased drain on maternal energy; the mother must have proper nutrition not only for herself but for the nursing infant
- it has been suggested that larger brains decrease the bipedal efficiency of females because they must have a wider pelvis and birth canal to give birth to a large brained infant

So, for large brains to become evolutionarily fixed in the *Homo* population, the advantages had to outweigh the disadvantages listed above.

One possible explanation incorporates the interaction of three different variables: group size, complex subsistence patterns (such

as foraging for food or domestication of animals and plants), and the nutritional value of meat (Campbell and Loy 2000: 318). Let's address group size first.

Research suggests that brain size and size of social groups correlate positively among living primates, implying that big brains helped individuals keep track of complex social information such as dominance hierarchies, alliances, enemies, etc.

Second, a big brain allows primates to keep track of large subsistence territories and allows omnivores to develop strategies for collecting a wide variety of foods.

Third, eating meat is a relatively easy way to get the nutrition needed to run a big brain, which, as mentioned above, in modern humans takes about 1/4 to 1/3 of our daily metabolic energy. However, raw meat requires a lot of energy to digest, so the invention of cooking meat over a fire may have played a role in evolution of larger brains because cooked meat is much easier, and requires less metabolic energy, to digest. Thus, cooking of meat provided a rich source of metabolic energy, supporting evolution of larger brains.

The argument for the social brain hypothesis is laid out by Robin Dunbar (1998). Dunbar also claims that it was changes in the neocortex, the 2-4 mm thick top layer of the cerebral hemispheres, that were critical in the "homininzation" (development of human cognitive abilities) of our ancestors (see chapter 14 for additional adaptive advantages associated with encephalization and increases in intelligence).

A related perspective on the evolution of the human brain emphasizes the role of culture in increasing brain size. As Geertz (2013, p. 180-181) states:

> The Australopithecine brain was approximately the same size as that of modern-day chimpanzees (some 400– 600 cm^3). The Homo sapiens brain is approximately 1200–1700 cm^3. But the expansion of the brain had begun already with the appearance of Homo habilis, the first hominine species that came out of the Australopithecine line some 2.5 million years ago (with a brain size of 500–800 cm^3) and became even more spectacular with the appearance 1.5 million years ago of the stone tool artist Homo erectus whose brain grew closer in size to modern humans at 750–1250 cm^3. It is today assumed by archeologists and paleontologists that the production and use of tools was incremental to the expansion of the brain. Because tool use is much more than simply knocking stones and bones together, and indeed, it depends very much on the recipes, rules and instructions of cultural patterns, it is widely accepted today that culture drove the expansion of the brain (along with other things, of course, such as eating meat). The causal chain, once again, however, is culture first, brain expansion afterwards. . . . 'Because tool manufacture puts a premium on manual skill and foresight, its introduction must have acted to shift selection pressures so as to favor the rapid growth of the forebrain as, in all likelihood, did the advances in social organization, communication, and moral regulation which there is reason to believe also occurred during this period of overlap between cultural and biological change. Nor were such nervous system changes merely quantitative; alterations in the interconnections among neurons and their manner of functioning may have been of greater importance than the simple increase in their number.'

The Forebrain includes the cerebral cortex (frontal, parietal, temporal, and occipital lobes) and a number of subcortical structures such as the thalamus, hypothalamus, limbic system, and basal ganglia. Different selection pressures arising from tool manufacture and use, complex social organization, communication, moral regulation, and other social and cultural factors would have likely affected different areas of the forebrain, and even different lobes of the cerebral cortex, in different ways. This follows from the fact of brain organization that different brain circuits and networks are specialized for different cognitive and behavioral functions (see Cosmides & Tooby, 2002).

Geology and Environmental Background

The Miocene period (roughly 23-5 million years ago) was geologically active in Africa. This is the period of the adaptive radiation of the apes and a period of mountain building that led to the formation of the Great Africa Rift Valley. With the emergence of the rift mountains, the rains that heretofore had moved across the continent from the Atlantic Ocean were blocked (referred to as a rain shadow), leading to the aridification of Eastern Africa. The savanna environment that evolved in Eastern Africa was and is a much more open environment than the forested environment of Western and Central Africa, leading to rise of new adaptations for plants and animals. It is in this newly emerging environment that hominin evolution takes off.

Paleoclimatic data has been correlated with speciation events in hominin evolution, but it does not seem to account for all speciation events. Nonetheless, the paleoclimatic data suggests the following:

- Grasslands spread in Africa between 10-5 million years ago during a cooling and drying phase. It is during this time frame that the common ancestor of African apes and humans lived. The common ancestor was more like a quadruped who was arboreal or at least spent a significant amount of time in the trees. In the middle of this period, approximately 7-6 million years ago, the first bipedal hominin emerged, and a few other early hominins are referred to as proto-hominins in recognition of their primitive, ape-like features.
- In the mid-Pliocene period, 3-2 million years ago, yet another cooling and drying phase is correlated with the adaptive radiation of the hominins, including the emergence of the robust australopithecines in the genus *Homo,* the same genus as modern humans.
- Near the beginning of the Pleistocene period, also known as the Ice Age, the environment continued to get drier. Open habitats spread in East Africa. During this period, *Homo ergaster* (*Homo erectus*) emerges and finally leaves the African continent.

This data has a tendency to make us think that hominin evolution was driven by environmental changes; however, geologic, climatic, and environmental changes in Africa during the Miocene, Pliocene and Pleistocene may have had little to do with the evolution of hominins, leaving open the possibility that the hypotheses discussed above, or others yet to be proposed, may be more causally related to the evolution of hominins.

Key Transitions in Human Evolution

On the evolutionary road to modern humans, some scientists have identified several "key transitions: (1) African ape to terrestrial bipedal ape (around 4 Ma)[Ma=million years ago]; (2) terrestrial bipedal ape (australopithecine) to ‘early Homo’ (around 2 Ma); (3) Early Homo [species] to Homo heidelbergensis (1–0.8Ma); (4) Homo heidelbergensis to larger-brained Homo (from 500 ka) [ka=thousand years ago], and (5) larger-brained Homo to H. sapiens (from 200 ka) . . . [Regarding social behavior,] "among archeologically based models, there is a total agreement that the emergence of basal hominin sociality, as part of our primate heritage, should be attributed to the very first evolutionary stages, possibly before the emergence of the Homo genus" (Anghelinu, 2013, p.13).

Proto-hominins

The oldest hominin discovered to date is from between 7.2 to 6.8 mya (million years ago).

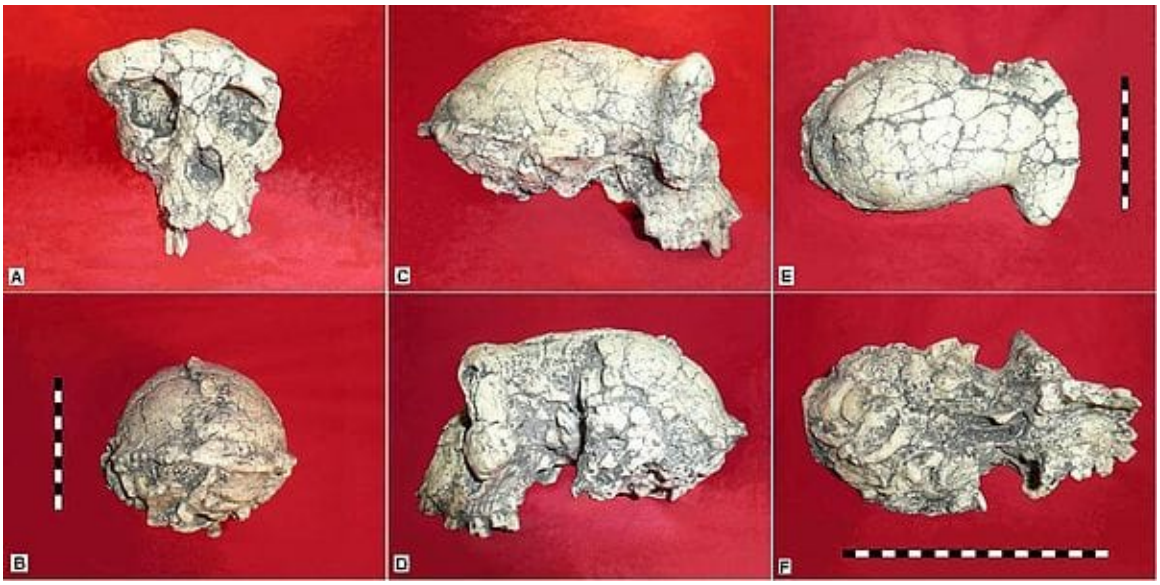

Figure 3.4.3.9: *Sahelanthropus tchadensis*. The oldest known hominin.

The skull is a combination of ape-like and human-like features. Ape-like features include brain size, heavy brow ridge. Its human-like features include forward position of the foramen magnum, smaller canine teeth, and intermediate thickness of the premolar and molar enamel. Due to the pronounced brow ridge, Brunet's team suggests that the specimen is male.

There is debate among researchers as to whether this fossil is a hominin or an ape. Some suggest that the specimen belongs to that of a female ape because it is likely to find canines worn at the tips in female apes.

Hominins

While the hominins will be presented more or less in chronological order, do not mistake chronological order for linear evolutionary relationships; some hominins that are presented are not in the direct line to modern humans. It is also important to keep in mind that new discoveries are made each year that refine what we know about human evolution.

It is highly recommended that you begin your exploration of human evolution by watching the PBS documentary, Becoming Human (https://www.pbs.org/wgbh/nova/video/...-human-part-1/).

Early hominins

Australopithecus afarensis

Discovered in 1974 at Hadar, Ethiopia, *Australopithecus afarensis* is arguably the most well know fossil hominin species. It is dated from 3.7-3.0 mya (Scarre 2014). Over 40% of the skeleton was recovered, which allowed the team to fully reconstruct the skeleton. This fossil specimen, named Lucy, coupled with footprints found at Laetoli, Tanzania, in 1978 by Mary Leakey, confirmed that *Au. afarensis* was fully bipedal, albeit not exactly like modern humans. The footprints at Laetoli indicate that *Au. afarensis* had a short stride and a strolling gait. Since the 1970s, hundreds of specimens of Au. afarensis have been found (60 individuals at least from Hadar alone!) in Ethiopia, Kenya, and Tanzania, allowing paleoanthropologists to make "definitive statements about the locomotor pattern and stature of" (Jurmain 2013: 211) this early hominin.

Figure 3.4.3.10: Reconstruction of the fossil skeleton of "Lucy" the *Australopithecus afarensis*

Au. afarensis has several primitive, or ape-like, features, including a relatively small brain in comparison to *Homo*, a u-shaped dental arcade, a flat nose, a flattened forehead (referred to as platycephaly) and prognathic face (characterized by a protruding lower jaw). Its canines, while larger than *Homo*, are smaller than earlier hominins. While its brain was larger than earlier hominins, it is still small in comparison to genus Homo. There is evidence for sexual dimorphism; *Au. afarensis* males were no taller than 5 feet and females about 3-4 feet, similar in proportion to modern African apes. *Au. afarensis* has a suite of derived traits associated with bipedalism; i.e., bowl-shaped pelvis, s-curve of the vertebral column, and knee anatomy. However, the curvature of the fingers and toes and the proportion of the arms to legs suggest to some researchers that *Au. afarensis* spent some time in the trees.

In 2006, a 3.3 million year old *Au. afarensis* child was discovered less than 4 km from where Lucy was found in 1974. It is not only the oldest juvenile fossil ever found, it is also the most complete hominin fossil found to date. Selam, as the fossil was nicknamed (or Lucy's baby or Dikika's baby), confirmed earlier suggestions that *Au. afarensis* was bipedal, yet spent time in the trees. The shoulder structure with its upward pointing shoulder joints and the bony ridge running along the shoulder blades are like that of apes, which would have facilitated arboreal movement even if they were not as fully capable as chimpanzees at moving in trees.

Paleoecological data indicates that *Au. afarensis* lived in both grassland (savanna) and woodland environments.

Australopithecus africanus

Figure 3.4.3.11: *Australopithecus africanus* (Mrs. Ples)

Australopithecus africanus (see Figure 3.7.2, above) has been dated to 3-2 mya (Scarre 2014). In comparison to *Au. afarensis*, *Au. africanus* has smaller incisors and larger molars; the canines no longer have the pointed, triangular appearance seen in apes and *Au. afarensis*; however, *Au. africanus* still exhibits some protrusion of the lower jaw and has a small brain like that of *Au. afarensis*. There is general consensus that *Au. africanus* is a direct descendent of *Au. afarensis*. Its relationship to *Homo* is less clear.

Australopithecus garhi

Found in Bouri, Ethiopia in 1997, *Au. garhi* (see Figure 3.7.2, above) dates to 2.5 mya. Few fossil specimens have been found and those that have are relatively fragmentary. One cranium and other skull fragments were found and serve as the basis of the species identification. The size and shape of its molar teeth suggest to some researchers that *Au. garhi* is related to *Paranthropus aethiopicus* (see below), but its other features, e.g., braincase, face, and other teeth, are more like genus *Homo*. In light of this, some researchers contend it is ancestral to *Homo*.

Figure 3.4.3.12: *Australopithecus garhi*.

Australopithecus sediba

Australopithecus sediba (Figure 3.3.13) was found in 2008 at Malapa Cave, South Africa, dating to 1.95-1.75 mya, has a mosaic of characteristics that suggest it may be transitional from the australopiths to genus *Homo*. However, this claim is controversial as

the earliest dates for *Homo* predate *Au. sediba* by about 500,000 years (Becoming Human 2008).

Figure 3.4.3.13: *Australopithecus sediba*.

The features that link *Au. sediba* to *Homo* include the pelvis shape, more vertical brain case, smaller cheek bones, and molar shape.

Robust Australopiths

Three robust species of hominins emerged in the Plio-Pleistocene period: *Paranthropus aethiopicus*, *Paranthropus boisei*, and *Paranthropus robustus* (see Figures 3.3.14-17). They have morphological features that suggest they were well adapted for eating hard foods that needed grinding, which led to their being identified as “robust.”

Note

There is debate over whether the differences mentioned above qualify the robust australopiths to be in a separate genus from the australopithecines. In some anthropological works the genus *Australopithecus* is used. In others, such as this work, *Paranthropus* is used.

Figure 3.4.3.14: *Paranthropus aethiopicus*.

P

Figure 3.4.3.15. *Paranthropus boisei*.

There is no evidence to suggest that *P. boisei* is ancestral to any subsequent hominin.

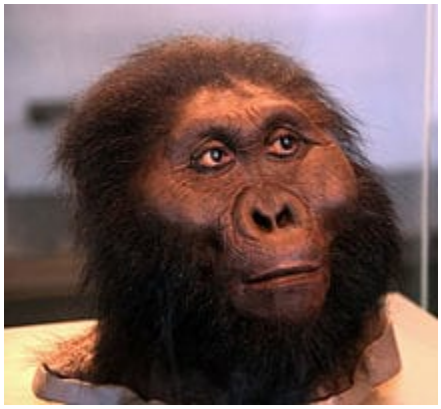

Figure 3.4.3.16. *Paranthropus boisei*; model of adult male (Smithsonian Museum of Natural History).

Figure 3.4.3.17. *Paranthropus robustus*.

Homo Genus

Above we described our oldest human ancestors, primarily members of the genus Australopithecus who lived between 2 million and 4 million years ago. Here we introduce the earliest members of the **genus Homo**, focusing on the species *Homo habilis* and *Homo erectus* (see Figure 3.3.19 and Figure 3.3.20, below).

Defining The Genus Homo

When grouping species into a common genus, biologists will consider criteria such as physical characteristics (morphology), evidence of recent common ancestry, and adaptive strategy (use of the environment). However, there is disagreement about which of those criteria should be prioritized, as well as how specific fossils should be interpreted in light of the criteria. There is general agreement that species classified as Homo should share characteristics broadly similar to our species. These include the following:

- a relatively large brain size, indicating a high degree of intelligence;
- a smaller and flatter face;
- smaller jaws and teeth; and
- increased reliance on culture, particularly the use of stone tools, to exploit a greater diversity of environments (adaptive zone).

Some researchers would include larger overall body size and limb proportions (longer legs/shorter arms) in this list. There is also an apparent decline in sexual dimorphism (body-size differences between males and females). While these criteria seem relatively clear-cut, evaluating them in the fossil record has proved more difficult, particularly for the earliest members of the genus. There are several reasons for this. First, many fossil specimens dating to this time period are incomplete and poorly preserved, making them difficult to evaluate. Second, early Homo fossils appear quite variable in brain size, facial features, and teeth and body size, and there is not yet consensus about how to best make sense of this diversity.

In this section, we will take several pathways toward examining the origin and evolution of the genus Homo. First, we will explore the environmental conditions of the Pleistocene epoch in which the genus Homo evolved. Next we will examine the fossil evidence for the two principal species traditionally identified as early Homo: Homo habilis and Homo erectus. Then we will use data from fossils and archeological sites to reconstruct the behavior of early members of Homo, including tool manufacture, subsistence practices, migratory patterns, and social structure. Finally, we will consider these together in an attempt to characterize the key adaptive strategies of early Homo and how they put our early ancestors on the trajectory that led to our own species, Homo

sapiens.

Climate

The early hominin species covered previously, such as Ardipithecus ramidus and Australopithecus afarensis, evolved during the late Pliocene epoch. The Pliocene (5.3 million to 2.6 million years ago) was marked by cooler and drier conditions, with ice caps forming permanently at the poles. Still, Earth's climate during the Pliocene was considerably warmer and wetter than at present.

The subsequent Pleistocene epoch (2.6 million years to 11,000 years ago) ushered in major environmental change. The Pleistocene is popularly referred to as the Ice Age. Since the term "Ice Age" tends to conjure up images of glaciers and woolly mammoths, one would naturally assume that this was a period of uniformly cold climate around the globe. But this is not actually the case. Instead, climate became much more variable, cycling abruptly between warm/wet (interglacial) and cold/dry (glacial) cycles.

In Africa, paleoclimate research has determined that grasslands expanded and shrank multiple times during this period, even as they expanded over the long term, becoming increasingly common during the Pleistocene. One solution adopted by some hominins was to specialize in feeding on the new types of plants growing in this landscape. The robust australopithecines probably developed their large molar teeth with thick enamel in order to exploit this particular dietary niche.

Members of the genus Homo took a different route. Faced with the unstable African climate and shifting landscape, they evolved bigger brains that enabled them to rely on cultural solutions such as crafting stone tools that opened up new foraging opportunities. This strategy of behavioral flexibility served them well during this unpredictable time and led to new innovations such as increased meat-eating, cooperative hunting, and the exploitation of new environments outside Africa, including Europe and Asia.

The Emergence of Homo (our Genus)

The emergence of the genus *Homo* marks the advent of larger brains, the emergence of material culture (at least material culture that survives in the archeological record), and the eventual colonization of the world outside of Africa. The earliest *Homo* species are contemporaneous with several australopiths: *Au. africanus*, *Au. garhi*, *Au. sediba*, and all of the *Paranthropus* species. Africa was flush with hominins (Figure 3.4.3.16). There are several trends we see in the evolution of the earliest *Homo* species to humans, *Homo sapiens*:

- Rounding of the cranium
- Enlargement and rewiring of the brain (judged from endocasts)
- Smaller faces and teeth
- Decreasing prognathism
- Tallness
- Diversity of cultural traits

As with the overview on early hominins, we will continue taking the "lumper" approach - a tendency to lump specimens into fewer species rather than tending to differentiate and hypothesizing a greater number of species. Several *Homo* species will not be discussed in detail, but may be mentioned in passing, e.g., *Homo rudolfensis*, *Homo ergaster*, *Homo gautengensis*, *Homo antecessor*, *Homo cepranensis*, *Homo rhodesiensis*, *Homo tsaichangensis*. We will first examine the morphological characteristics of various *Homo* species. Cultural traits will be addressed separately.

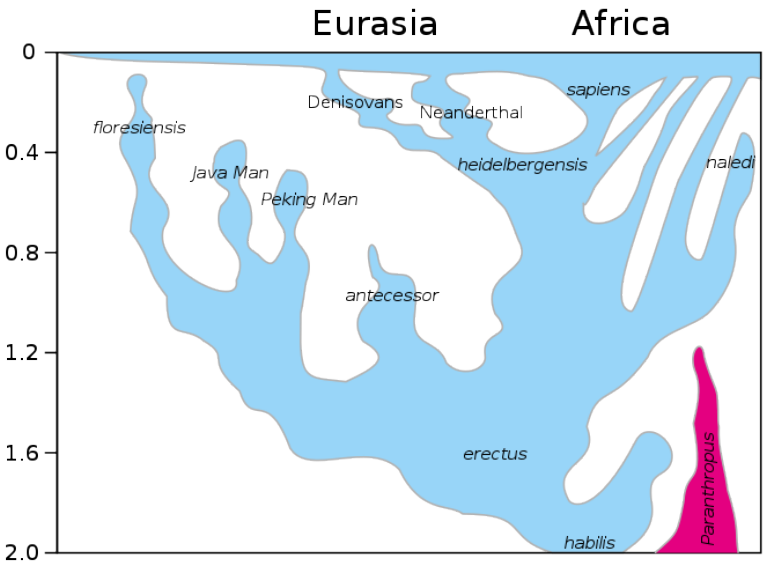

Figure 3.4.3.18: A model of the evolution of the genus Homo over the last 2 million years (millions of years, Mya, is on the vertical axis). The rapid "Out of Africa" expansion of H. sapiens is indicated at the top of the diagram by the lateral expansion of blue all the way across the top of the diagram, with admixture indicated with Neanderthals, Denisovans, and unspecified archaic African hominins. The late survival of robust australopithecines (Paranthropus) alongside Homo until 1.2 Mya is indicated in purple.

- H. heidelbergensis is shown as the link between Neanderthals, Denosiovans and H. sapiens
- Division of Asian H. erectus into Java Man and Peking Man
- H. antecessor shown as a branch of H. erectus reaching Europe
- After H. sapiens emerge from Africa some 60 kya they spread across the globe and interbred with other descendants of H. heidelbergensis, and Neanderthals, Denisovans

Homo Habilis: The Earliest Members of our Genus

Homo habilis has traditionally been considered the earliest species placed in the genus Homo. However, as we will see, there is substantial disagreement among paleoanthropologists about the fossils classified as Homo habilis, including whether they come from a single or multiple species, or even whether they should be part of the genus Homo at all.

Compared to the australopithecines, **Homo habilis has a somewhat larger brain size–an average of 650 cubic centimeters (cc) compared to less than 500 cc for Australopithecus.** Additionally, the skull is more rounded and the face less prognathic. However, the postcranial remains show a body size and proportions similar to Australopithecus. Known dates for fossils identified as Homo habilis range from about 2.5 million years ago to 1.7 million years ago.

Summary features of Homo habilis (adapted by Kenneth A. Koenigshofer, PhD, Chaffey College, from *Explorations: An Open Invitation to Biological Anthropology;* https://explorations.americananthro.....php/chapters/; Chapter 10, "Early Members of the Genus Homo" by Bonnie Yoshida-Levine Ph.D.; Beth Shook, Katie Nelson, Kelsie Aguilera, and Lara Braff, Eds.; licensed under a Creative Commons Attribution-NonCommercial 4.0 International License, except where otherwise noted).

Hominin: Homo habilis

Dates 2.5 million years ago to 1.7 million years ago
Region(s): East and South Africa
Famous Discoveries: Olduvai Gorge, Tanzania; Koobi Fora, Kenya; Sterkfontein, South Africa

Brain Size: 650 cc average (range from 510 cc to 775 cc)
Dentition: Smaller teeth with thinner enamel compared to Australopithecus; parabolic dental arcade shape
Cranial Features: Rounder cranium and less facial prognathism than Australopithecus
Postcranial Features: Small stature; similar body plan to Australopithecus
Culture: Oldowan tools; oldest of known stone tool type; scrapers, choppers; indication of changing cognitive abilities (see Module 3.8)

Stone tools almost certainly predated Homo habilis (possibly by Australopithecus garhi or the species responsible for the tools from Kenya dating to 3.7 million years ago). However, stone tools become more frequent at sites dating to about 2 million years ago, the time of Homo habilis (Roche, Blumenschine, and Shea 2009). This suggests that these hominins were increasingly reliant on stone tools to make a living.

Stone tools are assigned a good deal of importance in the study of human origins. **Studying the form of the tools, the raw materials selected, and how they were made and used can provide insight into the thought processes of early humans** and how they modified their environment in order to survive (see Supplementary Content, Chapter 18, Material Culture). Paleoanthropologists have traditionally classified collections of stone tools into industries, based on their form and mode of manufacture. There is not an exact correspondence between a tool industry and a hominin species; however, some general associations can be made between tool industries and particular hominins, locations, and time periods. The names for the four primary tool industries in human evolution (from oldest to most recent) are the Oldowan, Acheulean, Mousterian, and Upper Paleolithic. The oldest stone tool industry is the Oldowan, named after the site of Olduvai Gorge where the tools were first discovered. The time period of the Oldowan is generally considered to last from about 2.5 mya to 1.6 mya. The tools of this industry are described as “flake and chopper” tools—the choppers consisting of stone cobbles with a few flakes struck off them. To a casual observer, these tools might not look much different from randomly broken rocks. However, they are harder to make than their crude appearance suggests. The rock selected as the core must be struck by the rock serving as a hammerstone at just the right angle so that one or more flat flakes are removed. This requires selecting rocks that will fracture predictably instead of chunking, as well as the ability to plan ahead and envision the steps needed to create the finished product. The process leaves both the core and the flakes with sharp cutting edges that can be used for a variety of purposes.

What were the hominins doing with the tools? One key activity seems to have been butchering animals. Animal bones with cutmarks start appearing at sites with Oldowan tools. Studies of animal bones at the site show leg bones are often cracked open, suggesting that they were extracting the marrow from the bone cavities. It is interesting to consider whether the hominins hunted these animals or acquired them through other means. The butchered bones come from a variety of African mammals, ranging from small antelope to animals as big as wildebeest and elephants! It is difficult to envision slow, small-bodied Homo habilis with their Oldowan tools bringing down such large animals. One possibility is that the hominins were scavenging carcasses from lions and other large cats. Regardless of how they were acquiring the meat, all these activities suggest an important dietary shift from the way that the australopithecines were eating. The Oldowan toolmakers were exploiting a new ecological niche that provided them with more protein and calories. Overall, increasing use of stone tools allowed hominins to expand their ecological niche and exert more control over their environment. As we’ll see shortly, this pattern continued and became more pronounced with Homo erectus.

Discovery of *Homo habilis*

Homo habilis was first discovered by Louis and Mary Leakey at Olduvai Gorge, Tanzania in 1960. Associated with stone tools (Oldowan), the Leakeys named their discovery “handy man.” *H. habilis* fossils have been found in Tanzania, Kenya, Ethiopia, and South Africa, although there is some debate as to whether the South Africa specimens should be included in the species. Some researchers contend that there was another early *Homo* species, *Homo rudolfensis*, which dates back to 2.4-2.5 mya. The *H. rudolfensis* fossils are slightly larger than those of *H. habilis*, leading some researchers to suggest the *H. habilis* exhibited sexual dimorphism and what we are seeing are male and female specimens of *H. habilis*. Others claim the size differences are significant enough to warrant the two species designations (O’Neil 1999-2012). In 2013 a *Homo* mandible was discovered in the Ledi-Geraru research area, Afar, Ethiopia. Dated to 2.8 to 2.75mya, the mandible exhibits an *Australopithecus*-like chin and *Homo*-like teeth (Villmoare et al. 2015). While still early in the research process, this discovery and further research may push back the date of the origin of *Homo* and help to resolve the debate between the *H. rudolfensis* and *H. habilis* fossils. For our purpose, we will consider them all *H. habilis*, making the approximate date range for this hominin 2.5 to 1.4mya or less conservatively to 1.7mya.

Figure 3.4.3.19: *Homo habilis*.

Morphologically, *H. habilis* has a larger brain than the australopiths, about 35% larger (O'Neil c1999-2012). You will recall from the section on trends in human evolution that it is speculated that the brain also began to rewire at this point. *H. erectus* exhibits less prognathism (protrusion of the lower jaw) and platycephaly (flattening of the back of the head) than early hominins. The brow ridge is also smaller. All of these traits together make the face smaller than the australopiths. Postcranially, *H. habilis* exhibit a mix of primitive and derived traits. Primitive traits connecting it to an australopith ancestor are the longer forearms and the size of the finger bones along with how the tendons attach to the wrist bones. The tips of the finger bones are broad like humans. Smaller teeth, a dental arcade in the shape of a parabolic arch, foot morphology, and a more rounded skull complete the human-like traits. Microanalysis of tooth wear indicates that *H. habilis* was omnivorous.

Table 3.3.2

Key Homo habilis fossil locations and the corresponding fossils and dates (adapted by Kenneth A. Koenigshofer, PhD, Chaffey College, from *Explorations: An Open Invitation to Biological Anthropology;* https://explorations.americananthro.....php/chapters/; Chapter 10, "Early Members of the Genus Homo" by Bonnie Yoshida-Levine Ph.D.; Beth Shook, Katie Nelson, Kelsie Aguilera, and Lara Braff, Eds.; licensed under a Creative Commons Attribution-NonCommercial 4.0 International License, except where otherwise noted).

Location of Fossils Dates (mya = millions of years ago) Description
Ledi-Gararu, Ethiopia 2.8 mya Partial lower jaw with evidence of both Australopithecus and Homo traits; tentatively considered oldest Early Homo fossil evidence.
Olduvai Gorge, Tanzania 1.7 mya to 1.8 mya. Several different specimens classified as Homo habilis, including the type specimen found by Leakey, a relatively complete foot, and a skull with a cranial capacity of about 600 cc.
Koobi Fora, Lake Turkana Basin, Kenya 1.9 mya. Several fossils from Lake Turkana basin show considerable size differences, leading some experts to classify the larger specimen as a separate species, *Homo rudolfensis*.
Sterkfontein and other possible about 1.7 mya South African caves have yielded fragmentary remains identified as Homo habilis, but South African cave sites secure dates and specifics about the fossils are lacking.

Homo erectus

About 1.9 mya, a new species of Homo appeared. Known as *Homo erectus*, the prevailing scientific view was that this species was much more like us. These hominins were equipped with bigger brains and large bodies with limb proportions similar to our own. Perhaps most importantly, their way of life is now one that is recognizably human, with more advanced tools, hunting, use of fire, and colonizing new environments outside of Africa.

Compared to Homo habilis, Homo erectus had a larger brain size (average of about 900 cc compared to 650 cc to 750 cc for habilis). Instead of having a rounded shape like our skulls have, the erectus skull was long and low like a football, with a receding forehead, and a horizontal ridge called an occipital torus that gave the back of the skull a squared-off appearance. The cranial bones are thicker than those of modern humans, and some Homo erectus skulls have a slight thickening along the sagittal suture called a sagittal keel. Large, shelf-like brow ridges hang over the eyes. As noted above, the climate was increasingly arid and the forest canopy in parts of Africa was being replaced with a more open grassland environment, resulting in increased sun exposure for our ancestors. Compared to the earlier australopithecines, members of the genus Homo were also developing larger bodies and brains, starting to obtain meat by hunting or scavenging carcasses, and crafting sophisticated stone tools. For purposes of cooling, H. erectus may have had little body hair accompanied by darkened skin to protect against sun exposure. It is generally agreed that Homo erectus was the first hominin to migrate out of Africa and colonize Asia and later Europe (although recent discoveries in Asia may challenge this view).

Homo erectus Fossils

Based on current fossil data, *Homo erectus* existed between 1.9 million (mya) to 25 thousand years ago (Jurmain 2013). *H. erectus*, literally "upright human," fossils have been found in Java (Indonesia), Africa, China, Europe, and Israel. Based on morphological differences in the cranium, some scientists identify two species, *H. erectus* in Asia and *H. ergaster* in Africa with the African specimens being smaller than the Asian; however, we will use the *H. erectus* designation for both.

Figure 3.4.3.20: *Homo erectus,* Turkana Boy.

In 1984, a nearly complete *H. erectus* skeleton was found along a river in northern Kenya. Potassium-argon dating places "Turkana Boy" between 1.64 and 1.33 million years ago (mya). Aging and sexing of the fossil remains indicate that the individual was a male about age eight. He stood about 5'3" tall. Recent studies indicate that Turkana Boy followed the growth pattern of apes, so would have been near his adult height at the time of his death (Jurmain et al. 2013).

Homo erectus has a long history in Indonesia; fossils from Java were dated by argon dating to about 1.6 million to 1.8 million years. *H. erectus* fossils from the site of Ngandong in Java have yielded very recent dates of 43,000 years, although a more recent study with different dating methods concluded that they were much older—between 140,000 and 500,000 years old.

The pattern of increased brain size continued with *H. erectus*; its brain is up to 50% larger than its predecessor, *H. habilis* (O'Neil c1999-2012). This large brain was supported by a diet heavy in meat and other proteins. Its distinguishing characteristics include its sagittal keeling (a thickening of bone that runs from front to back on top of the skull; likely for muscle attachment) massive brow ridges (supraorbital tori) and bony prominences on the back of the skull. Postcranially, *H. erectus*' bones are thicker than *H. habilis*, as were its jaws and face bones, and the proportion of arms to legs is like that of modern humans, causing some to suggest that its bipedal gait was like ours. The length of its leg bones indicates that *H. erectus* would have been an efficient long-distance runner, allowing them to "run down small and even medium size game animals on the tropical savannas of East Africa" (O'Neil c1999-2012). If so, as mentioned above, it is likely that *H. erectus* had much less body hair than its predecessors,

as they would have needed to be able to sweat efficiently to cool the body. It is possible that *H. erectus* had little body hair (NOVA 2011). During the Pleistocene, the climate was increasingly arid and the forest canopy in parts of Africa was being replaced with a more open grassland environment, resulting in increased sun exposure for our ancestors.

Compared to the earlier australopithecines, members of the genus *Homo* were also developing larger bodies and brains, starting to obtain meat by hunting or scavenging carcasses, and crafting sophisticated stone tools. According to Nina Jablonski, an expert on the evolution of human skin, the loss of body hair and increased sweating capacity are part of the package of traits characterizing the genus *Homo*. While larger brains and long-legged bodies made it possible for humans to cover long distances while foraging, this new body form had to cool itself effectively to handle a more active lifestyle. Preventing the brain from overheating was especially critical. The ability to keep cool may have also enabled hominins to forage during the hottest part of the day, giving them an advantage over savanna predators, like lions, that typically rest during the heat of the day.

As noted above, scientists generally agree that *H. erectus* was the first hominin to leave Africa. As mentioned previously, fossils have been found in Africa, northern China, Indonesia, Europe, and Israel. In the Republic of Georgia, fossils were found in strata dated to 1.7mya suggesting that *H. erectus* left Africa soon after it evolved. A recent report (Dembo et al. 2015) posits that *H. habilis* was the first hominin to leave Africa, not *H. erectus*. Should this contention be supported with more data, it can still be argued that *H. erectus* was quite successful in colonizing the Old World (Africa, Europe, and Asia), helped, no doubt, by its advanced cultural behaviors.

Now we can address the question of why *Homo erectus* traveled such vast distances to these far-flung regions. To do this, we have to consider what we have learned about the biology, culture, and environmental circumstances of *Homo erectus*. The larger brain and body size of *Homo erectus* were fueled by a diet consisting of more meat, and longer more powerful legs made it possible to walk and run longer distances to acquire food. Since they were eating higher on the food chain, it was necessary for them to extend their home range to find sufficient game. Cultural developments including better stone tools and new technology such as fire gave them greater flexibility in adapting to different environments. Finally, the major Pleistocene climate shift discussed earlier in the chapter certainly played a role. Changes in air temperature, precipitation, access to water sources, and other habitat alteration had far-reaching effects on animal and plant communities; this included *Homo erectus*. If hominins were relying more on hunting, the migration patterns of their prey could have led them increasingly long distances.

There is evidence of *Homo erectus* in China from several regions and time periods. *Homo erectus* fossils from northern China, collectively known as “Peking Man,” are some of the most famous human fossils in the world, dated to about 400,000–700,000 years ago. The discovery of stone tools from China dating to 2.1 million years, older than any *Homo erectus* fossils anywhere, opens up the intriguing possibility that hominins earlier than *Homo erectus* could have migrated out of Africa.

At this time, researchers aren’t in agreement as to whether the first Europeans belonged to *Homo erectus* proper or to a later descendent species.

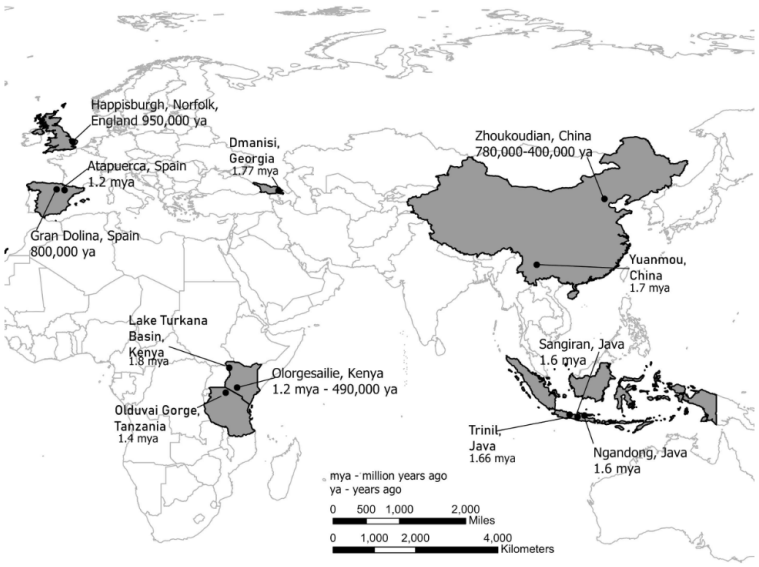

Figure 3.4.3.21: Map showing the locations of Homo erectus fossils around Africa and Eurasia (adapted by Kenneth A. Koenigshofer, PhD, Chaffey College, from *Explorations: An Open Invitation to Biological Anthropology;*

Homo erectus Culture

Homo erectus shows significant cultural innovations in diet, technology, life history, environments occupied, and perhaps even social organization, some that you will probably recognize as more “human-like” than any of the hominins previously covered. About 1.5 million years ago, some Homo erectus populations began making different forms of tools (known as "material culture;" see Section 3.14). These tools–classified together as constituting the Acheulean tool industry–are more complex in form and more consistent in their manufacture. Unlike the Oldowan tools, which were cobbles modified by striking off a few flakes, Acheulean toolmakers carefully shaped both sides of the tool. This type of technique, known as bifacial flaking, requires more planning and skill on the part of the toolmaker; he or she would need to be aware of principles of symmetry when crafting the tool. One of the most common tool forms of this period was the handaxe. Besides handaxes, forms such as scrapers, cleavers, and flake tools are present at Homo erectus sites. One striking aspect of Acheulean tools is their uniformity. They are more standardized in form and mode of manufacture than the earlier Oldowan tools. For example, the aforementioned handaxes vary in size, but they are remarkably consistent in regard to their shape and proportions. They were also an incredibly stable tool form over time—lasting well over a million years with little change.

Recently, newer methods—including microscopic analysis of burned rock and bone—have revealed clear evidence of fire use at Koobi Fora, Kenya, dating to 1.5 million years ago (Hlubik et al. 2017).

There is general consensus that *H. erectus* evolved from *H. habilis* and *Homo heidelbergensis* evolved from *H. erectus* in Africa, eventually supplanting *H. erectus* populations in the Old World--Africa, Asia, and Europe (Figure 3.4.3.18).

Tool Use and Cognitive Abilities of Homo erectus

What (if anything) do the Acheulean tools tell us about the mind of Homo erectus? Clearly, they took a fair amount of skill to manufacture. Apart from the actual shaping of the tool, other decisions made by toolmakers can reveal their use of foresight and planning. Did they just pick the most convenient rocks to make their tools, or did they search out a particular raw material that would be ideal for a particular tool? Analysis of Acheulean stone tools suggest that at some sites, the toolmakers selected their raw materials carefully—traveling to particular rock outcrops to quarry stones and perhaps even removing large slabs of rock at the quarries to get at the most desirable material. Such complex activities would require advanced planning. They also likely required cooperation and communication with other individuals, as such actions would be difficult to carry out solo. However, other Homo erectus sites lack evidence of such selectivity; instead of traveling even a short distance for better raw material, the hominins tended to use what was available in their immediate area (Shipton et al. 2018). In contrast to Homo erectus tools, the tools of early modern Homo sapiens during the Upper Paleolithic display tremendous diversity across regions and time periods. Additionally, Upper Paleolithic tools and artifacts communicate information such as status and group membership. Such innovation and social signaling seem to have been absent in Homo erectus, suggesting that they had a different relationship with their tools than did Homo sapiens (Coolidge and Wynn 2017). Some scientists assert that these contrasts in tool form and manufacture may signify key cognitive differences between the species, such as the ability to use a complex language.

Table 3.3.3. Characteristics of Homo erectus. (adapted by Kenneth A. Koenigshofer, PhD, Chaffey College, from *Explorations: An Open Invitation to Biological Anthropology;* https://explorations.americananthro.....php/chapters/; Chapter 10, "Early Members of the Genus Homo" by Bonnie Yoshida-Levine Ph.D.; Beth Shook, Katie Nelson, Kelsie Aguilera, and Lara Braff, Eds.; licensed under a Creative Commons Attribution-NonCommercial 4.0 International License, except where otherwise noted).

Hominin	*Homo erectus*
Dates	1.8 million years ago to about 200,000 years ago
Region(s)	East and South Africa; West Eurasia; China and Southeast Asia

Famous Discoveries	Lake Turkana, Olorgesailie, Kenya; Zhoukoudian, China; Dmanisi, Republic of Georgia
Brain Size	Average 900 cc; range between 650 cc and 1,100 cc
Dentition	Smaller teeth than *Homo habilis*
Cranial Features	Long, low skull with robust features including thick cranial vault bones and large brow ridge, sagittal keel, and occipital torus
Postcranial Features	Larger body size compared to *Homo habilis*; body proportions (longer legs and shorter arms) similar to *Homo sapiens*
Culture	Acheulean tools (in Africa) (see Module 3.8); evidence of increased hunting and meat-eating; use of fire; migration out of Africa

THE BIG PICTURE OF EARLY *HOMO*

We are discovering that the evolution of the genus *Homo* is more complex than what was previously thought. The earlier prevailing view of a simple progression from *Australopithecus* to *Homo habilis* to *Homo erectus* as clearly delineated stages in human evolution just doesn't hold up anymore.

Variability in the Fossil Record of Early Homo

As is apparent from the information presented here, there is tremendous variability during this time. While fossils classified as *Homo habilis* show many of the characteristics of the genus *Homo*, such as brain expansion and smaller tooth size, the small body size and long arms are more akin to australopithecines. There is also tremendous variability within the fossils assigned to *Homo habilis*, so there is no consensus on whether it is a single or multiple species of *Homo*, a member of the genus *Australopithecus*, or even a yet-to-be-defined new genus.

What does this diversity mean for how we should view early *Homo*? First, there isn't an abrupt break between *Australopithecus* and *Homo habilis* or even between *Homo habilis* and *Homo erectus*. Characteristics we define as *Homo* don't appear as a unified package; they appear in the fossil record at different times. This is known as mosaic evolution.

We can consider several explanations for the diversity we see within early *Homo* from about 2.5 million to 1.5 million years ago. One possibility is the existence of multiple contemporaneous species of early *Homo* during this period. In light of the pattern of environmental instability discussed earlier, it shouldn't be surprising to see fossils from different parts of Africa and Eurasia display tremendous variability. Multiple hominin forms could also evolve in the same region, as they diversified in order to occupy different ecological niches. However, even the presence of multiple species of hominin does not preclude their interacting and interbreeding with one another.

Diversity of brain and body sizes could also reflect developmental plasticity—short-term adaptations within a lifetime (Anton, Potts, and Aiello, 2014). These have the advantage of being more flexible than genetic natural selection, which could only occur over many generations. For example, among human populations today, different body sizes are thought to be adaptations to different climate or nutritional environments.

Trends in the Behavior of Early Homo

New discoveries are also questioning old assumptions about the behavior of *Homo habilis* and *Homo erectus*. Just as the fossil evidence doesn't neatly separate *Australopithecus* and *Homo*, evidence of the lifeways of early *Homo* show similar diversity. For example, one of the traditional dividing lines between *Homo* and *Australopithecus* was thought to be stone tools: *Homo* made them; *Australopithecus* didn't. However, the recent discovery of stone tools from Kenya dating to 3.3 million years ago challenges this point of view. Similarly, the belief that *Homo erectus* was the first species to settle outside Africa may now come into question with the report of 2.1 million-year-old stone tools from China. If this find is supported by additional evidence, it may cause a reevaluation of *Homo erectus* being first to leave. Instead, there could have been multiple earlier migrations of hominins such as *Homo habilis* or even *Australopithecus* species.

Rather than obvious demarcations between species and their corresponding behavioral advancements, it now looks like many behaviors were shared among species. Despite the haziness dominating the early *Homo* narrative, we can identify some overall trends for the million-year period associated with early *Homo*. These trends include brain expansion, a reduction in facial prognathism, smaller jaw and tooth size, larger body size, and evidence of full terrestrial bipedalism. These traits are associated with a key behavioral shift that emphasizes culture as a flexible strategy to adapt to unpredictable environmental circumstances. Included in this repertoire are the creation and use of stone tools to process meat obtained by scavenging and later hunting, a utilization of fire and cooking, and the roots of the human life history pattern of prolonged childhood, cooperation in child raising, and the practice of skilled foraging techniques. In fact, it's apparent that the cultural innovations are driving the biological changes, and vice versa, fueling a feedback loop that will continue during the later stages of human evolution.

Homo heidelbergensis : the common ancestor of *Homo neanderthalensis* in Europe and *Homo sapiens* in Africa.

Some publications, e.g. Larsen 2014, refer to *H. heidelbergensis* as archaic *Homo sapiens*, but for our purposes, we will use the *H. heidelbergensis* designation. Otto Schoetensack found the first *Homo heidelbergensis* fossils in 1907 in Mauer, Germany. Since then *H. heidelbergensis* fossils have been found in Africa, Europe, and Asia. The date range for the species is 800 kya (thousand years ago) to 350 kya. Primitive traits (traits like the ancestors) include its large supraorbital tori (brow ridge), sagittal keeling, and low frontal bone. Derived traits (traits different from the ancestor) include separate supraorbital tori over each eye orbit, a more vertical posterior cranial vault, wide parietal bones in relation to the cranial base, and a larger cranial capacity than *H. erectus* (Becoming Human c2008). Additionally, they exhibit sexual dimorphism similar to that of modern humans.

Figure 3.4.3.22: *Homo heidelbergensis* skull on mirrored steel stand showing reflection of palate and dentition in upper jaw.

There is regional variation in the morphology of *H. heidelbergensis*. European specimens found at Atapuerca, (Spain), Petralona (Greece), Seinheim (Germany), and Swancombe (England) show that they had compact bodies, which could have been a response to living in the cold climates of the north as it would help to conserve heat. Additionally, the cranium is a mosaic of *H. erectus* traits and derived traits. In Asia, data from sites such as Zhoukoudian, Jinniushan, and Dali (China) show a mix of *H. erectus* and *H. sapiens* traits; the latter includes large cranial capacity and thin braincase walls. African specimens from Kabwe (Zambia),

Florisbad (South Africa), Laetoli (Tanzania), and Bodo (Ethiopia) also show a combination of *H. erectus* and *H. sapiens* traits. It shares the massive supraorbital tori and prominent occipital torus with *H. erectus* and thin cranial vault bones, less angulated occipital, and cranial base with *H. sapiens*.

Significantly, *H. heidelbergensis* is the common ancestor of *Homo neanderthalensis* in Europe and *Homo sapiens* in Africa.

Homo neanderthalensis

Numerous Neanderthal fossils have been recovered since its discovery in 1856 in the Neander Valley, Germany. Neanderthals have been the speculation of scientists and the general public ever since. Some anthropologists classify Neanderthals as a subspecies of *Homo sapiens*, *Homo sapiens neanderthalensis*, while others interpret the morphological differences as significant enough to warrant classifying them as a different species, *Homo neanderthalensis*. Here, we will use the latter designation.

Figure 3.4.3.23: *Homo neanderthalensis*.

True Neanderthals first appear in the fossil record about 200,000 years ago (200 kya), with fossils exhibiting Neanderthal-like characteristics appearing as early as 400 kya. Recent research indicates that Neanderthals went extinct only about 40,000 years ago, between 41 kya and 39 kya (Higham et al., 2014). Molecular research denotes that some Neanderthal DNA lives on in modern humans, approximately 2% of the DNA of "people who descend from Europeans, Asians, and other non-Africans is Neanderthal" (Callaway, 2014). The Neanderthal genes are involved in fighting infections, dealing with ultraviolet radiation (Callaway, 2014), and living at high altitudes (Callaway, 2015). Neanderthal DNA has recently been linked with depression, obesity, and certain skin disorders, e.g., lesions caused by sun exposure (Callaway, 2015).

Neanderthals are the only hominin to originally evolve in a glacial environment, leading to some characteristics adapted for the cold climate. Many scientists contend that the midface prognathism (protruding midface) allowed for enlarged sinuses that functioned to warm and add moisture to the cold, dry air before entering the lungs. Small holes below the eye orbits, called the infraorbital foramina, are larger in the European Neanderthals that modern humans, suggesting that the blood vessels were larger, which allowed for more blood flow to the face. This would have helped keep the face warmer. They are relatively short and stocky, males averaging 5' 5" and females 5'1", with shorter appendages, both of which would help to conserve heat by providing less surface area from which to radiate heat. Their leg bones are thick and dense, suggesting that they frequently walked and ran, most likely in food procurement activities. Some postulate that some Neanderthals had pale skin that would have helped increase Vitamin D synthesis by increasing the amount of UV radiation to be absorbed by the body (O'Neil, c1999-2014). The width of their body trunks and short tibias fit the predictions for cold weather adaptation as proposed by Christopher Ruff (Larsen, 2013). The brain size of Neanderthals may also be related to cold weather. Averaging a cranial capacity between 1300 to 1400 cm3, they have the largest brains of all hominins, including our own species, Homo sapiens. The size may be associated with increased metabolic efficiency in cold weather, which is similar to modern Inuit peoples today who have a larger brain size than other human populations (Jurmain et al., 2013).

The presence of an occipital bun (a prominent bulge at the lower back of the skull) is one of the characteristics used to identify *H. neanderthalensis* specimens, although it should be noted that this characteristics persists in a small percentage of modern

human populations. The occipital bun may have evolved to counterbalance Neanderthal's heavy face when running; it prevents the head from making huge horizontal accelerations (NOVA 2002). The occipital bun also makes the skull elongated in comparison to most *Homo sapiens*. They had heavy brow ridges like those of *H. heidelbergensis*. Neanderthal skulls recovered from Amud and Tabun in Israel exhibit more *H. sapiens*-like cranial characteristics, including lack of an occipital bun, smaller eye orbits, tall and wide nasal openings, and smaller teeth (Larsen 2014).

Denisovans

The Denisovans were archaic humans closely related to Neanderthals, whose populations overlapped geographically with the ancestors of modern-day humans who existed at the same time. In 2010, scientists announced the discovery and DNA analysis of a finger bone and two teeth found in Denisova Cave, Siberia (Reich et al., 2010). The artifacts were recovered from a deposit dated to 50 kya to 30 kya. Data suggest that the remains were from an individual who shared a common origin with Neanderthals, but was not a Neanderthal, nor was it a modern human. The Denisovan individual(s) share 4-6% of its genetic material with modern peoples living in New Guinea, Bougainville Islands, and China. Further studies (Cooper and Stringer, 2013) indicate that the Denisovans crossed Eurasia and interbred with modern humans, but genetically the Denisovans were more closely related to Neanderthals than modern humans (Meyer et al., 2012). While further finds will shed more light on the Denisovans, it is clear that there was more genetic variability during the Pleistocene than previously thought (Larsen, 2014), but that gene flow between the various populations had implications for the emergence of modern humans (Pääbo, 2015).

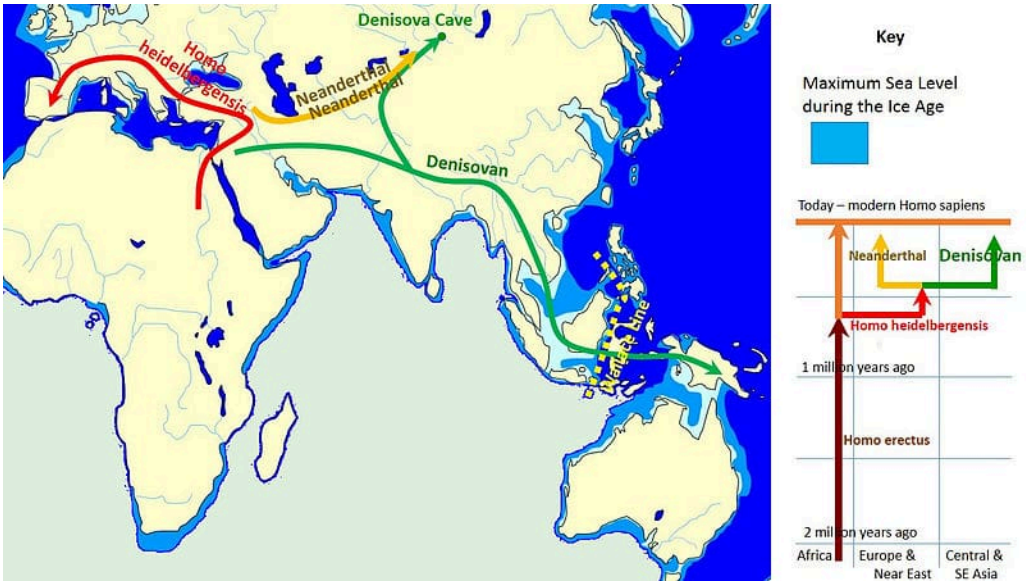

Figure 3.4.3.24: Spread and Evolution of Denisovans.

Homo floresiensis

In 2003, a team of scientists discovered unusual fossils in Liang Bua cave, Flores Island, Indonesia. The small stature of the individual led to the naming of a new species, *Homo floresiensis*. Since then twelve individuals have been found ranging in time from 74 kya to 17 kya. *H. floresiensis* had a small brain and stood only about 3.5' tall as an adult. They had receding foreheads, no chins, shrugged-forward shoulders, and large feet relative to their short legs. They share some characteristics with *H. sapiens*, including smaller dentition, separate brow ridges, and a non-prognathic face (flattened face).

Figure 3.4.3.25: *Homo floresiensis*.

Several hypotheses have been proposed to explain the appearance of *H. floresiensis*. One suggests that we are seeing island dwarfism, which is an evolutionary process resulting from long-term isolation on a small island. Limited resources and lack of predators selects for smaller bodied individuals who need fewer resources then large-bodied individuals. Another hypothesis claims that *H. floresiensis*is is not a separate species, but *H. sapiens* exhibiting microcephaly or some other developmental deficiency such as hyperthyroid cretinism (Oxnard et al. 2010) because the "...cranial features...are within the modern range of variation seen in living populations from the larger region [of Indonesia]" (Larsen 2014: 409), lending support to the second hypothesis. How *H. floresiensis* fits into the evolutionary picture is unclear based on the current data.

Homo sapiens

At present, only one hominin species inhabits planet Earth, *Homo sapiens*. All other *Homo* species became extinct by approximately 30,000 to 40,000 years ago. Many scientists believe that these extinctions were driven by competition from *Homo sapiens*. Morphologically, *H. sapiens* characteristics include the presence of a chin, a large brain, flat face, rounded or globular cranium, and a continuous, reduced brow ridge. Its bones are gracile (slender) in comparison to earlier hominins, although the earliest *H. sapiens* are more robust than modern populations and show none of the cold weather adaptations of Neanderthals. The more gracile nature lends credence to the hypothesis that modern humans evolved first in Africa. The leaner body proportions are more adaptive to the tropical African environments as there would be more body surface area to radiate heat. DNA evidence also supports an African origin. Modern African populations have more genetic diversity than any other modern human population, inferring that they have been evolving longer (Becoming Human c2008).

Figure 3.4.3.26: *Homo sapiens*.

The oldest *Homo sapiens* fossils were found in Africa at Omo Kibish, Ethiopia, dated to almost 200,000 years ago (195 kya; kya = 1,000 years ago). *Homo sapiens* fossils found at Herto, Ethiopia (160 kya–154 kya), Klasies River Mouth and Border Cave, South Africa (120 kya – 89 kya), Skhūl, Israel (130 kya–100 kya), and Qafzeh, Israel (120 kya–92 kya), add further support to the age of *Homo sapiens*. Sites in Asia, e.g., in China and Borneo, Indonesia date to 40 kya or younger and in Europe date no earlier then 31 kya (Mladeč, Czech Republic). Modern humans somehow made it to Australia over open ocean by 55 kya; however, no human remains have been found on the Australian continent dating earlier than 30 kya at Lake Mungo. This data lends little support for the Multiregional Hypothesis, a model that proposed that modern *H. sapiens* evolved in separate places in the Old World from local archaic *H. sapiens* populations. This model suggested that gene flow between the populations led to the genetic similarity of modern humans. Most anthropologists support the model of an African origin. There are two variants of this model. The Out of Africa model claims that modern humans arose in Africa and spread to Europe after 50 kya, replacing non-*H. sapiens* population with no gene flow. An alternative is the Assimilation model that also claimed modern human first arose in Africa and spread to Europe and Asia. The primary difference between the Out of Africa and Assimilation models is that the latter does claim gene flow between *H. sapiens* and *H. neanderthalensis*. Taking into account the recent DNA analyses of Neanderthals discussed above, multiple lines of evidence support the Assimilation model.

The case of the disappearing Neanderthals

We know that some Neanderthal genes are in the genome of modern humans, so in essence, some part of the Neanderthals survives today. However, there are no Neanderthals walking around in the modern world. So, what happened to the Neanderthals? Scientists suggest that *H. sapiens* out-competed Neanderthals with their more diverse diet and "sophisticated and cognitive abilities" (Becoming Human c2008), which may have included superior ability to form visual imagery in imagination to forecast outcomes of future actions, thereby enhancing planning and inventiveness (Koenigshofer, 2017). These traits allowed *H. sapiens* to readily adapt to rapidly changing climatic conditions during the Upper Paleolithic.

A recent hypothesis suggests that Neanderthals died out during a period of powerful volcanic activity in western Eurasia. Excavations at Mezmaiskaya Cave in the Caucasus Mountains in southern Russia have recovered a plethora of Neanderthal bones, stone tools, and remains of prey animals. The Neanderthal remains and artifacts appear in strata above a layer of volcanic ash and below a second layer of volcanic ash. No Neanderthal bones or artifacts have been found above the second level, suggesting that Neanderthals no longer occupied the area. Both of the ash layers contain levels of pollen associated with cooler, drier climates. "The ash layers correspond chronologically to what is known as the Campanian Ignimbrite super-eruption, which occurred around 40,000 years ago in modern day Italy, and a smaller eruption thought to have occurred around the same time in the Caucasus Mountains" (University of Chicago Press Journals 2010). The ensuing volcanic winter caused a dramatic climate shift that led to the demise of the Neanderthals. This data correlates with Higham et al.'s (2014) research that claims Neanderthals went extinct between 41,000 and 39,000 years ago.

Brain Evolution

Many scientists (Cajal, 1937; Crick & Koch, 1990; Edelman, 2004) believe that the human brain is the most complex machine in the known universe. Its complexity points to one undeniable fact—that it has evolved slowly over time from simpler forms. Evolution of the brain is intriguing not only because we can marvel at this complicated biological structure, but also because it reveals a long history of many less complex nervous systems (Figure 3.3.25), suggesting a record of adaptive behaviors in life forms other than humans. Thus, evolutionary study of the nervous system is important, and it is the first step in understanding its design, its workings, and its functional interface with the environment.

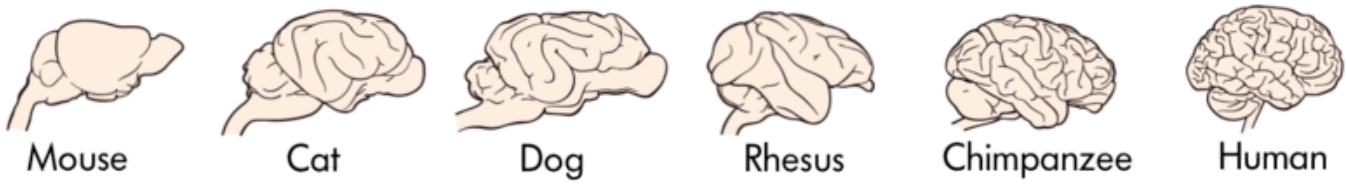

Figure 3.4.3.27: The brains of various mammals (not to scale). The brains shown are artificially depicted as approximately equal in size. Though the vast differences in the actual size of these brains is not shown, it is still possible to see the increasing degree of folding of the cerebral cortex as indicated by the greater number of fissures and gyri (valleys and hills on the surface of the cortex, indicated by the number of lines) on the surface of the chimpanzee and human brains compared to the others. Note that the mouse cortex is smooth, showing no folding at all indicating less corticalization--cortical development. The greatest folding of the cerebral cortex occurs in humans revealing a trend in mammalian and primate evolution toward increasing corticalization along with increasing brain size. For more on trends in brain evolution in mammals and primates, see section 18.13.

The brains of some animals, other mammals, like apes, monkeys, and rodents, are structurally similar to humans (Figure 3.3.27), while others are not (e.g., invertebrates such as the octopus). Does anatomical similarity of these brains suggest that behaviors that emerge in these species are also similar? Indeed, many animals display behaviors that are similar to humans, e.g., apes use nonverbal communication signals with their hands and arms that resemble nonverbal forms of communication in humans (Gardner & Gardner, 1969; Goodall, 1986; Knapp & Hall, 2009). If we study very simple physiological responses made by individual neurons (nerve cells), the neural responses of invertebrates such as the sea slug (Kandel & Schwartz, 1982) look very similar to the neural responses of single neurons in mammals, including humans, suggesting that from time immemorial such basic functions of individual nerve cells in the brains of many simple animal forms have been conserved over the course of evolution of more complex animals and that in fact these fundamental features of nerve cells are the foundation of more complex behaviors in animals that evolved later (Bullock, 1984).

Although basic physiological processes in nerve cells are very similar across species, nevertheless even at the micro-anatomical level, we note that individual neurons differ in complexity in some respects across animal species. Human neurons exhibit more intricate complexity than neurons in other animals; for example, neuronal processes (dendrites, which receive input from other neurons) in humans have many more branch points, branches, and dendritic spines associated with connections between neurons (see Chapter 10 on Learning and Memory).

Complexity in the structure of the nervous system, both at the macro- and micro-levels, gives rise to complex behaviors. We can observe similar movements of the limbs, as in nonverbal communication, in apes and humans, but the variety and intricacy of nonverbal behaviors using hands in humans surpasses apes. This is related to the fact that humans have more neurons for the control of movement of the hands than apes do. Deaf individuals who use American Sign Language (ASL) express themselves in English nonverbally; they use this language with such fine gradation that many accents of ASL exist (Walker, 1987). Complexity of behavior with increasing complexity of the nervous system, especially the cerebral cortex, can be observed in the genus *Homo* (Figures 3.3.27 and 3.3.28). If we compare sophistication of material culture in **Homo habilis** (2 million years ago; brain volume ~650 cm3) and **Homo sapiens** (300,000 years to now; brain volume ~1400 cm3), the evidence shows that *Homo habilis* used crude stone tools in stark contrast with modern tools used by *Homo sapiens* to erect cities, develop written languages, create complex industries, and embark on space travel. All of this is due to increasing complexity of the brain.

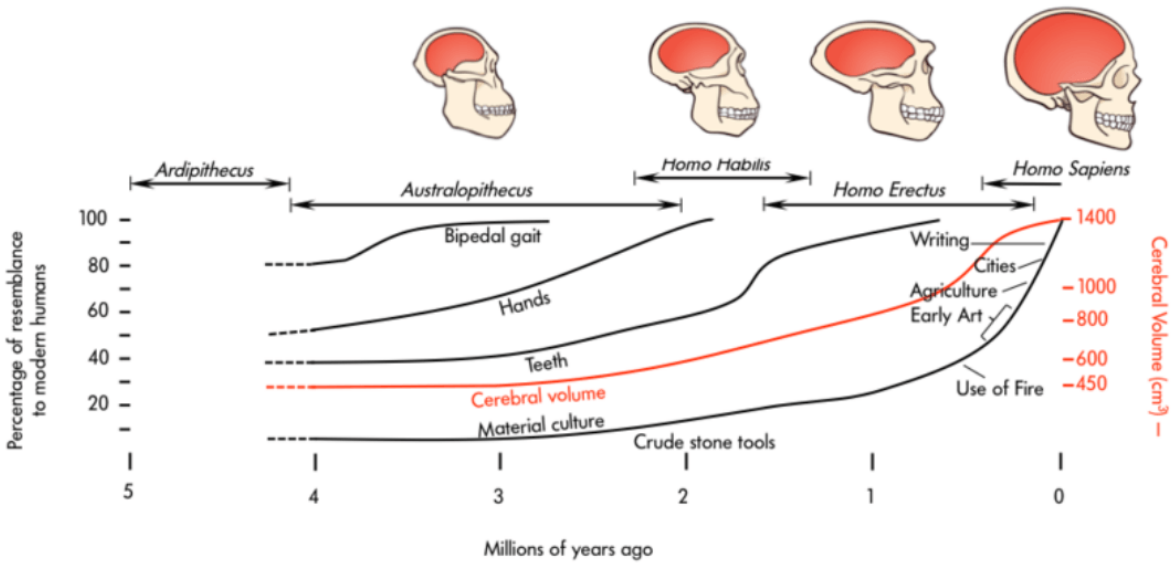

Figure 3.4.3.28: Increasing brain volume and other anatomical and behavioral features including development of material culture (including stone tools) over hominin evolution. Note that both brain volume and cultural advances accelerate after first use of fire. Missing from this diagram is the 1,400 cubic centimeter brain of Neanderthals, equal or slightly larger than the brain of modern humans.

What led to the complexity of the brain and nervous system during evolution, and the accompanying refinement of behavior and cognition? Darwin (1859, 1871) proposed two forces: natural selection and sexual selection as work engines driving these changes. As noted previously, Darwin prophesied, “psychology will be based on a new foundation, that of the necessary acquirement of each mental power and capacity by gradation.” In other words, Darwin predicted that psychology will be based on evolution (Rosenzweig, Breedlove, & Leiman, 2002).

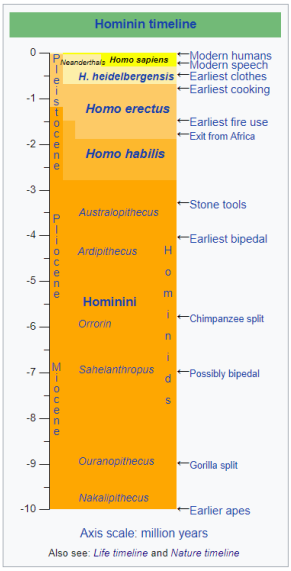

Figure 3.4.3.29: Hominin timeline highlighting evolutionary splits (divergences) from gorilla and chimpanzee genetic lines, major behavioral/cultural innovations, and migration out of Africa. Not shown is migration of Homo sapiens into Europe about 45,000 years ago where they co-existed with Neanderthals for thousands of years (Image from Wikimedia Commons; File:HumanTimeline-TemplateImage-20181222.png; https://commons.wikimedia.org/wiki/F...e-20181222.png; by Drbogdan; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

Tool Use, Evolution of Intelligence, and the Brain

As the discussion above attests, tool construction and use is ancient in the genus *Homo* dating back millions of years at least to Australopithecus. Cachel (2012, p. 222) states, "Human tool behavior is species-specific. It remains a diagnostic feature of humans." According to Osiurak and Massen (2014, p.1107),"Tool use has also been often viewed as an important step during evolution (van Schaik et al., 1999) or even as a marker of the evolution of human intelligence." Vaesen (2012, p. 203) argues that human tool making and tool use provide evidence of "unique higher cognitive ability" in humans and mark "a major cognitive discontinuity" between humans and apes. According to Vaesen (p. 203), there are "nine cognitive capacities deemed crucial to tool use: enhanced hand-eye coordination, body schema plasticity, causal reasoning, function representation, executive control, social learning, teaching, social intelligence, and language. Since striking differences between humans and great apes stand firm in eight out of nine of these domains, [he] conclude[s] that human tool use still marks a major cognitive discontinuity between us and our closest relatives." He also "address[es] the evolution of human technologies. In particular, [he] show[s] how the cognitive traits reviewed help to explain why technological accumulation evolved so markedly in humans, and so modestly in apes." Technological accumulation refers to the accumulation of technological innovations over generations leading to ever increasing technological complexity. This is closely tied to the great capacity of humans for efficient cultural transmission of learned behaviors over successive generations, an ability that occurs in apes only to a relatively limited degree. Vaesen (p. 213) explains: "The complexity of human technologies is tightly linked to our remarkable ability for **cumulative culture** [bold added]: Humans have been able to build complex systems by accumulating modifications over successive generations, gradually improving on previous achievements." This requires "sophisticated mechanisms for social learning and active teaching," in which language certainly played a part, but it is "likely that other cognitive capacities need to be added; for example, . . . causal thought is part and parcel of human social learning, and hence," is also needed for "high-fidelity cultural transmission" (p. 214). Vaesen further emphasizes this point: "causal thought (whenever it emerged) is a plausible explanans for why cumulative culture evolved so markedly in humans and so modestly in apes" (p.214). Cachel (2012, p. 222) goes further and states that experiments demonstrate the "great gulf that exists between human causal reasoning and the reasoning abilities of chimpanzees. In fact, chimpanzees do not seem to have a “theory of how the world works.” If this is so, then it epitomizes the unique character of human tool behavior – that it is based on the unconscious, sophisticated knowledge of energy, movement, objects, and the interaction of objects that Povinelli et al. (2000) label 'folk physics'.” Causal reasoning lowers individual learning costs, making learning by individuals more efficient, "by making individual learning reasoned rather than random" (Vaesen, 2012, p.215). Vaesen also argues that executive control involving inhibition of current drives and focus of attention contributes in a similar way.

Vaesen (2012) describes the work of other researchers who have identified brain areas involved in tool use. Vaesen (p.204) writes "Orban and colleagues (2006) identified a set of functional regions in the **dorsal intraparietal sulcus** (IPS) of the human brain that is involved in representations of the central visual field and in the extraction of three-dimensional form from motion. Crucially, these brain regions were not found in the brains of monkeys. The regions subserve, the authors conjectured, the enhanced visual analysis necessary for the precision with which humans manipulate tools. Second, Stout and Chaminade (2007) found that parts of these regions were indeed recruited when modern human subjects engaged in Oldowan-like tool making. Importantly, no increased activation was observed when the human subjects were asked just to strike cobbles together without intending to produce flakes. Human dorsal IPS, thus, may allow for better identification of suitable targets on the core, and as such, explain in part why humans outperform other primates in matters of tool use."

Additional insights regarding tool use and the brain come from study of brain-damaged individuals. Osiurak and Massen (2014, p. 1107) review results of studies of "patients with tool use disorders, also called apraxia of tool use. When asked to light a candle, for example, those patients can light the candle correctly but then put it to the mouth in an attempt to smoke it. Such observations have led traditional cognitive models of apraxia to assume that tool use is supported by sensorimotor knowledge about tool manipulation . . . This sensory-motor hypothesis assumes that manipulation knowledge stored within **inferior fronto-parietal** areas [of the cerebral cortex] is critical to tool use skills." This may be the case because "the **left inferior parietal lobe** might rather support technical reasoning, namely, the ability to reason about physical object properties. . . . the ability to understand mechanical actions might be the specificity of the **anterior** portions of the **inferior parietal lobe** (particularly the supramarginal gyrus) while the **posterior parietal cortex** might be involved in the planning of the grasping and reaching components of both tool-use and non-tool-use actions."

File:ParietCapts lateral.png

Figure 3.4.3.30: The human right cerebral cortex highlighting parts of the parietal lobe. Folds on the surface of the cortex form hills (gyri, singular, gyrus) and valleys (fissures or sulci; singular, sulcus). The central sulcus divides the frontal lobe from the parietal lobe behind it. The parietal lobe, especially on the right side of the brain, processes information about space and spatial relations. Regions of the parietal lobe are involved in tool construction and tool use, important in human evolution. See text for details. Tool construction and use, although critically important in human evolution as indicated by the discussion above, are just a single narrow aspect of the complex of abilities that make up human intelligence. In Chapter 14 on Intelligence and Cognition, we continue our discussion of this topic by examining the brain mechanisms which underlie other cognitive abilities that we collectively refer to as intelligence. In the next section of this chapter, David Buss from the University of Texas examines evolutionary theories in psychology.

3.4.4: Evolutionary Theories in Psychology

Learning Objectives

1. Explain the meaning of “evolution.”
2. Describe the primary mechanisms by which evolution takes place.
3. Describe the two major classes of adaptations.
4. Explain sexual selection and its two primary processes.
5. Describe gene selection theory.
6. Discuss psychological adaptations.
7. Explain the core premises of sexual strategies theory.
8. Explain the core premises of error management theory, and provide two empirical examples of adaptive cognitive biases.

Overview

Figure 3.4.4.1: It may seem like just a casual date, but don't doubt that the forces of evolution are hard at work below the surface. [Image: Best Couples, https://goo.gl/aBMY6W, CC BY-SA 2.0, https://goo.gl/jSSrcO]

If you have ever been on a first date, you’re probably familiar with the anxiety of trying to figure out what clothes to wear or what perfume or cologne to put on. In fact, you may even consider flossing your teeth for the first time all year. When considering why you put in all this work, you probably recognize that you’re doing it to impress the other person. But how did you learn these particular behaviors? Where did you get the idea that a first date should be at a nice restaurant or someplace unique? It is possible that we have been taught these behaviors by observing others. It is also possible, however, that these behaviors—the fancy clothes, the expensive restaurant—are biologically programmed into us. That is, just as peacocks display their feathers to show how attractive they are, or some lizards do push-ups to show how strong they are, when we style our hair or bring a gift to a date, we’re trying to communicate to the other person: “Hey, I’m a good mate! Choose me! Choose me!"

However, we all know that our ancestors hundreds of thousands of years ago weren’t driving sports cars or wearing designer clothes to attract mates. So how could someone ever say that such behaviors are “biologically programmed” into us? Well, even though our ancestors might not have been doing these specific actions, these behaviors are the result of the same driving force: the powerful influence of evolution (Links to an external site.) (Links to an external site.). Yes, evolution—certain traits and behaviors developing over time because they are advantageous to our survival. In the case of dating, doing something like offering a gift might represent more than a nice gesture. Just as chimpanzees will give food to mates to show they can provide for them, when you offer gifts to your dates, you are communicating that you have the money or “resources” to help take care of them. And even though the person receiving the gift may not realize it, the same evolutionary forces are influencing his or her behavior

as well. The receiver of the gift evaluates not only the gift but also the gift-giver's clothes, physical appearance, and many other qualities, to determine whether the individual is a suitable mate. But because these evolutionary processes are hardwired into us, it is easy to overlook their influence.

To broaden your understanding of evolutionary processes, this section will present some of the most important elements of evolution as they impact psychology. Evolutionary theory helps us piece together the story of how we humans have prospered. It also helps to explain why we behave as we do on a daily basis in our modern world: why we bring gifts on dates, why we get jealous, why we crave our favorite foods, why we protect our children, and so on. Evolution may seem like a historical concept that applies only to our ancient ancestors but, in truth, it is still very much a part of our modern daily lives.

Basics of Evolutionary Theory

Evolution simply means change over time. Many think of evolution as the development of traits and behaviors that allow us to survive this "dog-eat-dog" world, like strong leg muscles to run fast, or fists to punch and defend ourselves. However, physical survival is only important if it eventually contributes to successful reproduction. That is, even if you live to be a 100-year-old, if you fail to mate and produce children, your genes will die with your body. Thus, reproductive success, not survival success, is the engine of evolution by natural selection. Every mating success by one person means the loss of a mating opportunity for another. Yet every living human being is an evolutionary success story. Each of us is descended from a long and unbroken line of ancestors who triumphed over others in the struggle to survive (at least long enough to mate) and reproduce. However, in order for our genes to endure over time—to survive harsh climates, to defeat predators—we have inherited adaptive, psychological processes designed to ensure success.

At the broadest level, we can think of organisms, including humans, as having two large classes of adaptations —or traits and behaviors that evolved over time to increase our reproductive success. The first class of adaptations are called survival adaptations: mechanisms that helped our ancestors handle the "hostile forces of nature." For example, in order to survive very hot temperatures, we developed sweat glands to cool ourselves. In order to survive very cold temperatures, we developed shivering mechanisms (the speedy contraction and expansion of muscles to produce warmth). Other examples of survival adaptations include developing a craving for fats and sugars, encouraging us to seek out particular foods rich in fats and sugars that keep us going longer during food shortages. Some threats, such as snakes, spiders, darkness, heights, and strangers, often produce fear in us, which encourages us to avoid them and thereby stay safe. These are also examples of survival adaptations. However, all of these adaptations are for physical survival, whereas the second class of adaptations are for reproduction, and help us compete for mates. These adaptations are described in an evolutionary theory proposed by Charles Darwin, called sexual selection theory.

Sexual Selection Theory

Darwin noticed that there were many traits and behaviors of organisms that could not be explained by "survival selection." For example, the brilliant plumage of peacocks should actually lower their rates of survival. That is, the peacocks' feathers act like a neon sign to predators, advertising "Easy, delicious dinner here!" But if these bright feathers only lower peacocks' chances at survival, why do they have them? The same can be asked of similar characteristics of other animals, such as the large antlers of male stags or the wattles of roosters, which also seem to be unfavorable to survival. Again, if these traits only make the animals less likely to survive, why did they develop in the first place? And how have these animals continued to survive with these traits over thousands and thousands of years? Darwin's answer to this conundrum was the theory of sexual selection: the evolution of characteristics, not because of survival advantage, but because of mating advantage.

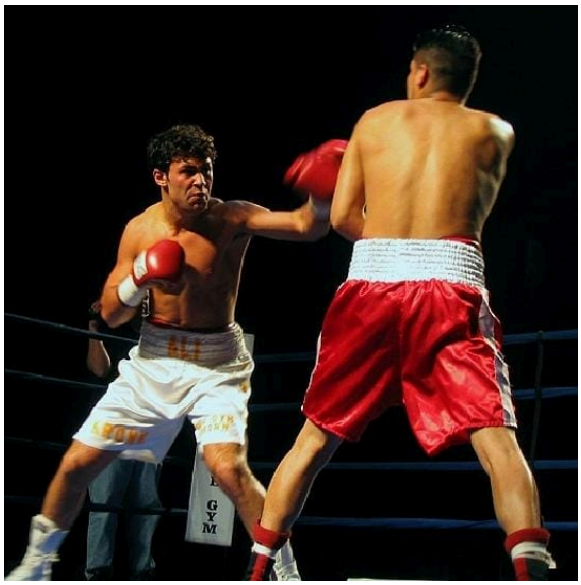

Figure 3.4.4.2: Modern sports like boxing can be seen as modified/stylized versions of the evolutionary behavior of intrasexual competition. [Image: Dave Hogg, https://goo.gl/fL5U2Z, CC BY 2.0, https://goo.gl/9uSnqN]

Sexual selection occurs through two processes. The first, intrasexual competition, occurs when members of one sex compete against each other, and the winner gets to mate with a member of the opposite sex. Male stags, for example, battle with their antlers, and the winner (often the stronger one with larger antlers) gains mating access to the female. That is, even though large antlers make it harder for the stags to run through the forest and evade predators (which lowers their survival success), they provide the stags with a better chance of attracting a mate (which increases their reproductive success). Similarly, human males sometimes also compete against each other in physical contests: boxing, wrestling, karate, or group-on-group sports, such as football. Even though engaging in these activities poses a "threat" to their survival success, as with the stag, the victors are often more attractive to potential mates, increasing their reproductive success. Thus, whatever qualities lead to success in intrasexual competition are then passed on with greater frequency due to their association with greater mating success.

The second process of sexual selection is preferential mate choice, also called intersexual selection. In this process, if members of one sex are attracted to certain qualities in mates—such as brilliant plumage, signs of good health, or even intelligence—those desired qualities get passed on in greater numbers, simply because their possessors mate more often. For example, the colorful plumage of peacocks exists due to a long evolutionary history of peahens' (the term for female peacocks) attraction to males with brilliantly colored feathers.

In all sexually-reproducing species, adaptations in both sexes (males and females) exist due to survival selection and sexual selection. However, unlike other animals where one sex has dominant control over mate choice, humans have "mutual mate choice." That is, both women and men typically have a say in choosing their mates. And both mates value qualities such as kindness, intelligence, and dependability that are beneficial to long-term relationships—qualities that make good partners and good parents.

Gene Selection Theory

In modern evolutionary theory, all evolutionary processes boil down to an organism's genes. Genes are the basic "units of heredity," or the information that is passed along in DNA that tells the cells and molecules how to "build" the organism and how that organism should behave. Genes that are better able to encourage the organism to reproduce, and thus replicate themselves in the organism's offspring, have an advantage over competing genes that are less able. For example, take female sloths: In order to attract a mate, they will scream as loudly as they can, to let potential mates know where they are in the thick jungle. Now, consider two types of genes in female sloths: one gene that allows them to scream extremely loudly, and another that only allows them to scream moderately loudly. In this case, the sloth with the gene that allows her to shout louder will attract more mates—increasing reproductive success—which ensures that her genes are more readily passed on than those of the quieter sloth.

Essentially, genes can boost their own replicative success in two basic ways. First, they can influence the odds for survival and reproduction of the organism they are in (individual reproductive success or fitness—as in the example with the sloths).

Second, genes can also influence the organism to help other organisms who also likely contain those genes—known as "genetic relatives"—to survive and reproduce (which is called inclusive fitness). For example, why do human parents tend to help their own kids with the financial burdens of a college education and not the kids next door? Well, having a college education increases one's attractiveness to other mates, which increases one's likelihood for reproducing and passing on genes. And because parents' genes are in their own children (and not the neighborhood children), funding their children's educations increases the likelihood that the parents' genes will be passed on.

Understanding gene replication is the key to understanding modern evolutionary theory. It also fits well with many evolutionary psychological theories. However, for the time being, we'll ignore genes and focus primarily on actual adaptations that evolved because they helped our ancestors survive and/or reproduce.

Evolutionary Psychology

Evolutionary psychology aims the lens of modern evolutionary theory on the workings of the human mind. It focuses primarily on psychological adaptations: mechanisms of the mind that have evolved to solve specific problems of survival or reproduction. These kinds of adaptations are in contrast to physiological adaptations, which are adaptations that occur in the body as a consequence of one's environment. One example of a physiological adaptation is how our skin makes calluses. First, there is an "input," such as repeated friction to the skin on the bottom of our feet from walking. Second, there is a "procedure," in which the skin grows new skin cells at the afflicted area. Third, an actual callus forms as an "output" to protect the underlying tissue—the final outcome of the physiological adaptation (i.e., tougher skin to protect repeatedly scraped areas). On the other hand, a psychological adaptation is a development or change of a mechanism in the mind. For example, take sexual jealousy. First, there is an "input," such as a romantic partner flirting with a rival. Second, there is a "procedure," in which the person evaluates the threat the rival poses to the romantic relationship. Third, there is a behavioral output, which might range from vigilance (e.g., snooping through a partner's email) to violence (e.g., threatening the rival).

Evolutionary psychology is fundamentally an interactionist framework, or a theory that takes into account multiple factors when determining the outcome. For example, jealousy, like a callus, doesn't simply pop up out of nowhere. There is an "interaction" between the environmental trigger (e.g., the flirting; the repeated rubbing of the skin) and the initial response (e.g., evaluation of the flirter's threat; the forming of new skin cells) to produce the outcome.

In evolutionary psychology, culture also has a major effect on psychological adaptations. For example, status within one's group is important in all cultures for achieving reproductive success, because higher status makes someone more attractive to mates. In individualistic cultures, such as the United States, status is heavily determined by individual accomplishments. But in more collectivist cultures, such as Japan, status is more heavily determined by contributions to the group and by that group's success. For example, consider a group project. If you were to put in most of the effort on a successful group project, the culture in the United States reinforces the psychological adaptation to try to claim that success for yourself (because individual achievements are rewarded with higher status). However, the culture in Japan reinforces the psychological adaptation to attribute that success to the whole group (because collective achievements are rewarded with higher status). Another example of cultural input is the importance of virginity as a desirable quality for a mate. Cultural norms that advise against premarital sex persuade people to ignore their own basic interests because they know that virginity will make them more attractive marriage partners. Evolutionary psychology, in short, does not predict rigid robotic-like "instincts." That is, there isn't one rule that works all the time. Rather, evolutionary psychology studies flexible, environmentally-connected and culturally-influenced adaptations that vary according to the situation.

Psychological adaptations are hypothesized to be wide-ranging, and include food preferences, habitat preferences, mate preferences, and specialized fears. These psychological adaptations also include many traits that improve people's ability to live in groups, such as the desire to cooperate and make friends, or the inclination to spot and avoid frauds, punish rivals, establish status hierarchies, nurture children, and help genetic relatives. Research programs in evolutionary psychology develop and empirically test predictions about the nature of psychological adaptations. Below, we highlight a few evolutionary psychological theories and their associated research approaches.

Sexual Strategies Theory

Sexual strategies theory is based on sexual selection theory. It proposes that humans have evolved a list of different mating strategies, both short-term and long-term, that vary depending on culture, social context, parental influence, and personal mate value (desirability in the "mating market").

In its initial formulation, sexual strategies theory focused on the differences between men and women in mating preferences and strategies (Buss & Schmitt, 1993). It started by looking at the minimum parental investment needed to produce a child. For women, even the minimum investment is significant: after becoming pregnant, they have to carry that child for nine months inside of them. For men, on the other hand, the minimum investment to produce the same child is considerably smaller—simply the act of sex.

Figure 3.4.4.3: Because women bear responsibility for pregnancy, they may use different sexual selection strategies than men do. [Image: CC0 Public Domain, https://goo.gl/m25gce]

These differences in parental investment have an enormous impact on sexual strategies. For a woman, the risks associated with making a poor mating choice is high. She might get pregnant by a man who will not help to support her and her children, or who might have poor-quality genes. And because the stakes are higher for a woman, wise mating decisions for her are much more valuable. For men, on the other hand, the need to focus on making wise mating decisions isn't as important. That is, unlike women, men 1) don't biologically have the child growing inside of them for nine months, and 2) do not have as high a cultural expectation to raise the child. This logic leads to a powerful set of predictions: In short-term mating, women will likely be choosier than men (because the costs of getting pregnant are so high), while men, on average, will likely engage in more casual sexual activities (because this cost is greatly lessened). Due to this, men will sometimes deceive women about their long-term intentions for the benefit of short-term sex, and men are more likely than women to lower their mating standards for short-term mating situations.

An extensive body of empirical evidence supports these and related predictions (Buss & Schmitt, 2011). Men express a desire for a larger number of sex partners than women do. They let less time elapse before seeking sex. They are more willing to consent to sex with strangers and are less likely to require emotional involvement with their sex partners. They have more frequent sexual fantasies and fantasize about a larger variety of sex partners. They are more likely to regret missed sexual opportunities. And they lower their standards in short-term mating, showing a willingness to mate with a larger variety of women as long as the costs and risks are low.

However, in situations where both the man and woman are interested in long-term mating, both sexes tend to invest substantially in the relationship and in their children. In these cases, the theory predicts that both sexes will be extremely choosy when pursuing a long-term mating strategy. Much empirical research supports this prediction, as well. In fact, the qualities women and men generally look for when choosing long-term mates are very similar: both want mates who are intelligent, kind, understanding, healthy, dependable, honest, loyal, loving, and adaptable.

Nonetheless, women and men do differ in their preferences for a few key qualities in long-term mating, because of somewhat distinct adaptive problems. Modern women have inherited the evolutionary trait to desire mates who possess resources, have qualities linked with acquiring resources (e.g., ambition, wealth, industriousness), and are willing to share those resources with them. On the other hand, men more strongly desire youth and health in women, as both are cues to fertility. These male and female differences are universal in humans. They were first documented in 37 different cultures, from Australia to Zambia (Buss, 1989), and have been replicated by dozens of researchers in dozens of additional cultures (for summaries, see Buss, 2012).

As we know, though, just because we have these mating preferences (e.g., men with resources; fertile women), people don't always

get what they want. There are countless other factors which influence who people ultimately select as their mate. For example, the sex ratio (the percentage of men to women in the mating pool), cultural practices (such as arranged marriages, which inhibit individuals' freedom to act on their preferred mating strategies), the strategies of others (e.g., if everyone else is pursuing short-term sex, it's more difficult to pursue a long-term mating strategy), and many others all influence who we select as our mates.

Sexual strategies theory—anchored in sexual selection theory— predicts specific similarities and differences in men and women's mating preferences and strategies. Whether we seek short-term or long-term relationships, many personality, social, cultural, and ecological factors will all influence who our partners will be.

Error Management Theory

Figure 3.4.4.4: If you were walking in the woods and heard a sound in the bushes you might be startled and act on the worst case scenario—such as the threat of a wild animal—by moving in the opposite direction. This is evolutionary psychology at work, keeping you safe so you can survive and reproduce. [Image: Nicholas T, https://goo.gl/gZ3zEL, CC BY 2.0, https://goo.gl/9uSnqN]

Error management theory (EMT) deals with the evolution of how we think, make decisions, and evaluate uncertain situations—that is, situations where there's no clear answer how we should behave (Haselton & Buss, 2000; Haselton, Nettle, & Andrews, 2005). Consider, for example, walking through the woods at dusk. You hear a rustle in the leaves on the path in front of you. It could be a snake. Or, it could just be the wind blowing the leaves. Because you can't really tell why the leaves rustled, it's an uncertain situation. The important question then is, what are the costs of errors in judgment? That is, if you conclude that it's a dangerous snake so you avoid the leaves, the costs are minimal (i.e., you simply make a short detour around them). However, if you assume the leaves are safe and simply walk over them—when in fact it is a dangerous snake—the decision could cost you your life.

Now, think about our evolutionary history and how generation after generation was confronted with similar decisions, where one option had low cost but great reward (walking around the leaves and not getting bitten) and the other had a low reward but high cost (walking through the leaves and getting bitten). These kinds of choices are called "cost asymmetries." If during our evolutionary history we encountered decisions like these generation after generation, over time an adaptive bias would be created: we would make sure to err in favor of the least costly (in this case, least dangerous) option (e.g., walking around the leaves). To put it another way, EMT predicts that whenever uncertain situations present us with a safer versus more dangerous decision, we will psychologically adapt to prefer choices that minimize the cost of errors.

EMT is a general evolutionary psychological theory that can be applied to many different domains of our lives, but a specific example of it is the visual descent illusion. To illustrate: Have you ever thought it would be no problem to jump off of a ledge, but as soon as you stood up there, it suddenly looked much higher than you thought? The visual descent illusion (Jackson & Cormack, 2008) states that people will overestimate the distance when looking down from a height (compared to looking up) so that people will be especially wary of falling from great heights—which would result in injury or death. Another example of EMT is the auditory looming bias: Have you ever noticed how an ambulance seems closer when it's coming toward you, but suddenly seems far away once it's immediately passed? With the auditory looming bias, people overestimate how close objects are when the sound is moving toward them compared to when it is moving away from them. From our evolutionary history, humans learned, "It's better to be safe than sorry." Therefore, if we think that a threat is closer to us when it's moving toward us (because it seems

louder), we will be quicker to act and escape. In this regard, there may be times we ran away when we didn't need to (a false alarm), but wasting that time is a less costly mistake than not acting in the first place when a real threat does exist.

EMT has also been used to predict adaptive biases in the domain of mating. Consider something as simple as a smile. In one case, a smile from a potential mate could be a sign of sexual or romantic interest. On the other hand, it may just signal friendliness. Because of the costs to men of missing out on chances for reproduction, EMT predicts that men have a sexual overperception bias: they often misread sexual interest from a woman, when really it's just a friendly smile or touch. In the mating domain, the sexual overperception bias is one of the best-documented phenomena. It's been shown in studies in which men and women rated the sexual interest between people in photographs and videotaped interactions. As well, it's been shown in the laboratory with participants engaging in actual "speed dating," where the men interpret sexual interest from the women more often than the women actually intended it (Perilloux, Easton, & Buss, 2012). In short, EMT predicts that men, more than women, will over-infer sexual interest based on minimal cues, and empirical research confirms this adaptive mating bias.

Summary

Sexual strategies theory and error management theory are two evolutionary psychological theories that have received much empirical support from dozens of independent researchers. But, there are many other evolutionary psychological theories, such as social exchange theory for example, that also make predictions about our modern day behavior and preferences, too. The merits of each evolutionary psychological theory, however, must be evaluated separately and treated like any scientific theory. That is, we should only trust their predictions and claims to the extent they are supported by scientific studies. However, even if the theory is scientifically grounded, just because a psychological adaptation was advantageous in our history, it doesn't mean it's still useful today. For example, even though women may have preferred men with resources in generations ago, our modern society has advanced such that these preferences are no longer apt or necessary. Nonetheless, it's important to consider how our evolutionary history has shaped our automatic or "instinctual" desires and reflexes of today, so that we can better shape them for the future ahead.

Discussion Questions

1. How does change take place over time in the living world?
2. Which two potential psychological adaptations to problems of survival are not discussed in this module?
3. What are the psychological and behavioral implications of the fact that women bear heavier costs to produce a child than men do?
4. Can you formulate a hypothesis about an error management bias in the domain of social interaction?

Vocabulary

- Adaptations: Evolved solutions to problems that historically contributed to reproductive success.
- Error management theory (EMT): A theory of selection under conditions of uncertainty in which recurrent cost asymmetries of judgment or inference favor the evolution of adaptive cognitive biases that function to minimize the more costly errors.
- Evolution: Change over time. Is the definition changing?
- Gene Selection Theory: The modern theory of evolution by selection by which differential gene replication is the defining

process of evolutionary change.

- Intersexual selection: A process of sexual selection by which evolution (change) occurs as a consequences of the mate preferences of one sex exerting selection pressure on members of the opposite sex.
- Intrasexual competition: A process of sexual selection by which members of one sex compete with each other, and the victors gain preferential mating access to members of the opposite sex.
- Natural selection: Differential reproductive success as a consequence of differences in heritable attributes.
- Psychological adaptations: Mechanisms of the mind that evolved to solve specific problems of survival or reproduction; conceptualized as information processing devices.
- Sexual selection: The evolution of characteristics because of the mating advantage they give organisms.
- Sexual strategies theory: A comprehensive evolutionary theory of human mating that defines the menu of mating strategies humans pursue (e.g., short-term casual sex, long-term committed mating), the adaptive problems women and men face when pursuing these strategies, and the evolved solutions to these mating problems.

3.4.5: DNA, Chromosomes, and Gene-Environment Correlations

Learning Objectives

1. Explain the role chromosomes play in carrying genetic information.
2. Explain the relationship between genes and environment including types of gene-environment correlations.
3. Discuss the role of twin and adoption studies in investigating genetic influences on mind and behavior.

Overview

Chromosomes are structures in the nucleus of a cell containing DNA, histone protein, and other structural proteins. Chromosomes also contain genes, most of which are made up of DNA and RNA. But our genes and chromosomes interact with environmental factors to determine our actual physical and behavioral traits (our phenotype). Teasing out the relative effects of genetic and environmental influences on the phenotype is often difficult because of the complex interactions between them. All traits, including psychological and behavioral traits, are determined by complex interactions between genetic and environmental factors.

DNA and the Genetic Code

DNA, or deoxyribonucleic acid, determines whether our eyes are blue or brown, how tall we will be, and even our dispositions for certain types of behavior. DNA holds our "genetic code;" it is shaped like a double helix, made of sequences of nucleic acids attached to a sugar phosphate backbone. Genes are subsections of DNA molecules linked together that encode a particular characteristic.

Each chromosome is made up of a single DNA molecule coiled around histone proteins. Research dating back to the 1800s shows that every living creature has a specific set of chromosomes in the nucleus of each of its cells.

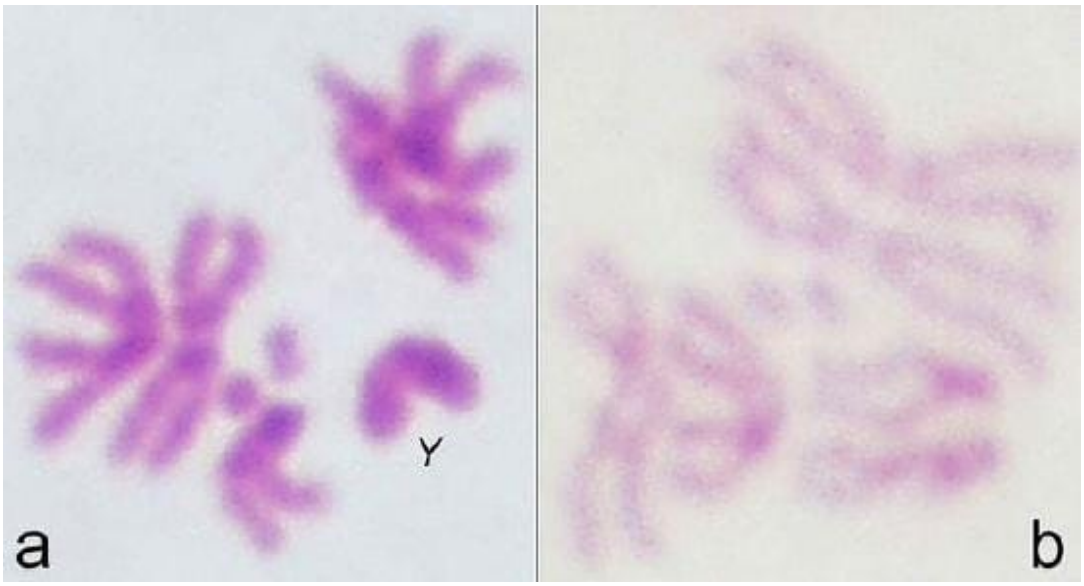

Figure 3.4.5.1: Human chromosome structure: Chromosomes are made up of a variety of gene sequences. By studying chromosomes and genes, scientists are able to determine the genetic basis for many diseases.

Human chromosomes are divided into two types—autosomes and sex chromosomes. Some genetic traits are linked to a person's sex and therefore passed on by the sex chromosomes. The autosomes contain the remainder of a person's genetic information. All human beings have 23 pairs of chromosomes by which genetic material is developed and characteristically demonstrated; 22

of these are autosomes, while the remaining pair (either XX, female, or XY, male) represents a person's sex chromosomes. These 23 pairs of chromosomes work together to create the person we ultimately become.

Chromosomal abnormalities can occur during fetal development if something goes wrong during the replication of the cells. Common abnormalities include Down syndrome (caused by an extra chromosome #21), Klinefelter syndrome (caused by an extra X chromosome), and Turner syndrome (caused by a missing X chromosome). Genetic counseling is available for families in order to determine if any abnormalities exist that may be passed along to offspring. Many chromosomal abnormalities are of psychological importance, with substantial impacts on mental processes; for example, Down syndrome can cause mild to moderate intellectual disabilities.

As science advances, the ability to manipulate genes and chromosomes is becoming increasingly sophisticated. Cloning is an example of taking chromosomal and genetic material and creating a new animal, and was first successfully achieved in the famous example of Dolly the sheep. There is much controversy surrounding the manipulation of chromosomes in human beings, with many people believing it to be unethical.

Figure 3.4.5.2: Dolly the sheep: The first successfully cloned animal.

Gene-Environment Correlations: Nature or Nurture

Our genetic destiny is not necessarily written in stone. Genetic expression can be influenced by the environment, including various social factors, as well as physical environmental factors, ranging from light and temperature to exposure to chemicals (see Section 3.7 on Epigenetics).

The environment in which a person is raised can trigger the expression of behavior for which a person is genetically predisposed, while the same person raised in a different environment may exhibit different behavior.

Long-standing debates have taken place over which factor is more important, genes or environment. Is a person destined to have a particular outcome in life because of his or her genetic makeup, or can the environment (and the people in it) work to change what might be considered "bad" genes? Today, it is generally agreed that neither genes nor environment work alone; rather, the two work in tandem to create the people we ultimately become. However, because of gene-environment correlations, discriminating the effects of environment from the effects of genes can be very difficult.

We now know that genes can be turned on and off. Environmental elements like light and temperature have been shown to induce certain changes in genetic expression; additionally, exposure to drugs and chemicals can significantly affect how genes are expressed. People often inherit sensitivity to the effects of various environmental risk factors, and therefore different individuals may be differently affected by exposure to the same environment in medically significant ways. For example, some people become very ill from exposure to peanuts, while others are entirely unaffected. Another example is exposure to sunlight. Sunlight exposure has a much stronger influence on skin cancer risk in fair-skinned humans than in individuals with an inherited tendency for darker skin. The color of a person's skin is largely genetic, but the environment also affects these genes in different ways.

Gene-environment Correlations by Type

Gene-environment correlations, represented as rGE, occur when genetic factors influence environmental exposure. Genes can affect environmental exposure indirectly via behavior. For example, high IQ parents may have more books in their homes than lower IQ parents leading to greater exposure to books and ideas in homes with high IQ parents compared to homes with lower IQ parents. In such a case, children of high IQ parents may read earlier and have greater facility with a wider range of ideas partly indirectly through the influence of genes for higher IQ on the selection of environments which facilitate exposure to books and ideas during childhood. However, the relation between early exposure to books and intellectual ability later in life may be misinterpreted as evidence of a purely environmental relationship and therefore support the view that nurture is the predominant influence. Such an interpretation would be mistaken because it missed the significant influence of the genes of the parents on selection of the home environment, along with direct genetic effects on intelligence, that led to later intellectual abilities of their children.

Gene-environment correlations, rGEs, can be causally related or non-causally related and can be categorized as passive, evocative, or active.

Passive Gene-Environment Correlations

In passive gene-environment correlation, an association exists between a person's genetic makeup and the environment in which he or she is raised. In other words, the person's environment, particularly in the case of children, is significantly determined by the parent's genetic characteristics. Parents create a home environment that is influenced by their own heritable characteristics. When the children's own genotype influences their behavior or cognitive outcomes, the result can be misinterpreted as a relationship between environment and psychological outcome. For example, an intelligent parent is likely to create a home environment rich in educational materials and experience. Since intelligence is moderately heritable, it can be argued that intelligence in the child is inherited rather than a factor of the home environment created by the parents. It is relatively unclear whether the genetic or environmental factors had more to do with the child's development because both genes and environment affected the child's development and many aspects of the child's environment were affected by the parents' genes when the home environment was created by the parents. Thus, correlations between environment and a child's cognitive characteristics may be misinterpreted as evidence for environmental influence that is really due more to genetic factors involved in selection of the environment, factors which have been missed and therefore left out of the analysis of causation.

Evocative Gene-Environment Correlations

Evocative gene-environment correlation happens when an individual's (heritable) behavior evokes an environmental response. For example, the association or correlation between marital conflict (arguing) and depression may reflect or be due to the tensions that arise from interacting with a depressed spouse rather than a causal effect of marital conflict on risk for depression. In other words, marital conflict may not cause increased risk for depression, but instead a genetic disposition for depression in one marriage partner may cause tensions between partners that lead to marital conflict. Therefore, what first appears as an environmental factor in depression may actually have genetic roots. Genes cause a disposition for depression, and depression in one partner leads to increased marital conflict. Therefore a correlation between marital conflict and depression may not be evidence for the influence of environment on depression, but the influence of genetics for depression on the environment (marital conflict).

Active Gene-Environment Correlations

In active gene-environment correlation, the person's genetic makeup may lead them to select particular environments. For example, a shy person is likely to choose quiet activities and less boisterous environments than an extroverted individual. He or she may be more likely to spend time at the library than at a dance club. Thus, a correlation between spending time at libraries and shyness may not indicate the influence of libraries, an environmental factor, on shyness, but instead reflects the effect of genes for shyness on selection of libraries as a place to spend time.

Adoption and Twin Studies in the Nature vs. Nurture Debate

Adoption and twin studies can help make sense of the influence of genes and the environment. Studies of adult twins are used to investigate which traits are heritable. Identical twins share the same genotype, meaning their genetic makeup is the same.

Identical twins raised apart tend to be similar in intelligence and, in some cases, life events and circumstance, when studied years later, even when raised separately. However, researchers have discovered that the phenotype (or the observable expression of a gene) of identical twins grows apart as they age.

In adoption studies, identical twins raised by different families can give insight into the nature-versus-nurture debate. Since the child is being raised by parents who are genetically different from his or her biological parents, the influence of the environment shows in how similar the child is to his or her adoptive parents or adoptive siblings vs. how similar the child is to his or her biological parents and siblings. Adoption studies and twin studies make a strong case for genetic influence. However, it is now generally accepted among scientists, that all traits are influenced by both genetic and environmental differences among individuals.

KEY TAKEAWAYS

Key Points

- Chromosomes are structures in the nucleus of a cell containing DNA coiled around histone proteins.
- All animals have some number of chromosomes, which transmit genetic material. Human beings have 46 chromosomes (23 pairs).
- Humans have two types of chromosomes: autosomes and sex chromosomes.
- Chromosomal abnormalities can result in genetic conditions such as Down syndrome.
- Today it is generally accepted that nature and nurture work in tandem to create the people we ultimately become.
- Adoption and twin studies show that both nature and nurture are factors in human development.
- The environment in which a person is raised can trigger expressions of behavior for which that person is genetically predisposed; genetically identical people raised in different environments may exhibit different behavior.
- Three types of gene -environment correlations (rGE) exist: passive (ambiguous correlation), evocative (one factor invokes a response in the other), and active (one factor influences a preference for another).

Key Terms

- **chromosome**: A structure in the cell nucleus that contains DNA, histone protein, and other structural proteins.
- **gene**: A unit of heredity; a segment of DNA or RNA transmitted from one generation to the next, carrying genetic information such as the sequence of amino acids for a protein.
- **autosome**: Any chromosome that is not a sex chromosome.
- **gene-environment correlation**: A relationship in which exposure to environmental conditions correlates with an individual's genotype.
- **phenotype**: The observable expression of a gene.

3.4.6: The Nature-Nurture Question

Learning Objectives

1. Discuss the nature–nurture debate and why the problem fascinates us.
2. Explain why nature–nurture questions are difficult to study empirically.
3. Describe the major research designs that can be used to study nature–nurture questions.
4. Discuss the complexities of nature–nurture and why questions that seem simple turn out not to have simple answers.
5. Explain the main claim of sociobiology and the reasons why it is controversial.

Overview

People have a deep intuition about what has been called the "nature–nurture question." Some aspects of our behavior feel as though they originate in our genetic makeup, while others feel like the result of our upbringing or our own hard work. The scientific field of behavior genetics attempts to study these differences empirically, either by examining similarities among family members with different degrees of genetic relatedness, or, more recently, by studying differences in the DNA of people with different behavioral traits. The scientific methods that have been developed are ingenious, but often inconclusive. Many of the difficulties encountered in the empirical science of behavior genetics turn out to be conceptual, and our intuitions about nature and nurture get more complicated the harder we think about them. In the end, it is an oversimplification to ask how "genetic" some particular behavior is. Genes and environments always combine to produce behavior, and the real science is in the discovery of how they combine for a given behavior.

Genes and Environment

It may seem obvious that we are born with certain characteristics while others are acquired, and yet in the history of psychology, no other question has caused so much controversy and offense: We are so concerned with nature–nurture because our very sense of moral character seems to depend on it. While we may admire the athletic skills of a great basketball player, we think of his height as simply a gift, a payoff in the "genetic lottery." For the same reason, no one blames a short person for his height or someone's congenital disability on poor decisions: To state the obvious, it's "not their fault." But we do praise the concert violinist (and perhaps her parents and teachers as well) for her dedication, just as we condemn cheaters, slackers, and bullies for their bad behavior.

The problem is, most human characteristics aren't usually as clear-cut as height or instrument-mastery, affirming our nature–nurture expectations strongly one way or the other. In fact, even the great violinist might have some inborn qualities—perfect pitch, or long, nimble fingers—that support and reward her hard work. And the basketball player might have eaten a diet while growing up that promoted his genetic tendency for being tall. When we think about our own qualities, they seem under our control in some respects, yet beyond our control in others. And often the traits that don't seem to have an obvious cause are the ones that concern us the most and are far more personally significant. What about how much we drink or worry? What about our honesty, or religiosity, or sexual orientation? They all come from that uncertain zone, neither fixed by nature nor totally under our own control.

Figure 3.4.6.1: Researchers have learned a great deal about the nature-nurture dynamic by working with animals. But of course many of the techniques used to study animals cannot be applied to people. Separating these two influences in human subjects is a greater research challenge. [Image: Sebastián Dario, https://goo.gl/OPiIWd, CC BY-NC 2.0, https://goo.gl/FIlc2e]

One major problem with answering nature-nurture questions about people is, how do you set up an experiment? In nonhuman animals, there are relatively straightforward experiments for tackling nature–nurture questions. Say, for example, you are interested in aggressiveness in dogs. You want to test for the more important determinant of aggression: being born to aggressive dogs or being raised by them. You could mate two aggressive dogs—angry Chihuahuas—together, and mate two nonaggressive dogs—happy beagles—together, then switch half the puppies from each litter between the different sets of parents to raise. You would then have puppies born to aggressive parents (the Chihuahuas) but being raised by nonaggressive parents (the Beagles), and vice versa, in litters that mirror each other in puppy distribution. The big questions are: Would the Chihuahua parents raise aggressive beagle puppies? Would the beagle parents raise nonaggressive Chihuahua puppies? Would the puppies' nature win out, regardless of who raised them? Or… would the result be a combination of nature and nurture? Much of the most significant nature–nurture research has been done in this way (Scott & Fuller, 1998), and animal breeders have been doing it successfully for thousands of years. In fact, it is fairly easy to breed animals for behavioral traits.

For example, Koenigshofer and Nachman (1974) selectively bred rats for their ability to learn taste aversions. When a novel flavor such as sugar water is followed by mild poisoning by injection 15 minutes later, rats learn to avoid that flavor in the future after a single pairing of flavor and illness (see section 10.2, Specialized Forms of Learning). However, rats varied in how well they learned aversion to the sugar water. A few rats when tested 4 days later showed that they had learned a strong aversion (they consumed very little of the flavor that had been previously followed by poison-induced illness) while a few others learned a weak aversion (they consumed a large amount of the flavor previously paired with illness), while most of the conditioned rats learned a moderate aversion to the flavor previously paired with illness (they consumed an intermediate amount of the flavor previously paired with poison-induced illness). After this first phase of the experiment, rats were selectively bred. Those males and females that learned a strong aversion were bred together, while male and female rats that learned a weak aversion were bred together. Those that learned an intermediate aversion were not bred. This process, involving the pairing of taste and illness followed by selective breeding for strong or weak learning, was repeated for several generations. After just five generations of this selective breeding procedure for taste aversion learning, two strains of rats resulted, strong learners and weak learners, which showed no overlap at all in the strength of taste aversion that they learned after just five generations of selective breeding. The worst learners of the strong learner strain were still much better learners than the best learners of the weak learner strain. The effect of selective breeding in these experiments was greater than the effects of brain lesions on learning ability. This suggests that learning abilities have a significant genetic component--a proposition that is consistent with the hypothesis that at least some differences among humans in learning ability involve genetic differences. That learning abilities have a genetic components suggests that learning abilities have evolved over time by selection (i.e. natural selection). If learning is an evolved genetic trait, how can any behavioral trait, even those that are learned, not have a genetic component?

Although we can experiment with animals, with people, however, we can't assign babies to parents at random, or select parents with certain behavioral characteristics to mate, merely in the interest of science (though history does include horrific examples of such practices, in misguided attempts at "eugenics," the shaping of human characteristics through intentional breeding). In typical human families, children's biological parents raise them, so it is very difficult to know whether children act like their parents

due to genetic (nature) or environmental (nurture) reasons. Nevertheless, despite our restrictions on setting up human-based experiments, we do see real-world examples of nature-nurture at work in the human sphere—though they only provide partial answers to our questions.

The science of how genes and environments work together to influence behavior is called behavioral genetics. The easiest opportunity we have to observe this is the **adoption study**. When children are put up for adoption, the parents who give birth to them are no longer the parents who raise them. This setup isn't quite the same as the experiments with dogs (children aren't assigned to random adoptive parents in order to suit the particular interests of a scientist) but adoption still tells us some interesting things, or at least confirms some basic expectations. For instance, if the biological child of tall parents were adopted into a family of short people, do you suppose the child's growth would be affected? What about the biological child of a Spanish-speaking family adopted at birth into an English-speaking family? What language would you expect the child to speak? And what might these outcomes tell you about the difference between height and language in terms of nature-nurture?

Figure 3.4.6.2: Studies focused on twins have led to important insights about the biological origins of many personality characteristics.

Another option for observing nature-nurture in humans involves **twin studies**. There are two types of twins: **monozygotic (MZ)** and **dizygotic (DZ)**. Monozygotic twins, also called "identical" twins, result from a single zygote (fertilized egg) and have the same DNA. They are essentially clones. Dizygotic twins, also known as "fraternal" twins, develop from two zygotes (fertilized eggs) and share 50% of their DNA. Fraternal twins are ordinary siblings who happen to have been born at the same time. To analyze nature–nurture using twins, we compare the similarity of MZ and DZ pairs. Sticking with the features of height and spoken language, let's take a look at how nature and nurture apply: Identical twins, unsurprisingly, are almost perfectly similar for height. The heights of fraternal twins, however, are like any other sibling pairs: more similar to each other than to people from other families, but hardly identical. This contrast between twin types gives us a clue about the role genetics plays in determining height. Now consider spoken language. If one identical twin speaks Spanish at home, the co-twin with whom she is raised almost certainly does too. But the same would be true for a pair of fraternal twins raised together. In terms of spoken language, fraternal twins are just as similar as identical twins, so it appears that the genetic match of identical twins doesn't make much difference. What language you speak is determined by environment; having more genes in common (MZ vs DZ) doesn't make any difference.

Twin and adoption studies are two instances of a much broader class of methods for observing nature-nurture called **quantitative genetics** , the scientific discipline in which similarities among individuals are analyzed based on how biologically related they are. We can do these studies with siblings and half-siblings, cousins, twins who have been separated at birth and raised separately (Bouchard, Lykken, McGue, & Segal, 1990 ; such twins are very rare and play a smaller role than is commonly believed in the science of nature–nurture), or with entire extended families (see Plomin, DeFries, Knopik, & Neiderhiser, 2012 , for a complete introduction to research methods relevant to nature–nurture).

For better or for worse, contentions about nature–nurture have intensified because quantitative genetics produces a number called a **heritability coefficient** , varying from 0 to 1, that is meant to provide a single measure of genetics' influence on a trait. In a general way, a heritability coefficient **measures how strongly differences among individuals are related to differences among their genes**. But beware: Heritability coefficients, although simple to compute, are deceptively difficult to interpret. Nevertheless, numbers that provide simple answers to complicated questions tend to have a strong influence on the

human imagination, and a great deal of time has been spent discussing whether the heritability of intelligence or personality or depression is equal to one number or another.

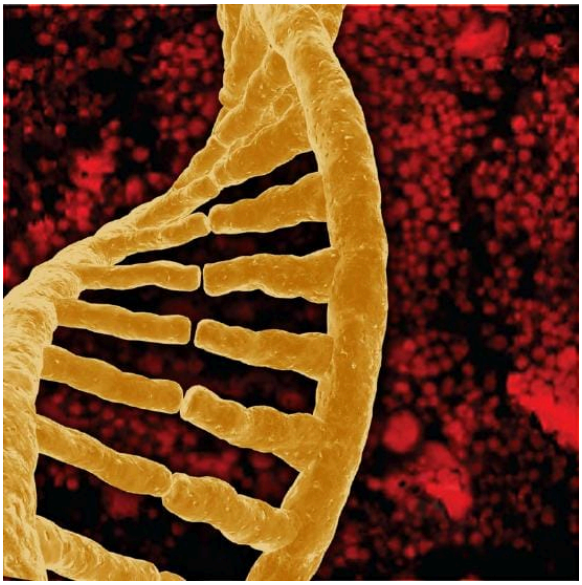

Figure 3.4.6.3: Artist's depiction of double helix of DNA. (Copyright; author via source)

One reason nature–nurture continues to fascinate us so much is that we live in an era of great scientific discovery in genetics, comparable to the times of Copernicus, Galileo, and Newton, with regard to astronomy and physics. Every day, it seems, new discoveries are made, new possibilities proposed. When Francis Galton first started thinking about nature–nurture in the late-19th century he was very influenced by his cousin, Charles Darwin, but genetics per se was unknown. Mendel's famous work with peas, conducted at about the same time, went undiscovered for 20 years; quantitative genetics was developed in the 1920s; DNA was discovered by Watson and Crick in the 1950s; the human genome was completely sequenced at the turn of the 21st century; and we are now on the verge of being able to obtain the specific DNA sequence of anyone at a relatively low cost. No one knows what this new genetic knowledge will mean for the study of nature–nurture, but as we will see in the next section, answers to nature–nurture questions have turned out to be far more difficult and mysterious than anyone imagined.

What have we learned about nature-nurture?

It would be satisfying to be able to say that nature–nurture studies have given us conclusive and complete evidence about where traits come from, with some traits clearly resulting from genetics and others almost entirely from environmental factors, such as childrearing practices and personal will; but that is not the case. Instead, **everything has turned out to have some footing in genetics**. The more genetically-related people are, the more similar they are—for everything: height, weight, intelligence, personality, mental illness, etc. Sure, it seems like common sense that some traits have a genetic bias. For example, adopted children resemble their biological parents even if they have never met them, and identical twins are more similar to each other than are fraternal twins. And while certain psychological traits, such as personality or mental illness (e.g., schizophrenia), seem reasonably influenced by genetics, it turns out that the same is true for political attitudes, how much television people watch (Plomin, Corley, DeFries, & Fulker, 1990), and whether or not they get divorced (McGue & Lykken, 1992).

Figure 3.4.6.4: Research over the last half century has revealed how central genetics are to behavior. The more genetically related people are the more similar they are not just physically but also in terms of personality and behavior. [Image: Paul Altobelli, https://goo.gl/SWLwm2, CC BY 2.0, https://goo.gl/9uSnqN]

It may seem surprising, but genetic influence on behavior is a relatively recent discovery. In the middle of the 20th century, psychology was dominated by the doctrine of behaviorism, which held that behavior could only be explained in terms of environmental factors. Psychiatry concentrated on psychoanalysis, which probed for roots of behavior in individuals' early life-histories. The truth is, neither behaviorism nor psychoanalysis is incompatible with genetic influences on behavior, and neither Freud nor Skinner was naive about the importance of organic processes in behavior. Nevertheless, in their day it was widely thought that children's personalities were shaped entirely by imitating their parents' behavior, and that schizophrenia was caused by certain kinds of "pathological mothering." Whatever the outcome of our broader discussion of nature–nurture, the basic fact that the best predictors of an adopted child's personality or mental health are found in the biological parents he or she has never met, rather than in the adoptive parents who raised him or her, presents a significant challenge to purely environmental explanations of personality or psychopathology. The message is clear: **You can't leave genes out of the equation. But keep in mind, no behavioral traits are completely inherited, so you can't leave the environment out altogether, either.**

Trying to untangle the various ways nature-nurture influences human behavior can be messy, and often common-sense notions can get in the way of good science. One very significant contribution of behavioral genetics that has changed psychology for good can be very helpful to keep in mind: When your subjects are biologically-related, no matter how clearly a situation may seem to point to environmental influence, it is never safe to interpret a behavior as wholly the result of nurture without further evidence. For example, when presented with data showing that children whose mothers read to them often are likely to have better reading scores in third grade, it is tempting to conclude that reading to your kids out loud is important to success in school; this may well be true, but the study as described is inconclusive, because there are genetic as well as environmental pathways between the parenting practices of mothers and the abilities of their children. This is a case where "correlation does not imply causation," as they say. To establish that reading aloud causes success, a scientist can either study the problem in adoptive families (in which the genetic pathway is absent) or by finding a way to randomly assign children to oral reading conditions.

The outcomes of nature–nurture studies have fallen short of our expectations (of establishing clear-cut bases for traits) in many ways. The most disappointing outcome has been the inability to organize traits from more-to less-genetic. As noted earlier, **everything has turned out to be at least somewhat heritable (passed down), yet nothing has turned out to be absolutely heritable**, and there hasn't been much consistency as to which traits are more heritable and which are less heritable once other considerations (such as how accurately the trait can be measured) are taken into account (Turkheimer, 2000). The problem is conceptual: The heritability coefficient, and, in fact, the whole quantitative structure that underlies it, does not match up with our nature–nurture intuitions. We want to know how "important" the roles of genes and environment are to the development of a trait, but in focusing on "important" maybe we're emphasizing the wrong thing. First of all, genes and environment are both crucial to every trait; without genes the environment would have nothing to work on, and too, genes cannot develop in a vacuum. Even more important, because nature–nurture questions look at the differences among people, the cause of a given trait depends not only on the trait itself, but also on the differences in that trait between members of the group being studied.

The classic example of the heritability coefficient defying intuition is the trait of having two arms. No one would argue

against the development of arms being **a biological, genetic process**. But fraternal twins are just as similar for "two-armedness" as identical twins, resulting in a **heritability coefficient of zero** for the trait of having two arms. Normally, according to the heritability model, this result (coefficient of zero) would suggest all nurture, no nature, but we know that's not the case. The reason this result is not a tip-off that arm development is less genetic than we imagine is **because people do not vary in the genes related to arm development**—which essentially upends the heritability formula. In fact, in this instance, the opposite is likely true: the extent that people differ in arm number is likely the result of accidents and, therefore, environmental. For reasons like these, we always have to be very careful when asking nature–nurture questions, especially when we try to express the answer in terms of a single number. The heritability of a trait is not simply a property of that trait, but a property of the trait in a particular context of relevant genes and environmental factors.

Another issue with the heritability coefficient is that it divides traits' determinants into two portions—genes and environment—which are then calculated together for the total variability. This is a little like asking how much of the experience of a symphony comes from the horns and how much from the strings; the ways instruments or genes integrate is more complex than that. It turns out to be the case that, **for many traits, genetic differences affect behavior under some environmental circumstances but not others—a phenomenon called gene-environment interaction**, or G x E. In one well-known example, Caspi et al. (2002) showed that among maltreated children, those who carried a particular allele of the MAOA gene showed a predisposition to violence and antisocial behavior, while those with other alleles did not. Whereas, in children who had not been maltreated, the gene had no effect. Making matters **even more complicated** are very recent studies of what is known as **epigenetics** (see module, "Epigenetics" http://noba.to/37p5cb8v), a process **in which the DNA itself is modified by environmental events, and those genetic changes transmitted to children.**

Figure 3.4.6.5: The answer to the nature–nurture question has not turned out to be as straightforward as we would like. The many questions we can ask about the relationships among genes, environments, and human traits may have many different answers, and the answer to one tells us little about the answers to the others. [Image and caption: Sundaram Ramaswamy, https://goo.gl/Bv8lp6, CC BY 2.0, https://goo.gl/9uSnqN]

Some common questions about nature–nurture are, how susceptible is a trait to change, how malleable is it, and do we "have a choice" about it? These questions are much more complex than they may seem at first glance. For example, phenylketonuria is an inborn error of metabolism caused by a single gene; it prevents the body from metabolizing phenylalanine. Untreated, it causes intellectual disability and death. But it can be treated effectively by a straightforward environmental intervention: avoiding foods containing phenylalanine. Height seems like a trait firmly rooted in our nature and unchangeable, but the average height of many populations in Asia and Europe has increased significantly in the past 100 years, due to changes in diet and the alleviation of poverty. Even the most modern genetics has not provided definitive answers to nature–nurture questions. When it was first becoming possible to measure the DNA sequences of individual people, it was widely thought that we would quickly progress to finding the specific genes that account for behavioral characteristics, but that hasn't happened. There are a few rare genes that have been found to have significant (almost always negative) effects, such as the single gene that causes Huntington's disease, or the Apolipoprotein gene that causes early onset dementia in a small percentage of Alzheimer's cases. Aside from these rare genes of great effect, however, the genetic impact on behavior is broken up over many genes, each with very small effects. For most behavioral traits, the effects are so small and distributed across so many genes that we have not been able to catalog them in a meaningful way. In fact, the same is true of environmental effects. We know that extreme environmental hardship causes catastrophic effects for many behavioral outcomes, but fortunately extreme environmental hardship is very rare. Within the normal

range of environmental events, those responsible for differences (e.g., why some children in a suburban third-grade classroom perform better than others) are much more difficult to grasp.

The difficulties with finding clear-cut solutions to nature–nurture problems bring us back to the other great questions about our relationship with the natural world: the mind-body problem and free will. Investigations into what we mean when we say we are aware of something reveal that consciousness is not simply the product of a particular area of the brain, nor does choice turn out to be an orderly activity that we can apply to some behaviors but not others. So it is with nature and nurture: What at first may seem to be a straightforward matter, able to be indexed with a single number, becomes more and more complicated the closer we look. The many questions we can ask about the intersection among genes, environments, and human traits—how sensitive are traits to environmental change, and how common are those influential environments; are parents or culture more relevant; how sensitive are traits to differences in genes, and how much do the relevant genes vary in a particular population; does the trait involve a single gene or a great many genes; is the trait more easily described in genetic or more-complex behavioral terms?—may have different answers, and the answer to one tells us little about the answers to the others.

It is tempting to predict that the more we understand the wide-ranging effects of genetic differences on all human characteristics—especially behavioral ones—our cultural, ethical, legal, and personal ways of thinking about ourselves will have to undergo profound changes in response. Perhaps criminal proceedings will consider genetic background. Parents, presented with the genetic sequence of their children, will be faced with difficult decisions about reproduction. These hopes or fears are often exaggerated. In some ways, our thinking may need to change—for example, when we consider the meaning behind the fundamental American principle that all men are created equal. Human beings differ, and like all evolved organisms they differ genetically. The Declaration of Independence predates Darwin and Mendel, but it is hard to imagine that Jefferson—whose genius encompassed botany as well as moral philosophy—would have been alarmed to learn about the genetic diversity of organisms. One of the most important things modern genetics has taught us is that almost all human behavior is too complex to be nailed down, even from the most complete genetic information, unless we're looking at identical twins. The science of nature and nurture has demonstrated that genetic differences among people are vital to human moral equality, freedom, and self-determination, not opposed to them. As Mordecai Kaplan said about the role of the past in Jewish theology, genetics gets a vote, not a veto, in the determination of human behavior. We should indulge our fascination with nature–nurture while resisting the temptation to oversimplify it.

Vocabulary

***Adoption study*: A behavior genetic research method that involves comparison of adopted children to their adoptive and biological parents.**

***Behavioral genetics*: The empirical science of how genes and environments combine to generate behavior.**

***Heritability coefficient*: An easily misinterpreted statistical construct that purports to measure the percentage of differences among individuals on a trait due to genetics.**

***Quantitative genetics*: Scientific and mathematical methods for inferring genetic and environmental processes based on the degree of genetic and environmental similarity among organisms.**

***Twin studies*: A behavior genetic research method that involves comparison of the similarity of identical (monozygotic; MZ) and fraternal (dizygotic; DZ) twins.**

Discussion Questions

1. Is your personality more like one of your parents than the other? If you have a sibling, is his or her personality like yours? In your family, how did these similarities and differences develop? What do you think caused them?
2. Can you think of a human characteristic for which genetic differences would play almost no role? Defend your choice.
3. Do you think the time will come when we will be able to predict almost everything about someone by examining their DNA

on the day they are born?
4. Identical twins are more similar than fraternal twins for the trait of aggressiveness, as well as for criminal behavior. Do these facts have implications for the courtroom? If it can be shown that a violent criminal had violent parents, should it make a difference in culpability or sentencing?

Sociobiology

Sociobiology is an interdisciplinary science originally popularized by social insect researcher E.O. Wilson in the 1970s. Wilson defined the science as "the extension of population biology and evolutionary theory to social organization." The main thrust of sociobiology is that animal and human behavior, including aggressiveness and other social interactions, can be explained almost solely in terms of genetics and natural selection (Wilson, 1975).

This science is controversial; some have criticized the approach for ignoring the environmental effects on behavior. This is another example of the "nature versus nurture" debate of the role of genetics versus the role of environment in determining an organism's characteristics.

Sociobiology also links genes with behaviors and has been associated with "biological determinism," the belief that all behaviors are hardwired into our genes. No one disputes that certain behaviors can be inherited and that natural selection plays a role in their organization. However, it is the application of such principles to human behavior that ruffles feathers and sparks this controversy, which remains active today.

Key Points

- Sociobiology argues that all animal and human behavior, including aggressiveness and other social interactions, can be explained almost solely in terms of genetics and natural selection.
- Sociobiology is controversial: some have criticized the approach for ignoring the environmental effects on behavior and for being similar to "biological determinism," or the belief that all behaviors are hardwired into our genes.

Key Terms

- **biological determinism**: also known as genetic determinism is the belief that most human traits, physical and psychological, are innate and determined by genes.
- **sociobiology**: the science that applies the principles of evolutionary biology to the study of social behaviour in both humans and animals, suggesting that social behavior in animals and humans is shaped primarily by genes and genetic evolution.

3.4.7: Epigenetics in Psychology

Learning Objectives

1. Explain what the term epigenetics means and the molecular machinery involved.
2. Describe important neural and developmental pathways that are regulated by epigenetic factors, and discuss examples of epigenetic effects on personality traits and cognitive behavior.
3. Explain how misregulation of epigenetic mechanisms can lead to disease states, and discuss examples.
4. Describe how epigenetic machinery can be targets for therapeutic agents, and discuss examples.
5. Discuss examples of genetic diseases and their patterns of inheritance.

Overview

Early life experiences exert a profound and long-lasting influence on physical and mental health throughout life. The efforts to identify the primary causes of this have significantly benefited from studies of the epigenome—a dynamic layer of information associated with DNA that differs between individuals and can be altered through various experiences and environments. The epigenome has been heralded as a key "missing piece" of the etiological puzzle for understanding how development of psychological disorders may be influenced by the surrounding environment, in concordance with the genome. Understanding the mechanisms involved in the initiation, maintenance, and heritability of epigenetic states is thus an important aspect of research in current biology, particularly in the study of learning and memory, emotion, and social behavior in humans. Moreover, epigenetics in psychology provides a framework for understanding how the expression of genes is influenced by experiences and the environment to produce individual differences in behavior, cognition, personality, and mental health. In this module, we survey recent developments revealing epigenetic aspects of mental health and review some of the challenges of epigenetic approaches in psychology to help explain how nurture shapes nature.

Introduction

Figure 3.4.7.1: DNA stands for Deoxyribonucleic Acid, and although each person's DNA is unique to that individual, it is 99.9% similar to every other human on the planet. [Image: CC0 Public Domain, https://goo.gl/m25gce]

Early childhood is not only a period of physical growth; it is also a time of mental development related to changes in the anatomy, physiology, and chemistry of the nervous system that influence mental health throughout life. Cognitive abilities associated with learning and memory, reasoning, problem solving, and developing relationships continue to emerge during childhood. Brain development is more rapid during this critical or sensitive period than at any other, with more than 700 neural connections

created each second. Herein, complex gene –environment interactions (or genotype–environment interactions, G×E) serve to increase the number of possible contacts between neurons, as they hone their adult synaptic properties and excitability. Many weak connections form to different neuronal targets; subsequently, they undergo remodeling in which most connections vanish and a few stable connections remain. These structural changes (or plasticity) may be crucial for the development of mature neural networks that support emotional, cognitive, and social behavior. The generation of different morphology, physiology, and behavioral outcomes from a single genome in response to changes in the environment forms the basis for "phenotypic plasticity," which is fundamental to the way organisms cope with environmental variation, navigate the present world, and solve future problems.

The challenge for psychology has been to integrate findings from genetics and environmental (social, biological, chemical) factors, including the quality of infant–mother attachments, into the study of personality and our understanding of the emergence of mental illness. These studies have demonstrated that common DNA sequence variation and rare mutations account for only a small fraction (1%–2%) of the total risk for inheritance of personality traits and mental disorders (Dick, Riley, & Kendler, 2010; Gershon, Alliey-Rodriguez, & Liu, 2011). Additionally, studies that have attempted to examine the mechanisms and conditions under which DNA sequence variation influences brain development and function have been confounded by complex cause-and-effect relationships (Petronis, 2010). The large unaccounted heritability of personality traits and mental health suggests that additional molecular and cellular mechanisms are involved.

Epigenetics has the potential to provide answers to these important questions and refers to the transmission of phenotype in terms of gene expression in the absence of changes in DNA sequence—hence the name epi- (Greek: επί- over, above) genetics (Waddington, 1942 ; Wolffe & Matzke, 1999). The advent of high-throughput techniques such as sequencing-based approaches to study the distributions of regulators of gene expression throughout the genome led to the collective description of the "epigenome." In contrast to the genome sequence, which is static and the same in almost all cells, the epigenome is highly dynamic, differing among cell types, tissues, and brain regions (Gregg et al., 2010). Recent studies have provided insights into epigenetic regulation of developmental pathways in response to a range of external environmental factors (Dolinoy, Weidman, & Jirtle, 2007). These environmental factors during early childhood and adolescence can cause changes in expression of genes conferring risk of mental health and chronic physical conditions. Thus, the examination of genetic–epigenetic–environment interactions from a developmental perspective may determine the nature of gene misregulation in psychological disorders.

This module will provide an overview of the main components of the epigenome and review themes in recent epigenetic research that have relevance for psychology, to form the biological basis for the interplay between environmental signals and the genome in the regulation of individual differences in physiology, emotion, cognition, and behavior.

Molecular control of gene expression: the dynamic epigenome

Figure 3.4.7.2: Identical twins are the perfect example of epigenetics. Although they share exactly the same DNA, their unique experiences in life will cause some genes (and not others) to express themselves. This is why, over time, identical twins come to look and behave differently. [Image: M., https://goo.gl/VU5iJv, CC BY-NC-SA 2.0, https://goo.gl/Toc0ZF]

Almost all the cells in our body are genetically identical, yet our body generates many different cell types, organized into different

tissues and organs, and expresses different proteins. Within each type of mammalian cell, about 2 meters of genomic DNA is divided into nuclear chromosomes. Yet the nucleus of a human cell, which contains the chromosomes, is only about 2 µm in diameter. To achieve this 1,000,000-fold compaction, DNA is wrapped around a group of 8 proteins called histones. This combination of DNA and histone proteins forms a special structure called a “nucleosome,” the basic unit of chromatin, which represents a structural solution for maintaining and accessing the tightly compacted genome. These factors alter the likelihood that a gene will be expressed or silenced. Cellular functions such as gene expression, DNA replication, and the generation of specific cell types are therefore influenced by distinct patterns of chromatin structure, involving covalent modification of both histones (Kadonaga, 1998) and DNA (Razin, 1998).

Importantly, epigenetic variation also emerges across the lifespan. For example, although identical twins share a common genotype and are genetically identical and epigenetically similar when they are young, as they age they become more dissimilar in their epigenetic patterns and often display behavioral, personality, or even physical differences, and have different risk levels for serious illness. Thus, understanding the structure of the nucleosome is key to understanding the precise and stable control of gene expression and regulation, providing a molecular interface between genes and environmentally induced changes in cellular activity.

The primary epigenetic mark: DNA modification

DNA methylation is the best-understood epigenetic modification influencing gene expression. DNA is composed of four types of naturally occurring nitrogenous bases: adenine (A), thymine (T), guanine (G), and cytosine (C). In mammalian genomes, DNA methylation occurs primarily at cytosine residues in the context of cytosines that are followed by guanines (CpG dinucleotides), to form 5-methylcytosine in a cell-specific pattern (Goll & Bestor, 2005 ; Law & Jacobsen, 2010 ; Suzuki & Bird, 2008). The enzymes that perform DNA methylation are called DNA methyltransferases (DNMTs) , which catalyze the transfer of a methyl group to the cytosine (Adams, McKay, Craig, & Burdon, 1979). These enzymes are all expressed in the central nervous system and are dynamically regulated during development (Feng, Chang, Li, & Fan, 2005 ; Goto et al., 1994). The effect of DNA methylation on gene function varies depending on the period of development during which the methylation occurs and location of the methylated cytosine. Methylation of DNA in gene regulatory regions (promoter and enhancer regions) usually results in gene silencing and reduced gene expression (Ooi, O’Donnell, & Bestor, 2009 ; Suzuki & Bird, 2008 ; Sutter and Doerfler, 1980 ; Vardimon et al., 1982). This is a powerful regulatory mechanism that ensures that genes are expressed only when needed. Thus DNA methylation may broadly impact human brain development, and age-related misregulation of DNA methylation is associated with the molecular pathogenesis of neurodevelopmental disorders.

Histone modification and the histone code

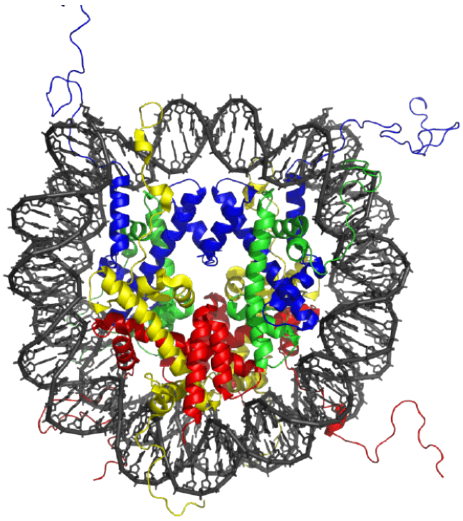

Figure 3.4.7.3: Life experiences, like a stressful event in childhood, can cause the modification of histone proteins (pictured) to help adapt to one’s environment. For example, in response to a stressful event, histone modification of one’s DNA might occur to encourage a more cautions personality—in order to avoid future, stressful encounters. [Image: Zephyris, https://goo.gl/gGrSQd, CC BY-SA 3.0, https://goo.gl/kB1Ogc]

The modification of histone proteins comprises an important epigenetic mark related to gene expression. One of the most

thoroughly studied modifications is histone acetylation, which is associated with gene activation and increased gene expression (Wade, Pruss, & Wolffe, 1997). Acetylation on histone tails is mediated by the opposing enzymatic activities of histone acetyltransferases (HATs) and histone deacetylases (HDACs) (Kuo & Allis, 1998). For example, acetylation of histone in gene regulatory regions by HAT enzymes is generally associated with DNA demethylation, gene activation, and increased gene expression (Hong, Schroth, Matthews, Yau, & Bradbury, 1993 ; Sealy & Chalkley, 1978). On the other hand, removal of the acetyl group (deacetylation) by HDAC enzymes is generally associated with DNA methylation, gene silencing, and decreased gene expression (Davie & Chadee, 1998). The relationship between patterns of histone modifications and gene activity provides evidence for the existence of a “histone code” for determining cell-specific gene expression programs (Jenuwein & Allis, 2001). Interestingly, recent research using animal models has demonstrated that histone modifications and DNA methylation of certain genes mediates the long-term behavioral effects of the level of care experienced during infancy.

Early childhood experience

The development of an individual is an active process of adaptation that occurs within a social and economic context. For example, the closeness or degree of positive attachment of the parent (typically mother)–infant bond and parental investment (including nutrient supply provided by the parent) that define early childhood experience also program the development of individual differences in stress responses in the brain, which then affect memory, attention, and emotion. In terms of evolution, this process provides the offspring with the ability to physiologically adjust gene expression profiles contributing to the organization and function of neural circuits and molecular pathways that support (1) biological defensive systems for survival (e.g., stress resilience), (2) reproductive success to promote establishment and persistence in the present environment, and (3) adequate parenting in the next generation (Bradshaw, 1965).

Parental investment and programming of stress responses in the offspring

The most comprehensive study to date of variations in parental investment and epigenetic inheritance in mammals is that of the maternally transmitted responses to stress in rats. In rat pups, maternal nurturing (licking and grooming) during the first week of life is associated with long-term programming of individual differences in stress responsiveness, emotionality, cognitive performance, and reproductive behavior (Caldji et al., 1998 ; Francis, Diorio, Liu, & Meaney, 1999 ; Liu et al., 1997 ; Myers, Brunelli, Shair, Squire, & Hofer, 1989 ; Stern, 1997). In adulthood, the offspring of mothers that exhibit increased levels of pup licking and grooming over the first week of life show increased expression of the glucocorticoid receptor in the hippocampus (a brain structure associated with stress responsivity as well as learning and memory) and a lower hormonal response to stress compared with adult animals reared by low licking and grooming mothers (Francis et al., 1999 ; Liu et al., 1997). Moreover, rat pups that received low levels of maternal licking and grooming during the first week of life showed decreased histone acetylation and increased DNA methylation of a neuron-specific promoter of the glucocorticoid receptor gene (Weaver et al., 2004). The expression of this gene is then reduced, the number of glucocorticoid receptors in the brain is decreased, and the animals show a higher hormonal response to stress throughout their life. The effects of maternal care on stress hormone responses and behaviour in the offspring can be eliminated in adulthood by pharmacological treatment (HDAC inhibitor trichostatin A, TSA) or dietary amino acid supplementation (methyl donor L-methionine), treatments that influence histone acetylation, DNA methylation, and expression of the glucocorticoid receptor gene (Weaver et al., 2004 ; Weaver et al., 2005). This series of experiments shows that histone acetylation and DNA methylation of the glucocorticoid receptor gene promoter is a necessary link in the process leading to the long-term physiological and behavioral sequelae of poor maternal care. This points to a possible molecular target for treatments that may reverse or ameliorate the traces of childhood maltreatment.

Figure 3.4.7.4: Parental care during one's childhood has important and consequential effects on the development of an individual, effects that persist even into adulthood. [Image: The White Ribbon Alliance, https://goo.gl/KgY6N5, CC BY-NC-SA 2.0, https://goo.gl/Toc0ZF]

Several studies have attempted to determine to what extent the findings from model animals are transferable to humans. Examination of post-mortem brain tissue from healthy human subjects found that the human equivalent of the glucocorticoid receptor gene promoter (NR3C1 exon 1F promoter) is also unique to the individual (Turner, Pelascini, Macedo, & Muller, 2008). A similar study examining newborns showed that methylation of the glucocorticoid receptor gene promoter maybe an early epigenetic marker of maternal mood and risk of increased hormonal responses to stress in infants 3 months of age (Oberlander et al., 2008). Although further studies are required to examine the functional consequence of this DNA methylation, these findings are consistent with our studies in the neonate and adult offspring of low licking and grooming mothers that show increased DNA methylation of the promoter of the glucocorticoid receptor gene, decreased glucocorticoid receptor gene expression, and increased hormonal responses to stress (Weaver et al., 2004). Examination of brain tissue from suicide victims found that the human glucocorticoid receptor gene promoter is also more methylated in the brains of individuals who had experienced maltreatment during childhood (McGowan et al., 2009). These finding suggests that DNA methylation mediates the effects of early environment in both rodents and humans and points to the possibility of new therapeutic approaches stemming from translational epigenetic research. Indeed, similar processes at comparable epigenetic labile regions could explain why the adult offspring of high and low licking/grooming mothers exhibit widespread differences in hippocampal gene expression and cognitive function (Weaver, Meaney, & Szyf, 2006).

However, this type of research is limited by the inaccessibility of human brain samples. The translational potential of this finding would be greatly enhanced if the relevant epigenetic modification can be measured in an accessible tissue. Examination of blood samples from adult patients with bipolar disorder, who also retrospectively reported on their experiences of childhood abuse and neglect, found that the degree of DNA methylation of the human glucocorticoid receptor gene promoter was strongly positively related to the reported experience of childhood maltreatment decades earlier. For a relationship between a molecular measure and reported historical exposure, the effects size is extraordinarily large. This opens a range of new possibilities: given the large effect size and consistency of this association, measurement of the GR promoter methylation may effectively become a blood test measuring the physiological traces left on the genome by early experiences. Although this blood test cannot replace current methods of diagnosis, this unique and addition information adds to our knowledge of how disease may arise and be manifested throughout life. Near-future research will examine whether this measure adds value over and above simple reporting of early adversities when it comes to predicting important outcomes, such as response to treatment or suicide.

Child nutrition and the epigenome

Figure 3.4.7.5: Whether or not your parents knew the science behind it, telling you to eat your veggies as a kid really does make you healthier and stronger—at least your DNA, that is. [Image: U.S. Department of Agriculture, https://goo.gl/tpyYzA, CC BY 2.0, https://goo.gl/BRvSA7]

The old adage “you are what you eat” might be true on more than just a physical level: The food you choose (and even what your parents and grandparents chose) is reflected in your own personal development and risk for disease in adult life (Wells, 2003). Nutrients can reverse or change DNA methylation and histone modifications, thereby modifying the expression of critical genes associated with physiologic and pathologic processes, including embryonic development, aging, and carcinogenesis. It appears that nutrients can influence the epigenome either by directly inhibiting enzymes that catalyze DNA methylation or histone modifications, or by altering the availability of substrates necessary for those enzymatic reactions. For example, rat mothers fed a diet low in methyl group donors during pregnancy produce offspring with reduced DNMT-1 expression, decreased DNA methylation, and increased histone acetylation at promoter regions of specific genes, including the glucocorticoid receptor, and increased gene expression in the liver of juvenile offspring (Lillycrop, Phillips, Jackson, Hanson, & Burdge, 2005) and adult offspring (Lillycrop et al., 2007). These data suggest that early life nutrition has the potential to influence epigenetic programming in the brain not only during early development but also in adult life, thereby modulating health throughout life. In this regard, nutritional epigenetics has been viewed as an attractive tool to prevent pediatric developmental diseases and cancer, as well as to delay aging-associated processes.

The best evidence relating to the impact of adverse environmental conditions development and health comes from studies of the children of women who were pregnant during two civilian famines of World War II: the Siege of Leningrad (1941–44) (Bateson, 2001) and the Dutch Hunger Winter (1944–1945) (Stanner et al., 1997). In the Netherlands famine, women who were previously well nourished were subjected to low caloric intake and associated environmental stressors. Women who endured the famine in the late stages of pregnancy gave birth to smaller babies (Lumey & Stein, 1997) and these children had an increased risk of insulin resistance later in life (Painter, Roseboom, & Bleker, 2005). In addition, offspring who were starved prenatally later experienced impaired glucose tolerance in adulthood, even when food was more abundant (Stanner et al., 1997). Famine exposure at various stages of gestation was associated with a wide range of risks such as increased obesity, higher rates of coronary heart disease, and lower birth weight (Lumey & Stein, 1997). Interestingly, when examined 60 years later, people exposed to famine prenatally showed reduced DNA methylation compared with their unexposed same-sex siblings (Heijmans et al., 2008).

Epigenetic regulation of learning and memory

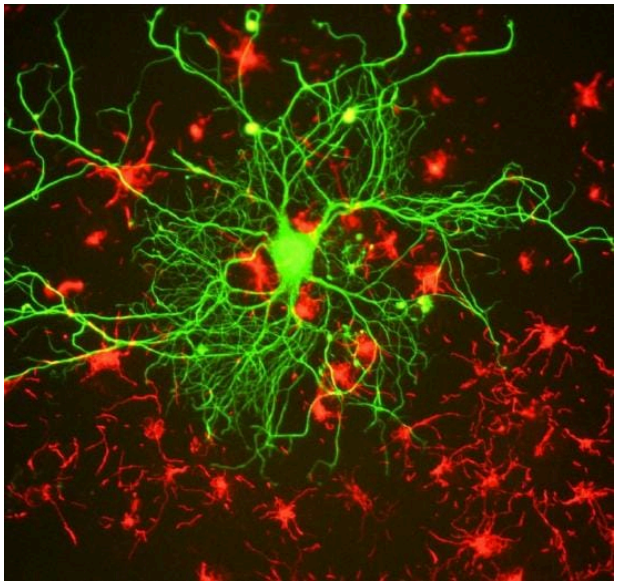

Figure 3.4.7.6: Neural plasticity is the change of neural pathways and synapses which allows for our ability to learn new things and remember them. [Image: Gerry Shaw, https://goo.gl/JBqlY7, CC BY-SA 3.0, https://goo.gl/eLCn2O]

Memories are recollections of actual events stored within our brains. But how is our brain able to form and store these memories? Epigenetic mechanisms influence genomic activities in the brain to produce long-term changes in synaptic signaling, organization, and morphology, which in turn support learning and memory (Day & Sweatt, 2011).

Neuronal activity in the hippocampus of mice is associated with changes in DNA methylation (Guo et al., 2011), and disruption to genes encoding the DNA methylation machinery cause learning and memory impairments (Feng et al., 2010). DNA methylation has also been implicated in the maintenance of long-term memories, as pharmacological inhibition of DNA methylation and impaired memory (Day & Sweatt, 2011 ; Miller et al., 2010). These findings indicate the importance of DNA methylation in mediating synaptic plasticity and cognitive functions, both of which are disturbed in psychological illness.

Changes in histone modifications can also influence long-term memory formation by altering chromatin accessibility and the expression of genes relevant to learning and memory. Memory formation and the associated enhancements in synaptic transmission are accompanied by increases in histone acetylation (Guan et al., 2002) and alterations in histone methylation (Schaefer et al., 2009), which promote gene expression. Conversely, a neuronal increase in histone deacetylase activity, which promotes gene silencing, results in reduced synaptic plasticity and impairs memory (Guan et al., 2009). Pharmacological inhibition of histone deacetylases augments memory formation (Guan et al., 2009 ; Levenson et al., 2004), further suggesting that histone (de)acetylation regulates this process.

In humans genetic defects in genes encoding the DNA methylation and chromatin machinery exhibit profound effects on cognitive function and mental health (Jiang, Bressler, & Beaudet, 2004). The two best-characterized examples are Rett syndrome (Amir et al., 1999) and Rubinstein-Taybi syndrome (RTS) (Alarcon et al., 2004), which are profound intellectual disability disorders. Both MECP2 and CBP are highly expressed in neurons and are involved in regulating neural gene expression (Chen et al., 2003 ; Martinowich et al., 2003).

Rett syndrome patients have a mutation in their DNA sequence in a gene called MECP2. MECP2 plays many important roles within the cell: One of these roles is to read the DNA sequence, checking for DNA methylation, and to bind to areas that contain methylation, thereby preventing the wrong proteins from being present. Other roles for MECP2 include promoting the presence of particular, necessary, proteins, ensuring that DNA is packaged properly within the cell and assisting with the production of proteins. MECP2 function also influences gene expression that supports dendritic and synaptic development and hippocampus-dependent memory (Li, Zhong, Chau, Williams, & Chang, 2011 ; Skene et al., 2010). Mice with altered MECP2 expression exhibit genome-wide increases in histone acetylation, neuron cell death, increased anxiety, cognitive deficits, and social withdrawal (Shahbazian et al., 2002). These findings support a model in which DNA methylation and MECP2 constitute a cell-specific epigenetic mechanism for regulation of histone modification and gene expression, which may be disrupted in Rett syndrome.

RTS patients have a mutation in their DNA sequence in a gene called CBP. One of these roles of CBP is to bind to specific

histones and promote histone acetylation, thereby promoting gene expression. Consistent with this function, RTS patients exhibit a genome-wide decrease in histone acetylation and cognitive dysfunction in adulthood (Kalkhoven et al., 2003). The learning and memory deficits are attributed to disrupted neural plasticity (Korzus, Rosenfeld, & Mayford, 2004). Similar to RTS in humans, mice with a mutation of CBP perform poorly in cognitive tasks and show decreased genome-wide histone acetylation (for review, see Josselyn, 2005). In the mouse brain CBP was found to act as an epigenetic switch to promote the birth of new neurons in the brain. Interestingly, this epigenetic mechanism is disrupted in the fetal brains of mice with a mutation of CBP, which, as pups, exhibit early behavioral deficits following removal and separation from their mother (Wang et al., 2010). These findings provide a novel mechanism whereby environmental cues, acting through histone modifying enzymes, can regulate epigenetic status and thereby directly promote neurogenesis, which regulates neurobehavioral development.

Together, these studies demonstrate that misregulation of epigenetic modifications and their regulatory enzymes is capable of orchestrating prominent deficits in neuronal plasticity and cognitive function. Knowledge from these studies may provide greater insight into other mental disorders such as depression and suicidal behaviors.

Epigenetic mechanisms in psychological disorders

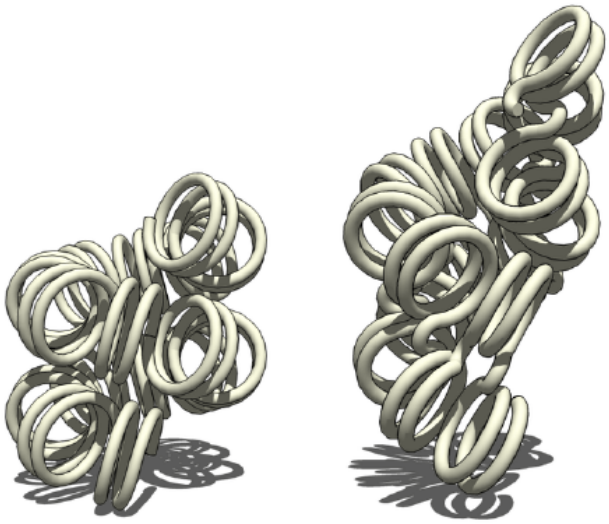

Figure 3.4.7.7: Pictured above is a chromatin, the spiral-looking macromolecule involved in depression. [Image: Zephyris, https://goo.gl/6DBQ1g, CC BY-SA 3.0, https://goo.gl/eLCn2O]

Epigenome-wide studies have identified several dozen sites with DNA methylation alterations in genes involved in brain development and neurotransmitter pathways, which had previously been associated with mental illness (Mill et al., 2008). These disorders are complex and typically start at a young age and cause lifelong disability. Often, limited benefits from treatment make these diseases some of the most burdensome disorders for individuals, families, and society. It has become evident that the efforts to identify the primary causes of complex psychiatric disorders may significantly benefit from studies linking environmental effects with changes observed within the individual cells.

Epigenetic events that alter chromatin structure to regulate programs of gene expression have been associated with depression-related behavior and action of antidepressant medications, with increasing evidence for similar mechanisms occurring in post-mortem brains of depressed individuals. In mice, social avoidance resulted in decreased expression of hippocampal genes important in mediating depressive responses (Tsankova et al., 2006). Similarly, chronic social defeat stress was found to decrease expression of genes implicated in normal emotion processing (Lutter et al., 2008). Consistent with these findings, levels of histone markers of increased gene expression were down regulated (reduction in gene expression) in human post-mortem brain samples from individuals with a history of clinical depression (Covington et al., 2009).

Administration of antidepressants increased histone markers of increased gene expression and reversed the gene repression induced by defeat stress (Lee, Wynder, Schmidt, McCafferty, & Shiekhattar, 2006 ; Tsankova et al., 2006 ; Wilkinson et al., 2009). These results provide support for the use of HDAC inhibitors against depression. Accordingly, several HDAC inhibitors have been found to exert antidepressant effects by each modifying distinct cellular targets (Cassel et al., 2006 ; Schroeder, Lin, Crusio, & Akbarian, 2007).

There is also increasing evidence that aberrant gene expression resulting from altered epigenetic regulation is associated with the pathophysiology of suicide (McGowan et al., 2008 ; Poulter et al., 2008). Thus, it is tempting to speculate that there is an epigenetically determined reduced capacity for gene expression, which is required for learning and memory, in the brains of suicide victims.

Epigenetic strategy to understanding gene-environment interactions

Figure 3.4.7.8: Although there is some evidence that a dysfunctional upbringing can increase one's likelihood for schizophrenia (an epigenetically inherited disease), some people who have both the predisposition and the stressful environment never develop the mental illness. [Image: Steve White, CC0 Public Domain, https://goo.gl/m25gce]

While the cellular and molecular mechanisms that influence on physical and mental health have long been a central focus of neuroscience, only in recent years has attention turned to the epigenetic mechanisms behind the dynamic changes in gene expression responsible for normal cognitive function and increased risk for mental illness. The links between early environment and epigenetic modifications suggest a mechanism underlying gene-environment interactions. Early environmental adversity alone is not a sufficient cause of mental illness, because many individuals with a history of severe childhood maltreatment or trauma remain healthy. It is increasingly becoming evident that inherited differences in the segments of specific genes may moderate the effects of adversity and determine who is sensitive and who is resilient through a gene-environment interplay. Genes such as the glucocorticoid receptor appear to moderate the effects of childhood adversity on mental illness. Remarkably, epigenetic DNA modifications have been identified that may underlie the long-lasting effects of environment on biological functions. This new epigenetic research is pointing to a new strategy to understanding gene-environment interactions.

The next decade of research will show if this potential can be exploited in the development of new therapeutic options that may alter the traces that early environment leaves on the genome. However, as discussed in this module, the epigenome is not static and can be molded by developmental signals, environmental perturbations, and disease states, which present an experimental challenge in the search for epigenetic risk factors in psychological disorders (Rakyan, Down, Balding, & Beck, 2011). The sample size and epigenomic assay required is dependent on the number of tissues affected, as well as the type and distribution of epigenetic modifications. The combination of genetic association maps studies with epigenome-wide developmental studies may help identify novel molecular mechanisms to explain features of inheritance of personality traits and transform our understanding of the biological basis of psychology. Importantly, these epigenetic studies may lead to identification of novel therapeutic targets and enable the development of improved strategies for early diagnosis, prevention, and better treatment of psychological and behavioral disorders.

Discussion Questions

1. Describe the physical state of the genome when genes are active and inactive.
2. Often, the physical characteristics of genetically identical twins become increasingly different as they age, even at the molecular level. Explain why this is so (use the terms “environment” and “epigenome”).
3. Name 3–4 environmental factors that influence the epigenome and describe their effects.
4. The rat nurturing example shows us how parental behavior can shape the behavior of offspring on a biochemical level. Discuss how this relates to humans and include the personal and social implications.
5. Explain how the food we eat affects gene expression.
6. Can the diets of parents affect their offspring’s epigenome?
7. Why is converging evidence the best kind of evidence in the study of brain function?
8. If you were interested in whether a particular brain area was involved in a specific behavior, what neuroscience methods could you use?
9. If you were interested in the precise time in which a particular brain process occurred, which neuroscience methods could you use?

Vocabulary (click on each word to reveal the definition)

DNA methylation
Covalent modifications of mammalian DNA occurring via the methylation of cytosine, typically in the context of the CpG dinucleotide.

DNA methyltransferases (DNMTs)
Enzymes that establish and maintain DNA methylation using methyl-group donor compounds or cofactors. The main mammalian DNMTs are DNMT1, which maintains methylation state across DNA replication, and DNMT3a and DNMT3b, which perform de novo methylation.

Epigenetics
The study of heritable changes in gene expression or cellular phenotype caused by mechanisms other than changes in the underlying DNA sequence. Epigenetic marks include covalent DNA modifications and posttranslational histone modifications.

Epigenome
The genome-wide distribution of epigenetic marks.

Gene
A specific deoxyribonucleic acid (DNA) sequence that codes for a specific polypeptide or protein or an observable inherited trait.

Genome-wide association study (GWAS)
A study that maps DNA polymorphisms in affected individuals and controls matched for age, sex, and ethnic background with the aim of identifying causal genetic variants.

Genotype
The DNA content of a cell’s nucleus, whether a trait is externally observable or not.

Histone acetyltransferases (HATs) and histone deacetylases (HDACs)
HATs are enzymes that transfer acetyl groups to specific positions on histone tails, promoting an “open” chromatin state and transcriptional activation. HDACs remove these acetyl groups, resulting in a “closed” chromatin state and

transcriptional repression.

Histone modifications
: Posttranslational modifications of the N-terminal “tails” of histone proteins that serve as a major mode of epigenetic regulation. These modifications include acetylation, phosphorylation, methylation, sumoylation, ubiquitination, and ADP-ribosylation.

Identical twins
: Two individual organisms that originated from the same zygote and therefore are genetically identical or very similar. The epigenetic profiling of identical twins discordant for disease is a unique experimental design as it eliminates the DNA sequence-, age-, and sex-differences from consideration.

Phenotype
: The pattern of expression of the genotype or the magnitude or extent to which it is observably expressed—an observable characteristic or trait of an organism, such as its morphology, development, biochemical or physiological properties, or behavior.

3.4.8: Human Genetics

Learning Objectives

1. Explain the basic principles of the theory of evolution by natural selection.
2. Discuss evolutionary psychology and behavior genetics.
3. Describe the difference between genotype and phenotype.
4. Explain the structure and function of codons in protein synthesis.
5. Describe transcription and translation and the roles of DNA, mRNA, and tRNA in protein synthesis.
6. Describe types of inheritance.
7. Discuss examples of genetic diseases and their patterns of inheritance.
8. Describe non-heritable genetic disorders and give examples.

Overview

Psychological researchers study genetics in order to better understand the biological basis that contributes to certain behaviors. While all humans share certain biological mechanisms, we are each unique. And while our bodies have many of the same parts—brains and hormones and cells with genetic codes—these are expressed in a wide variety of behaviors, thoughts, and reactions.

Why do two people infected by the same disease have different outcomes: one surviving and one succumbing to the ailment? How are genetic diseases passed through family lines? Are there genetic components to psychological disorders, such as depression or schizophrenia? To what extent might there be a psychological basis to health conditions such as childhood obesity?

To explore these questions, let's start by focusing on a specific disease, sickle-cell anemia, and how it might affect two infected sisters. Sickle-cell anemia is a genetic condition in which red blood cells, which are normally round, take on a crescent-like shape. The changed shape of these cells affects how they function: sickle-shaped cells can clog blood vessels and block blood flow, leading to high fever, severe pain, swelling, and tissue damage.

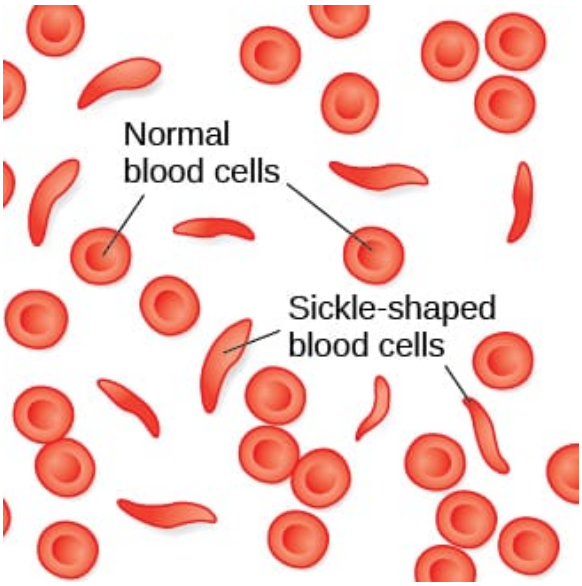

Figure 3.4.8.1: Normal blood cells travel freely through the blood vessels, while sickle-shaped cells form blockages preventing blood flow.

Many people with sickle-cell anemia—and the particular genetic mutation that causes it—die at an early age. While the notion of "survival of the fittest" may suggest that people suffering from this disease have a low survival rate and therefore the disease will become less common, this is not the case. Despite the negative evolutionary effects associated with this genetic mutation, the sickle-cell gene remains relatively common among people of African descent. Why is this? The explanation is illustrated with the

following scenario.

Imagine two young women—Luwi and Sena—sisters in rural Zambia, Africa. Luwi carries the gene for sickle-cell anemia; Sena does not carry the gene. Sickle-cell carriers have one copy of the sickle-cell gene but do not have full-blown sickle-cell anemia. They experience symptoms only if they are severely dehydrated or are deprived of oxygen (as in mountain climbing). Carriers are thought to be immune from malaria (an often deadly disease that is widespread in tropical climates) because changes in their blood chemistry and immune functioning prevent the malaria parasite from having its effects (Gong, Parikh, Rosenthal, & Greenhouse, 2013). However, full-blown sickle-cell anemia, with two copies of the sickle-cell gene, does not provide immunity to malaria.

While walking home from school, both sisters are bitten by mosquitos carrying the malaria parasite. Luwi does not get malaria because she carries the sickle-cell mutation. Sena, on the other hand, develops malaria and dies just two weeks later. Luwi survives and eventually has children, to whom she may pass on the sickle-cell mutation.

Malaria is rare in the United States, so the sickle-cell gene benefits nobody: the gene manifests primarily in health problems—minor in carriers, severe in the full-blown disease—with no health benefits for carriers. However, the situation is quite different in other parts of the world. In parts of Africa where malaria is prevalent, having the sickle-cell mutation does provide health benefits for carriers (protection from malaria).

This is precisely the situation that Charles Darwin describes in the theory of evolution by natural selection. In simple terms, the theory states that organisms that are better suited for their environment will survive and reproduce, while those that are poorly suited for their environment will die off. In our example, we can see that as a carrier, Luwi's mutation is highly adaptive in her African homeland; however, if she resided in the United States (where malaria is much less common), her mutation could prove costly—with a high probability of the disease in her descendants and minor health problems of her own.

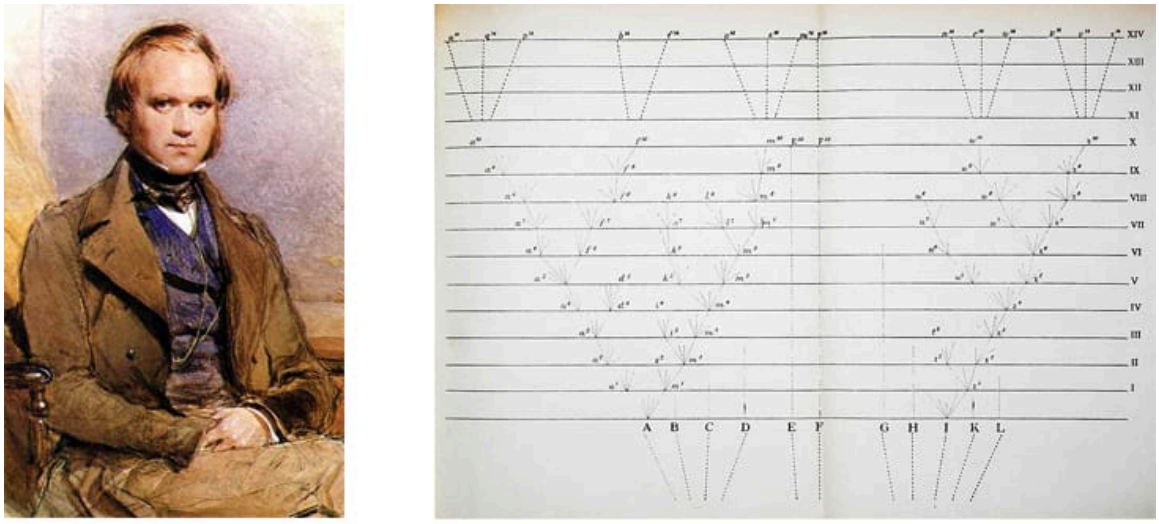

Figure 3.4.8.2: (a) In 1859, Charles Darwin proposed his theory of evolution by natural selection in his book, *On the Origin of Species*. (b) The book contains just one illustration: this diagram that shows how species evolve over time through natural selection.

Two Perspectives on Genetics and Behavior

It's easy to get confused about two fields that study the interaction of genes and the environment, such as the fields of **evolutionary psychology** and **behavioral genetics**. How can we tell them apart?

In both fields, it is understood that genes not only code for particular traits, but also contribute to certain patterns of cognition and behavior. Evolutionary psychology focuses on how universal patterns of behavior and cognitive processes have evolved over time. Therefore, variations in cognition and behavior would make individuals more or less successful in reproducing and passing those genes to their offspring. Evolutionary psychologists study a variety of psychological phenomena that may have evolved as adaptations, including fear response, food preferences, mate selection, and cooperative behaviors (Confer et al., 2010).

Whereas evolutionary psychologists focus on universal patterns that evolved over millions of years, behavioral geneticists study how individual differences arise, in the present, through the interaction of genes and the environment. When studying human behavior, behavioral geneticists often employ twin and adoption studies to research questions of interest. Twin studies compare the rates that a given behavioral trait is shared among identical and fraternal twins; adoption studies compare those rates among biologically related relatives and adopted relatives. Both approaches provide some insight into the relative importance of genes and environment for the expression of a given trait.

Watch this interview with renowned **evolutionary psychologist** Davis Buss for an explanation of how a psychologist approaches evolution and how this approach fits within the field of social science.

Chromosomes, Genes, and Genetic Variation

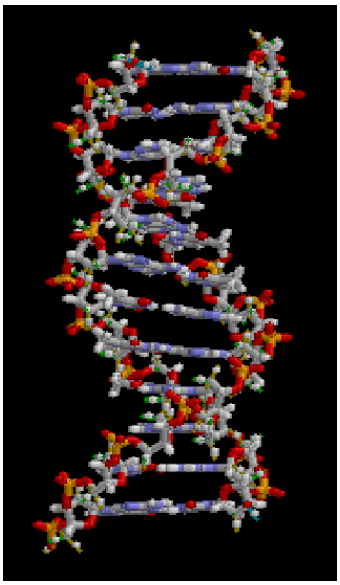
Genetics is the science of the way traits are passed from parent to offspring. For all forms of life, continuity of the species depends upon the genetic code being passed from parent to offspring. Evolution by natural selection is dependent on traits being heritable. Genetics is very important in human physiology because all attributes of the human body are affected by a person's genetic code. It can be as simple as eye color, height, or hair color. Or it can be as complex as how well your liver processes toxins, whether you will be prone to heart disease or breast cancer, and whether you will be color blind. Defects in the genetic code can be tragic. For example: Down Syndrome, Turner Syndrome, and Klinefelter's Syndrome are diseases caused by chromosomal abnormalities. Cystic fibrosis is caused by a single change in the genetic sequence.

Genetic inheritance begins at the time of conception. You inherited 23 chromosomes from your mother and 23 from your father. Together they form 22 pairs of autosomal chromosomes and a pair of sex chromosomes (either XX if you are female, or XY if you are male). Homologous chromosomes have the same genes in the same positions, but may have different alleles (varieties) of those genes. There can be many alleles of a gene within a population, but an individual within that population only has two copies, and can be homozygous (both copies the same) or heterozygous (the two copies are different) for any given gene. The sequence of the human genome (approximately 3 billion base pairs in a human haploid genome with an estimated 20,000-25,000 protein-coding genes) was completed in 2003, but we are far from understanding the functions and regulations of all the genes.

Deoxyribonucleic acid (DNA) is the macromolecule that stores the information necessary to build structural and functional cellular components. It has a double-helix structure (see figure below) in which two strands wrap around one another. Stretched end-to-end, the DNA molecules in a single human cell would come to a **length of about 2 meters**. Thus, the DNA for a cell must be packaged in a very ordered way to fit and function within the cell. To fit their DNA inside the nucleus, DNA is wrapped around proteins known as histones.

DNA has three types of chemical component: phosphate, a sugar called deoxyribose, and four bases—**adenine, guanine, cytosine, and thymine**. Groups of three bases, known as **base triplets**, or **codons**, are the basic coding unit. **Each base triplet** (also known as a **codon**) **codes for a specific amino acid**. **Proteins** are composed of **strings of amino acids.**

DNA provides the basis for inheritance when DNA is passed from parent to offspring. A **gene** is a segment of DNA that codes for the synthesis of a protein and acts as a unit of inheritance that can be transmitted from generation to generation. The external appearance (***phenotype***) of an organism is determined to a large extent by the genes it inherits (***genotype***). Thus, one can begin to see how variation at the DNA level can cause variation at the level of the entire organism. These concepts form the basis of **genetics** and **evolutionary theory**. Genetic variation in a species provides the raw material, the genetic variants, for natural selection to operate upon thereby creating evolutionary change.



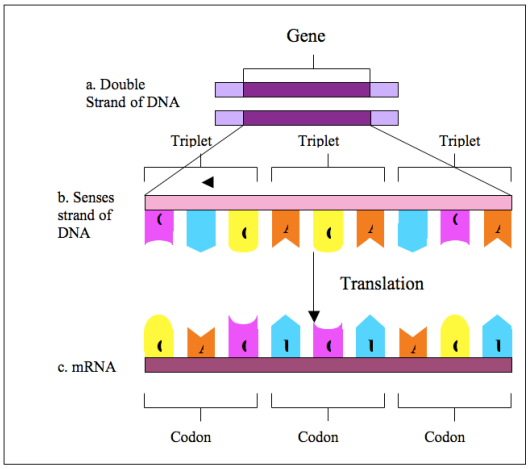


Figure 3.4.8.3: Rotating animation of a DNA molecule, showing its double-helix structure in which two strands of nucleotides wind around each other in a spiral shape (Image from Wikimedia Commons; File:DNA animation.gif; https://commons.wikimedia.org/wiki/F..._animation.gif; by brian0918&#153. This work has been released into the **public domain** by its author, **brian0918**. This applies worldwide. Caption by Kenneth A. Koenigshofer, Ph.D., Chaffey College).

A **gene** is made up of short sections of DNA which are contained on a chromosome within the nucleus of a cell. Genes control the development and function of all organs and all working systems in the body. A gene has a certain influence on how the cell works; the same gene in many different cells determines a certain physical or biochemical feature of the whole body (e.g. eye color or reproductive functions). All human cells hold approximately 20,000-30,000 different protein-coding genes.

a. genes are portions of DNA that code for a particular protein.
b. Triplets, the three-base sequences code for amino acid sequences.
c. Transcribed mRNA codons, which are complementary to the code in DNA triplets.

Figure 3.4.8.4: Genes, codons, and transcription (the process of making RNA) and translation (the synthesis of the protein on the ribosome as the mRNA moves across the ribosome). Also see Figures 3.13.5 and 3.13.6 and text for additional details. (Image from Wikibooks; Human Physiology/Genetics and inheritance; https://en.wikibooks.org/wiki/Human_...nheritance#DNA; under the Creative Commons Attribution-ShareAlike License).

Even though each cell has identical copies of all of the same genes, different cells express or repress different genes. This is what accounts for the differences between, let's say, a liver cell and a brain cell. **Genotype** is the actual pair of genes that a person has for a trait of interest. For example, a woman could be a carrier for hemophilia by having one normal copy of the gene for a particular clotting protein and one defective copy. A **Phenotype** is the organism's physical appearance or functioning as it relates

to a certain trait. In the case of the woman carrier, her phenotype is normal (because the normal copy of the gene is dominant to the defective copy). The phenotype can be for any measurable trait, such as eye color, finger length, height, physiological traits like the ability to pump calcium ions from mucosal cells, behavioral traits like smiles, and biochemical traits like blood types and cholesterol levels. Genotype cannot always be predicted by phenotype (we would not know the woman was a carrier of hemophilia just based on her appearance), but can be determined through pedigree charts or direct genetic testing. Even though genotype is a strong predictor of phenotype, environmental factors can also play a strong role in determining phenotype. Identical twins, for example, are genetic clones resulting from the early splitting of an embryo, but they can be quite different in personality, body mass, and even fingerprints.

Genes encode the information necessary for synthesizing the amino-acid sequences in proteins, which in turn play a large role in determining the final phenotype, or physical appearance and functioning of the organism. In **diploid** organisms (organisms that have paired chromosomes, one from each parent), a dominant allele on one chromosome will mask the expression of a recessive allele on the other. While most genes are dominant/recessive, others may be codominant or show different patterns of expression. The phrase "to code for" is often used to mean a gene contains the instructions about a particular protein, (as in the gene codes for the protein). The "one gene, one protein" concept is now known to be the simplistic. For example, a single gene may produce multiple products, depending on how its transcription is regulated. Genes code for the nucleotide sequence in **messenger RNA** (mRNA) and **transfer RNA** (rRNA), required for protein synthesis (see Figure 3.13.5 below).

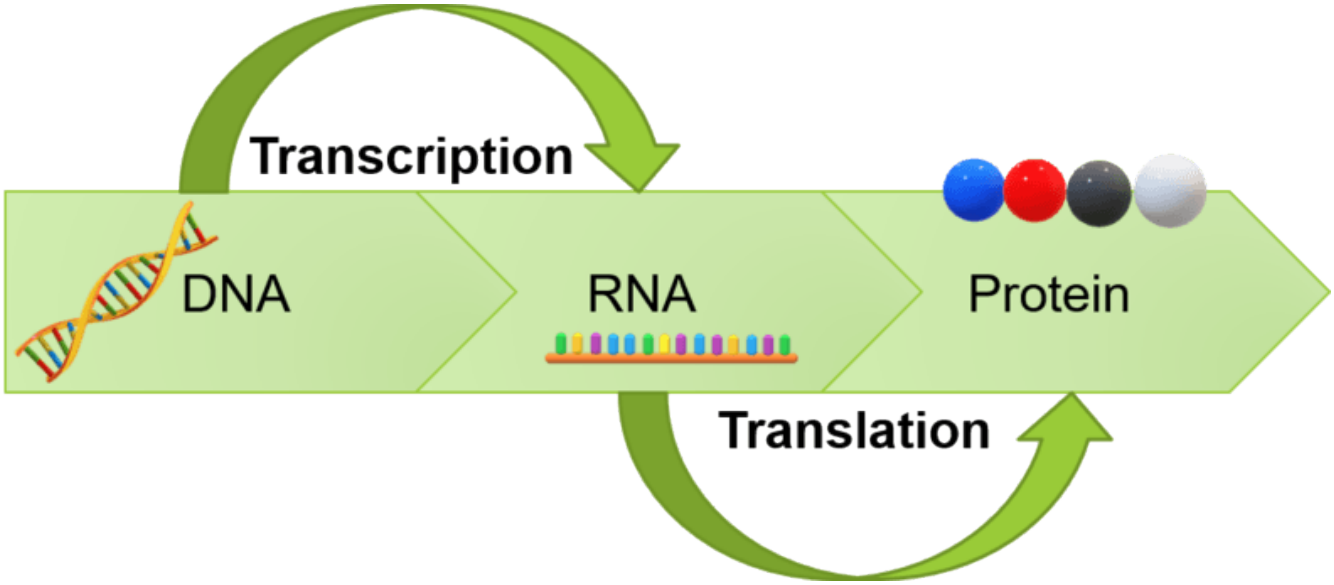

Figure 3.4.8.5: Transcription (information transcribed from DNA to RNA) and Translation (messenger RNA to protein synthesis on the ribosome). (Image from Wikimedia Commons; File:Transcription and Translation.png; https://commons.wikimedia.org/wiki/F...ranslation.png; by Christinelmiller; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

DNA must be “read” to produce the molecules, such as proteins, to carry out the functions of the cell. This "reading" of information in DNA involves two related processes--transcription and translation. **Transcription** is the process of making RNA (ribonucleic acid) directed by information in DNA. RNA is in all cells and like DNA is composed of nucleotides. RNA nucleotides contain the bases adenine, cytosine, and guanine. However, they do **not contain thymine**, which is instead **replaced by uracil**, symbolized by a “U.” RNA exists as a single-stranded molecule rather than a double-stranded helix like that of DNA. There are several kinds of RNA, named on the basis of their function. As mentioned above, these include messenger RNA (mRNA), transfer RNA (tRNA), and ribosomal RNA (rRNA)—molecules that are involved in the production of proteins from the DNA code. **Translation** is the synthesis of the protein on the **ribosome** as the messenger RNA (mRNA) moves across the ribosome. Ribosomes are macromolecular machines, found within all living cells, that perform biological protein synthesis.

As noted, the gene is a segment of DNA which contains the information for making a protein. In response to an enzyme RNA polymerase breaks the hydrogen bonds of the gene. As it breaks the hydrogen bonds it begins to move down the gene. Next the RNA polymerase will line up the nucleotides so they are complementary. **Transcription occurs in** the **nucleus**, and once transcription is completed the **messenger RNA (mRNA) will leave** the **nucleus, and go into the cytoplasm where** the **mRNA will bind to** a free floating **ribosome. mRNA carries the protein blueprint from a cell's DNA to its ribosomes**, which are **the "machines" that drive protein synthesis. Transfer RNA (tRNA) carries** the appropriate **amino acids into** the **ribosome for inclusion in the new protein. Ribosomes link amino acids together in** the **order specified by the codons (base triplets)**

of messenger RNA molecules to form polypeptide chains. **The mRNA base sequence determines the order of assembling of the amino acids to form specific proteins.**

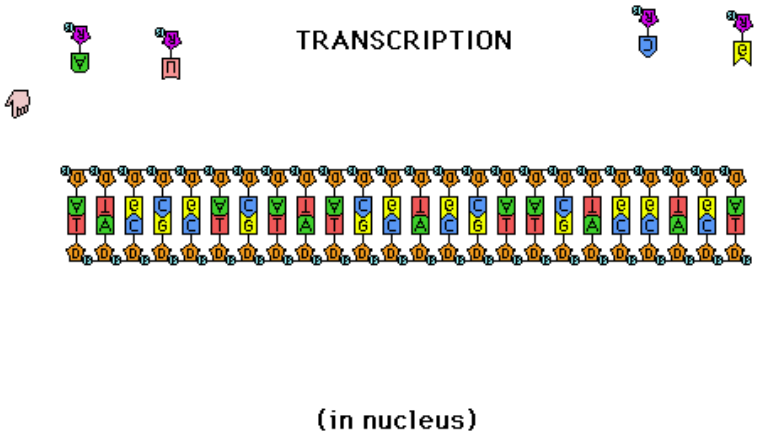

Figure 3.4.8.6: This file represents the transcription of a gene into messenger RNA, followed by the translation of mRNA into a polypeptide. Inherited information from DNA is transcribed to mRNA in the nucleus, then mRNA moves to the cytoplasm, tRNA brings amino acids, small ribosomal unit, including rRNA, attaches to mRNA which assembles polypeptides in synthesis of specific protein; finally, ribosome detaches from mRNA. (Image from Wikimedia Commons; File:DNA Transcription and Translation.gif; https://commons.wikimedia.org/wiki/F...ranslation.gif; by Steven Kuensting; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

Inheritance

A person's cells hold the exact genes that originated from the sperm and egg of his parents at the time of conception. The genes of a cell are formed into long strands of DNA. Most of the genes that control characteristic are in pairs, one gene from mom and one gene from dad. Everybody has 22 pairs of chromosomes (*autosomes*) and two more genes called sex-linked chromosomes. Females have two X (XX) chromosomes and males have an X and a Y (XY) chromosome. Inherited traits and disorders can be divided into three categories: **unifactorial inheritance, sex-linked inheritance, and multifactor inheritance.**

Unifactorial Inheritance

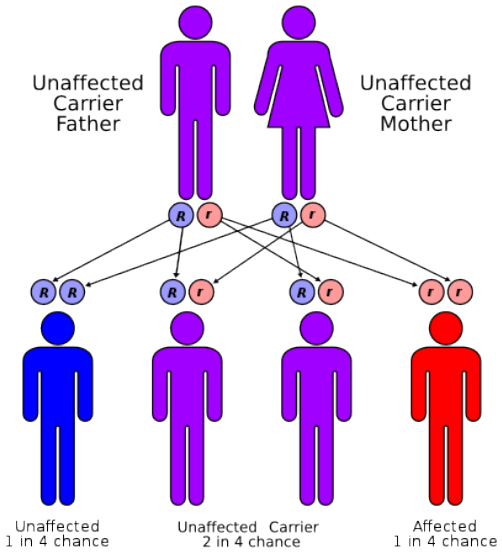

Figure 3.4.8.7: Chart showing the possibilities of contracting a recessive defect, from two carrier parents.

Traits such as blood type, eye color, hair color, and taste are each thought to be controlled by a single pair of genes. The Austrian monk Gregor Mendel was the first to discover this phenomenon, and it is now referred to as *the laws of Mendelian inheritance*. The genes deciding a single trait may have several forms (*alleles*). For example, the gene responsible for hair color has two main alleles: red and brown. The four possibilities are thus

Brown/red, which would result in brown hair,
Red/red, resulting in red hair,
Brown/brown, resulting in brown hair, or
Red/brown, resulting in red hair.

The genetic codes for red and brown can be either dominant or recessive. In any case, the dominant gene overrides the recessive.

When two people create a child, they each supply their own set of genes. In simplistic cases, such as the red/brown hair, each parent supplies one "code", contributing to the child's hair color. For example, if dad has brown/red he has a 50% chance of passing brown hair to his child and a 50% of passing red hair. When combined with a mom who has brown/brown (who would supply 100% brown), the child has a 75% chance of having brown hair and a 25% chance of having red hair. Similar rules apply to different traits and characteristics, though they are usually far more complex.

Multifactorial inheritance

Some traits are found to be determined by genes and environmental effects. Height for example seems to be controlled by multiple genes, some are "tall" genes and some are "short" genes. A child may inherit all the "tall" genes from both parents and will end up taller than both parents. Or the child my inherit all the "short" genes and be the shortest in the family. More often than not the child inherits both "tall" and "short" genes and ends up about the same height as the rest of the family. Good diet and exercise can help a person with "short" genes end up attaining an average height. Babies born with drug addiction or alcohol addiction are a sad example of environmental inheritance. When mom is doing drugs or drinking, everything that she takes the baby takes. These babies often have developmental problems and learning disabilities. A baby born with *Fetal alcohol syndrome* is usually abnormally short, has small eyes and a small jaw, may have heart defects, a cleft lip and palate, may suck poorly, sleep poorly, and be irritable. About one fifth of the babies born with fetal alcohol syndrome die within the first weeks of life, those that live are often mentally and physically handicapped.

Sex-linked Inheritance

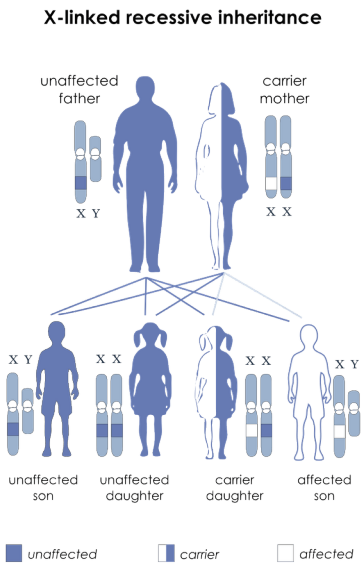

Figure 3.4.8.8: X-linked recessive inheritance.

Sex-linked inheritance is quite obvious, it determines your gender. Male gender is caused by the Y chromosome which is only found in males and is inherited from their fathers. The genes on the Y chromosomes direct the development of the male sex organs. The x chromosome is not as closely related to the female sex because it is contained in both males and females. Males have a single X and females have double XX. The X chromosome is to regulate regular development and it seems that the Y is added just for the male genitalia. When there is a default with the X chromosomes in males it is almost always persistent because there is not the extra X chromosome that females have to counteract the problem. Certain traits like colorblindness and hemophilia are on alleles carried on the X chromosome. For example if a woman is colorblind all of her sons will be colorblind. Whereas all of her daughters will be carriers for colorblindness.

Exceptions to simple inheritance

Our knowledge of the mechanisms of genetic inheritance has grown a lot since Mendel's time. It is now understood, that if you inherit one allele, it can sometimes increase the chance of inheriting another and can affect when or how a trait is expressed in an individuals phenotype. There are levels of dominance and recessiveness with some traits. Mendel's simple rules of inheritance does not always apply in these exceptions.

Polygenic Traits

Polygenic traits are traits determined by the combined effect of more than one pair of genes. Human stature is an example of this trait. The size of all body parts from head to foot combined determines height. The size of each individual body part are determined by numerous genes. Human skin, eyes, and hair are also polygenic genes because they are determined by more than one allele at a different location.

Intermediate Expressions

When there is incomplete dominance, blending can occur resulting in heterozygous individuals. An example of intermediate expression is the pitch of a human male voice. Homozygous men have the lowest and highest voice for this trait (AA and aa). Tay-Sachs, causing death in childhood, is also characterized by incomplete dominance.

Co-dominance

For some traits, two alleles can be co-dominant. Were both alleles are expressed in heterozygous individuals. An example of that

would be a person with AB blood. These people have the characteristics of both A and B blood types when tested.

Multiple-Allele Series

There are some traits that are controlled by far more alleles. For example, the human HLA system, which is responsible for accepting or rejecting foreign tissue in our bodies, can have as many as 30,000,000 different genotypes! The HLA system is what causes the rejection of organ transplants. The multiple allele series is very common, as geneticists learn more about genetics, they realize that it is more common than the simple two allele ones.

Modifying and Regulator Genes

Modifying and regulator genes are the two classes of genes that may have an effect on how the other genes function. *Modifying Genes* alter how other genes are expressed in the phenotype. For example, a dominant cataracts gene may impair vision at various degrees, depending on the presence of a specific allele for a companion modifying gene. However, cataracts can also come from excessive exposure to ultraviolet rays and diabetes. *Regulator Genes* also known as homoerotic genes, can either initiate or block the expression of other genes. They also control a variety of chemicals in plants and animals. For example, Regulator genes control the time of production of certain proteins that will be new structural parts of our bodies. Regulator genes also work as a master switch starting the development of our body parts right after conception and are also responsible for the changes in our bodies as we get older. They control the aging processes and maturation.

Incomplete penetrates

Some genes are incomplete penetrate, which means, unless some environmental factors are present, the effect does not occur. For example, you can inherit the gene for diabetes, but never get the disease, unless you were greatly stressed, extremely overweight, or didn't get enough sleep at night. These interactions between genotype and environment fall under the category of epigenetics to be discussed in more detail later in this chapter.

Genetic Diseases and Patterns of Inheritance

Inheritance pattern	Description	Examples
Autosomal dominant	Only one mutated copy of the gene is needed for a person to be affected by an autosomal dominant disorder. Each affected person usually has one affected parent. There is a 50% chance that a child will inherit the mutated gene. Many disease conditions that are autosomal dominant have low penetrance, which means that although only one mutated copy is needed, a relatively small proportion of those who inherit that mutation go on to develop the disease, often later in life.	Huntingtons disease, Neurofibromatosis 1, HBOC syndrome, Hereditary nonpolyposis colorectal cancer
Autosomal recessive	Two copies of the gene must be mutated for a person to be affected by an autosomal recessive disorder. An affected person usually has unaffected parents who each carry a single copy of the mutated gene (and are referred to as carriers). Two unaffected people who each carry one copy of the mutated gene have a 25% chance with each pregnancy of having a child affected by the disorder.	Cystic fibrosis, Sickle cell anemia, Tay-Sachs disease, Spinal muscular atrophy, Muscular dystrophy
X-linked dominant	X-linked dominant disorders are caused by mutations in genes on the X chromosome. Only a few disorders have this inheritance pattern. Females are more frequently affected than males, and the chance of passing on an X-linked dominant disorder differs between men and women. The sons of a man with an X-linked dominant disorder will not be affected, and his daughters will all inherit the condition. A woman with an X-linked dominant disorder has a 50% chance of having an affected daughter or son with each pregnancy. Some X-linked dominant conditions, such as Aicardi Syndrome, are fatal to boys, therefore only girls have them (and boys with Klinefelter Syndrome).	Hypophosphatemia, Aicardi Syndrome

X-linked recessive	X-linked recessive disorders are also caused by mutations in genes on the X chromosome. Males are more frequently affected than females, and the chance of passing on the disorder differs between men and women. The sons of a man with an X-linked recessive disorder will not be affected, and his daughters will carry one copy of the mutated gene. With each pregnancy, a woman who carries an X-linked recessive disorder has a 50% chance of having sons who are affected and a 50% chance of having daughters who carry one copy of the mutated gene.	Hemophilia A, Duchenne muscular dystrophy, Color blindness, Turner Syndrome
Y-linked	Y-linked disorders are caused by mutations on the Y chromosome. Only males can get them, and all of the sons of an affected father are affected. Since the Y chromosome is very small, Y-linked disorders only cause infertility, and may be circumvented with the help of some fertility treatments.	Male Infertility
Mitochondrial	This type of inheritance, also known as maternal inheritance, applies to genes in mitochondrial DNA. Because only egg cells contribute mitochondria to the developing embryo, only females can pass on mitochondrial conditions to their children.	Leber's Hereditary Optic Neuropathy (LHON)

Table 3.13.1. Genetic Diseases (above).

Non-heritable Genetic Disorders

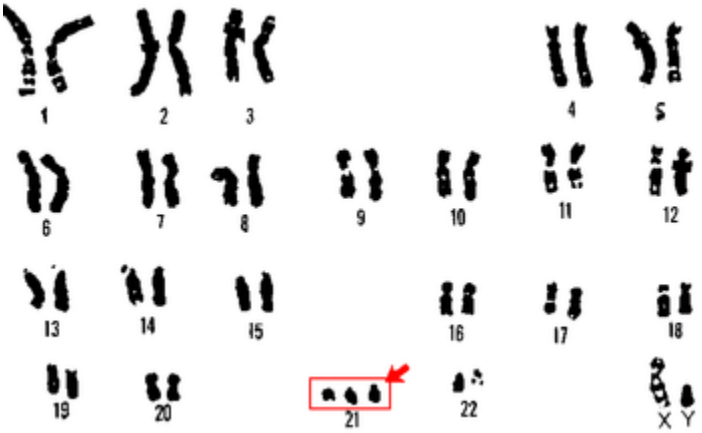

Figure 3.4.8.9: Karyotype of 21 trisomy-Down syndrome.

Any disorder caused totally or in part by a fault (or faults) of the genetic material passed from parent to child is considered a genetic disorder. The genes for many of these disorders are passed from one generation to the next, and children born with a heritable genetic disorder often have one or more extended family members with the same disorder. There are also genetic disorders that appear due to spontaneous faults in the genetic material, in which case a child is born with a disorder with no apparent family history.

Down Syndrome, also known as Trisomy 21, is a chromosome abnormality that effects one out of every 800-1000 newborn babies. During anaphase II of meiosis the sister chromatids of chromosome 21 fail to separate, resulting in an egg with an extra chromosome, and a fetus with three copies (trisomy) of this chromosome. At birth this defect is recognizable because of the physical features such as almond shaped eyes, a flattened face, and less muscle tone than a normal newborn baby. During pregnancy, it is possible to detect the Down Syndrome defect by doing amniocentesis testing. There is a risk to the unborn baby and it is not recommended unless the pregnant mother is over the age of thirty-five. Other non-lethal chromosomal abnormalities include additional osex chromosome abnormalities which is when a baby girl (about 1 in 2,500)is born with one x instead of two (xx) this can cause physical abnormalities and defective reproduction systems. Boys can also be born with extra X's (XXY or XXXY) which will cause reproductive problems and sometimes mental retardation.

Chromosomal Abnormalities In most cases with a chromosomal abnormality all the cells are affected. Defects can have anywhere from little effect to a lethal effect depending on the type of abnormality. Of the 1 in 200 babies born having some sort of chromosomal abnormality, about 1/3 of these results in spontaneous abortion. Abnormalities usually form shortly after fertilization and mom or dad usually has the same abnormality. There is no cure for these abnormalities. Tests are possible early in pregnancy

and if a problem is detected the parents can choose to abort the fetus.

Genetics (from the Greek *genno* = give birth) is the science of genes, heredity, and the variation of organisms.

Genetic variation, the genetic difference between individuals, is what contributes to a species' adaptation to its environment by providing genetic alternatives that natural selection can "pick" from to achieve improved adaptation over generations by evolution. In humans, genetic variation begins with an egg, about 100 million sperm, and fertilization. Fertile women ovulate roughly once per month, releasing an egg from follicles in the ovary. The egg travels, via the fallopian tube, from the ovary to the uterus, where it may be fertilized by a sperm.

The egg and the sperm each contain 23 chromosomes. **Chromosomes** are long strings of genetic material, deoxyribonucleic acid (DNA). DNA is a helix-shaped molecule made up of nucleotide base pairs. In each chromosome, sequences of DNA make up **genes** that control or partially control a number of visible characteristics, known as traits, such as eye color, hair color, and so on. A single gene may have multiple possible variations, or alleles. An allele is a specific version of a gene. So, a given gene may code for the trait of hair color, and the different alleles of that gene affect which hair color an individual has.

When a sperm and egg fuse, their 23 chromosomes pair up and create a zygote with 23 pairs of chromosomes. Therefore, each parent contributes half the genetic information carried by the offspring; the resulting physical characteristics of the offspring (called the phenotype) are determined by the interaction of genetic material supplied by the parents (called the genotype). A person's genotype is the genetic makeup of that individual. **Phenotype**, on the other hand, refers to the individual's inherited physical characteristics.

Figure 3.4.8.10: (a) Genotype refers to the genetic makeup of an individual based on the genetic material (DNA) inherited from one's parents. (b) Phenotype describes an individual's observable characteristics, such as hair color, skin color, height, and build. (credit a: modification of work by Caroline Davis; credit b: modification of work by Cory Zanker)

Most traits are controlled by multiple genes, but some traits are controlled by one gene. A characteristic like cleft chin, for example, is influenced by a single gene from each parent. In this example, we will call the gene for cleft chin "B," and the gene for smooth chin "b." Cleft chin is a dominant trait, which means that having the dominant allele either from one parent (Bb) or both parents (BB) will always result in the phenotype associated with the dominant allele. When someone has two copies of the same allele, they are said to be homozygous for that allele. When someone has a combination of alleles for a given gene, they are said to be heterozygous. For example, smooth chin is a recessive trait, which means that an individual will only display the smooth chin phenotype if they are homozygous for that recessive allele (bb).

Imagine that a woman with a cleft chin mates with a man with a smooth chin. What type of chin will their child have? The answer to that depends on which alleles each parent carries. If the woman is homozygous for cleft chin (BB), her offspring will always have cleft chin. It gets a little more complicated, however, if the mother is heterozygous for this gene (Bb). Since the father has a smooth chin—therefore homozygous for the recessive allele (bb)—we can expect the offspring to have a 50% chance of having a cleft chin and a 50% chance of having a smooth chin.

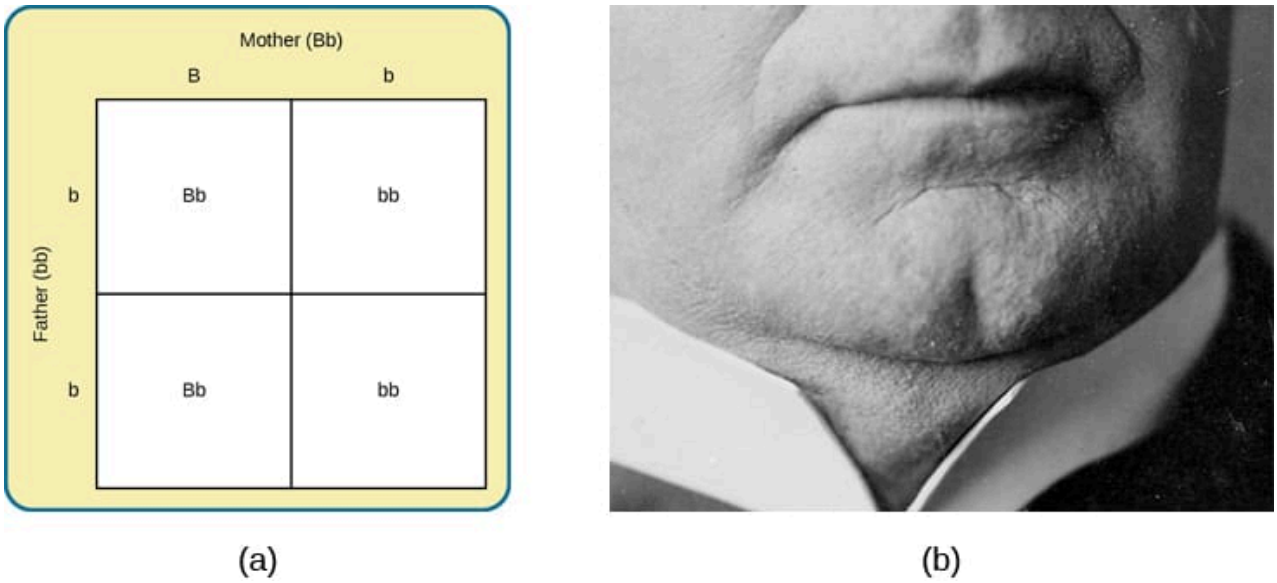

Figure 3.4.8.11: (a) A **Punnett square** is a tool used to predict how genes will interact in the production of offspring. The capital B represents the dominant allele, and the lowercase b represents the recessive allele. In the example of the cleft chin, where B is cleft chin (dominant allele), wherever a pair contains the dominant allele, B, you can expect a cleft chin phenotype. You can expect a smooth chin phenotype only when there are two copies of the recessive allele, bb. (b) A cleft chin, shown here, is an inherited trait.

Sickle-cell anemia is just one of many genetic disorders caused by the pairing of two recessive genes. For example, **phenylketonuria** (PKU) is a condition in which individuals lack an enzyme that normally converts harmful amino acids into harmless byproducts. If someone with this condition goes untreated, he or she will experience significant deficits in cognitive function, seizures, and increased risk of various psychiatric disorders. Because PKU is a recessive trait, each parent must have at least one copy of the recessive allele in order to produce a child with the condition (Figure (Links to an external site.)).

So far, we have discussed traits that involve just one gene, but few human characteristics are controlled by a single gene. Most traits are polygenic: controlled by more than one gene. Height is one example of a polygenic trait, as are skin color and weight.

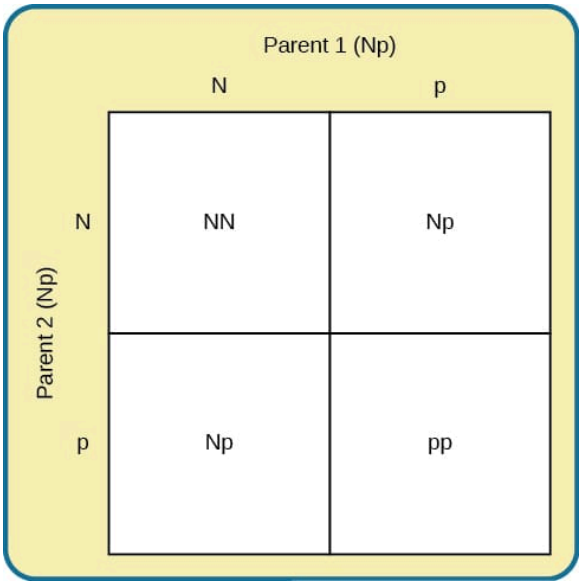

Figure 3.4.8.12: In this **Punnett square**, N represents the normal allele, and p represents the recessive allele that is associated with PKU. If two individuals mate who are both heterozygous for the allele associated with PKU, their offspring have a 25% chance of expressing the PKU phenotype.

Mutant Genes

Mutation is a permanent change in a segment of DNA.

Mutations are changes in the genetic material of the cell. Substances that can cause genetic mutations are called mutagen agents. Mutagen agents can be anything from radiation from x-rays, the sun, toxins in the earth, air, and water viruses. Many gene mutations are completely harmless since they do not change the amino acid sequence of the protein the gene codes for.

Mutations can be good, bad, or indifferent. They can be good for you because their mutation can be better and stronger than the original. They can be bad because it might take away the survival of the organism. However, most of the time, they are indifferent because the mutation is no different than the original.

The not so harmless ones can lead to cancer, birth defects, and inherited diseases. Mutations usually happen at the time of cell division. When the cell divides, one cell contracts a defect, which is then passed down to each cell as they continue to divide.

Teratogens refers to any environmental agent that causes damage during the prenatal period. Examples of Common Teratogens:

- drugs: prescription, non-prescription, and illegal drugs
- tobacco, alcohol,
- radiation,
- environmental pollution,
- infectious disease,
- STD's,
- Aids,
- Parasites

The sensitive period to teratogen exposure, in the embryonic period, is most vital and most harmful. By contrast, damage from exposure during the fetal stage is typically minor.

Gene mutations provide one source of harmful genes. As noted above, a mutation is a sudden, permanent change in a gene. While many mutations can be harmful or lethal, once in a while, a mutation benefits an individual by giving that person an advantage over those who do not have the mutation. Recall that the theory of evolution asserts that individuals best adapted to their particular environments are more likely to reproduce and pass on their genes to future generations. In order for this process to occur, there must be competition—more technically, there must be variability in genes (and resultant traits) that allow for variation in adaptability to the environment. If a population consisted of identical individuals, then any dramatic changes in the environment would affect everyone in the same way, and there would be no variation in selection, making evolution impossible. In contrast, diversity in genes and associated traits allows some individuals to perform slightly better than others when faced with environmental change. This creates a distinct advantage for individuals best suited for their environments in terms of successful reproduction and genetic transmission, leading to natural selection and evolutionary change.

Summary

Genes are sequences of DNA that code for a particular trait. Different versions of a gene are called alleles—sometimes alleles can be classified as dominant or recessive. A dominant allele always results in the dominant phenotype. In order to exhibit a recessive phenotype, an individual must be homozygous for the recessive allele. Genes affect both physical and psychological characteristics. Ultimately, how and when a gene is expressed, and what the outcome will be—in terms of both physical and psychological characteristics—is a function of the interaction between our genes and our environments.

Review Questions

A(n) _____ is a sudden, permanent change in a sequence of DNA.

1. allele
2. chromosome
3. epigenetic
4. mutation

_____ refers to a person's genetic makeup, while _____ refers to a person's physical characteristics.

1. Phenotype; genotype
2. Genotype; phenotype

3. DNA; gene
4. Gene; DNA

_____ is the field of study that focuses on genes and their expression.

1. Social psychology
2. Evolutionary psychology
3. Epigenetics
4. Behavioral neuroscience

Humans have _____ pairs of chromosomes.

1. 15
2. 23
3. 46
4. 78

Critical Thinking Questions

The theory of evolution by natural selection requires variability of a given trait. Why is variability necessary and where does it come from?

Personal Application Questions

You share half of your genetic makeup with each of your parents, but you are no doubt very different from both of them. Spend a few minutes jotting down the similarities and differences between you and your parents. How do you think your unique environment and experiences have contributed to some of the differences you see?

3.4.9: Genes and Behavior

Learning Objectives

1. Describe the field of behavioral genetics.
2. Define epigenetics.
3. Describe the major ideas that comprise an evolutionary and computational view of the mind.
4. Explain the steps involved in how genes make proteins including how gene expression is regulated.
5. Describe the types of variation in the genetic code.
6. Discuss the ways in which behavior can influence genes.
7. Describe gene-environment interactions.

Overview

Genes, in interaction with the environment, have an enormous influence on the organization of minds and behavior. Each species, with its own unique genetic makeup, has an evolved brain structure and functional organization that determines its innate psychological nature. Human nature is one example, but other species possess their own psychological natures as well, determined by their own brain evolution. Wolves have an innate wolf nature, lions have an innate lion nature, hawks have an innate hawk nature, and so on (Koenigshofer, 2010, 2016). The innate psychological nature of each species is the result of the genes affecting brain organization and function that each species carries in its cells, and the complement of genes that each species possesses is a consequence of the evolutionary history of that species. Behavior genetics studies the effects of genes on behavior and on the information processing operations of the brain, as expressed in behavior. It also investigates the influence of environment and behavior on the expression of genes in the organism--a field called epigenetics (see Module 3.14).

The Influence of Genes on Mind and Behavior

Genetic makeup has a large role in determining human behavior. The influence of genes on behavior has been well established in the scientific community. To a large extent, who we are and how we behave is a result of our genetic makeup. While genes do not strictly determine behavior or our mental processes, they play a huge role in what we do and why we do it.

An Evolutionary and Computational View of the Mind

Since we will be talking not only about behavior, but also about the mind, it is best to talk a little bit about what the mind is. Everyone knows something about what the mind is because we each have a mind and we experience our own mental activities such as conscious awareness of our surroundings, feelings, thoughts, and memories each and every moment of our waking lives. You are using some parts of your mind right now as you read this. So, we know the mind as the collection of our own mental processes and experiences.

But there is another way to think about the mind--as a form of biological adaptation, as a collection of information processing solutions to problems of survival and reproduction that have persisted over much of our evolutionary history as a species. On this evolutionary view, the mind is a collection or bundle of information processing "organs" or "modules" each of which has evolved, over our evolutionary history as a species, to process particular kinds of information from the environment in quite specific ways to help us to survive and reproduce our genes. This is a Darwinian or evolutionary model of what the mind is.

This evolutionary model of the mind makes several assumptions (Cosmides & Tooby, 1997): 1) the mind is brain activity (i.e. the mind is what the brain does), 2) the mind/brain of each species, including the human species, has been constructed to take its present day form as a result of evolution by natural selection in that species (therefore, minds just like bodies differ in some ways from species to species, but also like bodies are also similar across species in some ways), 3) this means that the human mind is "hard wired" in many ways by genetic evolution and thus each individual brain comes "hard wired" by genetic information (genes, DNA) which direct brain development from conception onward, 4) this means that each species has its own genetically evolved psychological nature--applied to humans this means that humans are born with an innate human nature, 5) the mind has many different parts that do many different information processing tasks important to survival and reproduction, especially in

the evolutionary past of each species, 6) different parts of our minds are localized in different parts of our brains or in different circuits in our brains (localization of function), 7) the human brain is not a general purpose learning machine but a collection of specialized information processing organs or modules that collectively create in our heads a workable model of reality that guides our behavior successfully toward effective adaptation to the environment, 8) although learning is important in shaping our minds and behavior, its role is secondary and supplementary compared to the much larger role played by our genes in shaping our innate human nature.

The following quote from Steven Pinker (1997) expresses these ideas eloquently:

"The mind is a system of organs of computation, designed by natural selection to solve the kinds of problems our ancestors faced in their foraging way of life, in particular, understanding and outmaneuvering objects, animals, plants, and other people. [This view] can be unpacked into several claims. The mind is what the brain does; specifically, the brain processes information, and thinking is a kind of computation. The mind is organized into modules or mental organs, each with a specialized design that makes it an expert in one arena of interaction with the world. The modules' basic logic is specified by our genetic program. Their operation was shaped by natural selection to solve the problems of the hunting and gathering life led by our ancestors in most of our evolutionary history. The various problems for our ancestors were sub-tasks of one big problem for their genes, maximizing the number of copies that made it into the next generation."

How Genes Affect Body and Brain

Genes are responsible for producing the proteins that run everything in our bodies. Some proteins are visible, such as the ones that compose our hair and skin. Others work out of sight, coordinating our basic biological functions.

For the most part, every cell in our body contains exactly the same genes, but inside individual cells some genes are active while others are not. When genes are active, they are capable of producing proteins. This process is called gene expression. When genes are inactive, they are silent or inaccessible for protein production.

At least a third of the approximately 20,000 different genes that make up the human genome are active (expressed) primarily in the brain. This is the highest proportion of genes expressed in any part of the body. These genes influence the development and function of the brain, and ultimately control how we move, think, feel, and behave.

From DNA

In order to understand how genes work in the brain, we have to understand how genes make proteins. This begins with DNA (deoxyribonucleic acid).

DNA is a long molecule packaged into structures called chromosomes. Humans have 23 pairs of chromosomes, including a single pair of sex chromosomes (XX in females and XY in males). Within each pair, one chromosome comes from an individual's mother and the other comes from the father. In other words, we inherit half of our DNA from each of our parents.

DNA consists of two strands wound together to form a double helix. Within each strand, chemicals called nucleotides are used as a code for making proteins. DNA contains only four nucleotides – adenine (A), thymine (T), cytosine (C), and guanine (G) – but this simple genetic alphabet is the starting point for making all of the proteins in the human body, estimated to be as many as one million. Coding this many proteins with just 4 "letters" is possible because these "letters" can be combined into long chains in an enormous number of different combinations and sequences.

To Gene

A gene is a stretch of DNA that contains the instructions for making or regulating a specific protein.

Genes that make proteins are called protein-coding genes. In order to make a protein, a molecule closely related to DNA called ribonucleic acid (RNA) first copies the code within DNA. Then, protein-manufacturing machinery within the cell scans the RNA, reading the nucleotides in groups of three. These triplets encode 20 distinct amino acids, which are the building blocks for proteins. The largest known human protein is a muscle protein called titin, which consists of about 27,000 amino acids.

Some genes encode small bits of RNA that are not used to make proteins, but are instead used to tell proteins what to do and where to go. These are called non-coding or RNA genes. There are many more RNA genes than protein-coding genes.

To Protein

Proteins form the internal machinery within brain cells and the connective tissue between brain cells. They also control the chemical reactions that allow brain cells to communicate with each other.

Some genes make proteins that are important for the early development and growth of the infant brain. For example, the ASPM gene makes a protein that is needed for producing new nerve cells (or neurons) in the developing brain. Alterations in this gene can cause microcephaly, a condition in which the brain fails to grow to its normal size.

Certain genes make proteins that in turn make neurotransmitters, which are chemicals that transmit information from one neuron to the next. Other proteins are important for establishing physical connections that link various neurons together in networks.

Still other genes make proteins that act as housekeepers in the brain, keeping neurons and their networks in good working order. Harmful mutations in these genes can cause some neurological diseases such as amytrophic lateral sclerosis (ALS, Lou Gehrig's Disease).

How Gene Expression Is Regulated

We know which protein a gene will make by looking at its code, also called its DNA sequence. What we cannot predict is the amount of protein that will be made, when it will be made, or what cell will make it.

Each cell turns on only a fraction of its genes, while it silences the rest. For example, genes that are expressed in brain cells may be silenced in liver cells or heart cells. Some genes are only turned on during the early months of human development and then are silenced later.

What determines these unique patterns of gene expression? Like people, cells have a unique lineage, and they tend to inherit traits from their parents. So, a cell's origins influence the genes it turns on to make proteins. The cell's environment – its exposure to surrounding cells and to hormones and other signals – also helps determine which proteins the cell makes. These cues from a cell's past and from its environment act through many regulatory factors inside the cell, some of which are described in the following sections.

DNA Binding Proteins
About 10 percent of the genes in the human genome encode DNA binding proteins. Some of these proteins recognize and attach to specific bits of DNA to activate gene expression. Another type of DNA binding protein, called a histone, acts as a spool that can keep DNA in tight coils and thus suppress gene expression.

sRNA
Scattered throughout the genome are many types of small RNA (sRNA) that actively regulate gene expression. Because of their short length, they are able to target, match, and deactivate small bits of genetic code.

Epigenetic Factors
The word epigenetics comes from the Greek word epi, meaning above or beside. In a broad sense, epigenetics refers to long-lasting changes in gene expression without any changes to the genetic code. Epigenetic factors include chemical marks or tags on DNA or on histones that can affect gene expression. We shall discuss more about epigenetics later in this chapter.

Variations In Genetic Code

A genetic variation is a permanent change in the DNA sequence that makes up a gene. Most variations are harmless or have no effect at all. However, other variations can have harmful effects leading to disease. Still others can be beneficial in the long run, helping a species adapt to change.

Single Nucleotide Polymorphism (SNP)
SNPs are variations that involve a change in just one nucleotide. It is estimated that the human genome contains more than 10 million different SNPs. Because SNPs are such small changes within DNA, most of them have no effect upon gene expression. Some SNPs, however, are responsible for giving us unique traits, such as our hair and eye color. Other SNPs may have subtle effects on our risk of developing common diseases, such as heart disease, diabetes, or stroke.

Copy Number Variation (CNV)
At least 10 percent of the human genome is made up of CNVs, which are large chunks of DNA that are deleted, copied, flipped or otherwise rearranged in combinations that can be unique for each individual. These chunks of DNA often involve protein-coding genes. This means that CNVs are likely to change how a gene makes its protein.

Since genes usually occur in two copies, one inherited from each parent, a CNV that involves a single missing gene could lower the production of a protein below the amount needed.

Having too many copies of a gene can be harmful, too. Although most cases of Parkinson's disease are sporadic (without a known cause), some cases have been linked to having two or more copies of the SNCA gene, which encodes a protein called alpha-synuclein. The excess alpha-synuclein accumulates in clumps inside brain cells, and appears to jam the cells' machinery. For reasons that are not clear, similar clumps are associated with sporadic Parkinson's disease.

Single Gene Mutation
Some genetic variations are small and affect only a single gene. These single gene mutations can have large consequences, however, because they affect a gene's instructions for making a protein. Single gene mutations are responsible for many rare inherited neurological diseases, such as Huntington's disease.

Behavioral Genetics

Behavioral genetics studies heritability of behavioral traits, and it overlaps with genetics, psychology, and ethology (the scientific study of human and animal behavior). Genetics plays a large role in when and how learning, growing, and development occurs. For example, although environment has an effect on the walking behavior of infants and toddlers, children are unable to walk at all before an age that is predetermined by their genome. However, while the genetic makeup of a child determines the age range for when he or she will begin walking, environmental influences determine how early or late within that range the event will actually occur.

Figure 3.4.9.1: Gregor Mendel, the father of genetics: Mendel's work with pea plants demonstrated that certain traits follow particular patterns.

Classical Genetics

Classical, or Mendelian, genetics examines how genes are passed from one generation to the next, as well as how the presence or absence of a gene can be determined via sexual reproduction. Gregor Mendel is known as the father of the field of genetics, and his work with plant hybridization (specifically pea plants) demonstrated that certain traits follow particular patterns. This is referred to as the law of Mendelian inheritance.

Genes can be manipulated by selective breeding, which can have an enormous impact on behavior. For example, some dogs are bred specifically to be obedient, like golden retrievers; others are bred to be protective, like German shepards. In another

example, Seymour Benzer discovered he could breed certain fruit flies with others to create distinct behavioral characteristics and change their circadian rhythms.

The Influence of Behavior on Genes

Behavior can influence genetic expression in humans and animals by activating or deactivating genes. Behavior can have an impact on genetic makeup, even as early as the prenatal period. It is important to understand the implications of behavior on genetic makeup in order to reduce negative environmental and behavioral influences on genes.

EEG and PET scans have the ability to show psychologists how certain behaviors trigger reactions in the brain. This has led to the discovery of specific genes, such as those that influence addictive behaviors. A variety of behaviors have been shown to influence gene expression, including—but not limited to—drug use, exposure to the elements, and dietary habits.

Drugs and Alcohol

Prenatal exposure to certain substances, particularly drugs and alcohol, has detrimental effects on a growing fetus. The most serious consequences of prenatal drug or alcohol exposure involve newborn addiction and fetal alcohol syndrome (FAS). Fetal alcohol syndrome affects both physical and mental development, damaging neurons within the brain and often leading to cognitive impairment and below-average weight. Exposure to drugs and alcohol can also influence the genes of children and adults. Addiction is thought to have a genetic component, which may or may not be caused by a genetic mutation resulting from drug or alcohol use.

Temperature

Temperature exposure can affect gene expression. For example, in Himalayan rabbits, the genetic expressions of fur, skin, and eyes are regulated by temperature. In the warm areas of the rabbits' bodies, the fur lacks pigment due to gene inactivity and turns white. On the extremities of the rabbits' bodies (nose, ears and feet) the gene is activated and therefore pigmented (usually black).

Figure 3.4.9.2: Himalayan rabbit: Exposure to cold temperatures activates pigment-producing genes in the rabbit's extremities.

Light

Light exposure also influences genetic expression. Thomas Hunt Morgan performed an experiment in which he exposed some caterpillars to light and kept others in darkness. Those exposed to certain light frequencies had corresponding wing colors when they became butterflies (for example, red produced vibrant wing color, whereas blue led to pale wings). Darkness resulted in the

palest wing color, leading him to conclude that light exposure influenced the genes of the butterflies. In this manner a caterpillar's behavior can directly affect gene expression; a caterpillar that actively seeks out light will appear different as a butterfly than one that avoids it.

Nutrition

Lack of proper nutrition in early childhood is yet another factor that can lead to the alteration of genetic makeup. Human children who lack proper nutrition in the first three years of life tend to have more genetic problems later in life, such as health issues and problems with school performance.

Gene-Environment Interactions

Genes do not exist in a vacuum. Although we are all biological organisms, we also exist in an environment that is incredibly important in determining not only when and how our genes express themselves, but also in what combination. Each of us represents a unique interaction between our genetic makeup and our environment; range of reaction is one way to describe this interaction. **Range of reaction** asserts that our genes set the boundaries within which we can operate, and our environment interacts with the genes to determine where in that range we will fall. For example, if an individual's genetic makeup predisposes her to high levels of intellectual potential and she is reared in a rich, stimulating environment, then she will be more likely to achieve her full potential than if she were raised under conditions of significant deprivation. According to the concept of range of reaction, genes set definite limits on potential, and environment determines how much of that potential is achieved. Some disagree with this theory and argue that genes do not set a limit on a person's potential.

Another perspective on the interaction between genes and the environment is the concept of genetic environmental correlation. Stated simply, our genes influence our environment, and our environment influences the expression of our genes. Not only do our genes and environment interact, as in range of reaction, but they also influence one another bidirectionally. For example, the child of an NBA player would probably be exposed to basketball from an early age. Such exposure might allow the child to realize his or her full genetic, athletic potential. Thus, the parents' genes, which the child shares, influence the child's environment, and that environment, in turn, is well suited to support the child's genetic potential.

Figure 3.4.9.3: Nature and nurture work together like complex pieces of a human puzzle. The interaction of our environment and genes makes us the individuals we are. (credit "puzzle": modification of work by Cory Zanker; credit "houses": modification of work by Ben Salter; credit "DNA": modification of work by NHGRI)

In another approach to gene-environment interactions, the field of epigenetics looks beyond the genotype itself and studies how the same genotype can be expressed in different ways. In other words, researchers study how the same genotype can lead to very different phenotypes. As mentioned earlier, gene expression is often influenced by environmental context in ways that are not entirely obvious. For instance, identical twins share the same genetic information (identical twins develop from a single fertilized egg that split, so the genetic material is exactly the same in each; in contrast, fraternal twins develop from two different eggs

fertilized by different sperm, so the genetic material varies as with non-twin siblings). But even with identical genes, there remains an incredible amount of variability in how gene expression can unfold over the course of each twin's life. Sometimes, one twin will develop a disease and the other will not. In one example, Tiffany, an identical twin, died from cancer at age 7, but her twin, now 19 years old, has never had cancer. Although these individuals share an identical genotype, their phenotypes differ as a result of how that genetic information is expressed over time. The epigenetic perspective is very different from range of reaction, because here the genotype is not fixed and limited.

Genes affect more than our physical characteristics. Indeed, scientists have found genetic linkages to a number of behavioral characteristics, ranging from basic personality traits to sexual orientation to spirituality (for examples, see Mustanski et al., 2005; Comings, Gonzales, Saucier, Johnson, & MacMurray, 2000). Genes are also associated with temperament and a number of psychological disorders, such as depression and schizophrenia. So while it is true that genes provide the biological blueprints for our cells, tissues, organs, and body, they also have significant impact on our experiences and our behaviors.

Let's look at the following findings regarding schizophrenia in light of our three views of gene-environment interactions. Which view do you think best explains this evidence?

In a study of people who were given up for adoption, adoptees whose biological mothers had schizophrenia *and* who had been raised in a disturbed family environment were much more likely to develop **schizophrenia** or another psychotic disorder than were any of the other groups in the study:

- Of adoptees whose biological mothers had schizophrenia (high genetic risk) and who were raised in disturbed family environments, 36.8% were likely to develop schizophrenia.
- Of adoptees whose biological mothers had schizophrenia (high genetic risk) and who were raised in healthy family environments, 5.8% were likely to develop schizophrenia.
- Of adoptees with a low genetic risk (whose mothers did not have schizophrenia) and who were raised in disturbed family environments, 5.3% were likely to develop schizophrenia.
- Of adoptees with a low genetic risk (whose mothers did not have schizophrenia) and who were raised in healthy family environments, 4.8% were likely to develop schizophrenia (Tienari et al., 2004).

The study shows that adoptees with high genetic risk were especially likely to develop schizophrenia only if they were raised in disturbed home environments. This research lends credibility to the notion that both genetic vulnerability and environmental stress are necessary for schizophrenia to develop, and that genes alone do not tell the full tale.

Summary

Genes are sequences of DNA that code for a particular trait. Different versions of a gene are called alleles—sometimes alleles can be classified as dominant or recessive. A dominant allele always results in the dominant phenotype. In order to exhibit a recessive phenotype, an individual must be homozygous for the recessive allele. Genes affect both physical and psychological characteristics. The mind has evolved as a bundle of information processing modules "designed" by natural selection to increase survival and reproduction. Like other biological traits, the computational modules of the brain/mind are organized by genetic information during brain development. Ultimately, how and when a gene is expressed, and what the outcome will be—in terms of both physical and psychological characteristics—is a function of the interaction between our genes and our environments.

KEY TAKEAWAYS

Key Points

- Classical, or Mendelian, genetics examines how genes are passed from one generation to the next.
- Behavioral genetics examines the role of genetic and environmental influences on animal (including human) behavior.
- There are many ways to manipulate genetic makeup, such as cross-breeding to achieve certain characteristics.
- It is difficult to ascertain whether genetics ("nature") or the environment ("nurture") has a stronger influence on behavior. It is generally believed that human behavior is determined by complex interactions of both nature and nurture.
- Drug use, environmental exposure, and eating habits have all been linked to changes in gene expression. While some such influences are harmless or even beneficial, others can be extremely detrimental. Researchers hope to identify these behaviors and their effects.
- EEG and PET scans show psychologists how certain behaviors trigger reactions in the brain, which can lead to the discovery of certain determinant genes, such as those that influence addictive behaviors.

- Exposure of a fetus to alcohol and drugs can lead to a host of developmental problems after birth, the most serious of which is fetal alcohol syndrome.

Key Terms

- **behavioral genetics**: The field of study that examines the role of genetics in animal (including human) behavior; often involves the nature-versus-nurture debate.
- **ethology**: The scientific study of human and animal behavior.
- **genetics**: The branch of biology that deals with the transmission and variation of inherited characteristics, particularly chromosomes and DNA.
- **gene**: A unit of heredity; a segment of DNA or RNA that is transmitted from one generation to the next and that carries genetic information such as the sequence of amino acids for a protein.
- **fetal alcohol syndrome**: Any of a spectrum of birth defects resulting from excessive alcohol consumption by the mother during pregnancy.

Review Questions

A(n) _____ is a sudden, permanent change in a sequence of DNA.

1. allele
2. chromosome
3. epigenetic
4. mutation

_____ refers to a person's genetic makeup, while _____ refers to a person's physical characteristics.

1. Phenotype; genotype
2. Genotype; phenotype
3. DNA; gene
4. Gene; DNA

_____ is the field of study that focuses on genes and their expression.

1. Social psychology
2. Evolutionary psychology
3. Epigenetics
4. Behavioral neuroscience

Humans have _____ pairs of chromosomes.

1. 15
2. 23
3. 46
4. 78

Critical Thinking Questions

The theory of evolution by natural selection requires variability of a given trait. Why is variability necessary and where does it come from?

Personal Application Questions

You share half of your genetic makeup with each of your parents, but you are no doubt very different from both of them. Spend a few minutes jotting down the similarities and differences between you and your parents. How do you think your unique environment and experiences have contributed to some of the differences you see?

4.1: INTELLIGENCE

Introduction to Intelligence, Neuroscience, and the Brain

Introduction

Intelligence is a concept that has been studied and debated for centuries, with different scholars emphasizing different aspects of what it means to be intelligent. Most definitions include the ability to learn from experience, adapt to new situations, and solve problems effectively. Psychologists often describe intelligence as a set of cognitive skills, including reasoning, memory, attention, and verbal ability. These skills are important because they determine how well a person can process information and respond to challenges. Neuroscientists expand on this idea by studying how neural networks in the brain support these skills. For example, when you solve a complex math problem, multiple areas of your brain work together, including regions responsible for logic, working memory, and attention. Understanding intelligence in this way helps explain why some people excel in certain tasks while others struggle. It also highlights that intelligence is not a single trait but a combination of many abilities. Charles Spearman argued that there is a single underlying factor, called general intelligence or "g," that influences all cognitive tasks. Others, like Howard Gardner, suggest that there are multiple intelligences, such as linguistic, logical-mathematical, spatial, musical, bodily-kinesthetic, interpersonal, intrapersonal, and naturalistic abilities. These different views show how complex the concept of intelligence is and why it continues to be studied. Robert Sternberg proposed the Triarchic Theory of Intelligence, which includes analytical, creative, and practical components. Analytical intelligence involves problem solving and logical reasoning. Creative intelligence involves generating new ideas and thinking outside the box. Practical intelligence involves applying knowledge to real-world situations. These theories illustrate that intelligence is not just about doing well on a test but also about how we navigate everyday life. They also show that intelligence is influenced by both biology and environment. By understanding these theories, we gain a broader perspective on human potential. This understanding also helps educators develop teaching methods that cater to different types of intelligence. In neuroscience, these theories guide research into how specific brain regions support different kinds of thinking. Overall, defining intelligence is a dynamic process that reflects advances in both psychology and neuroscience.

Understanding intelligence requires exploring not only psychological concepts but also the biological foundations within the brain, which form the physical structures that make learning, memory, and reasoning possible. Neuroscience, which is the study of the nervous system, offers powerful insights into how brain structures and functions contribute to cognitive abilities. These cognitive abilities include problem solving, logical reasoning, the ability to store and recall memories, and the speed with which information can be processed. By looking at intelligence through the lens of neuroscience, we begin to see that intelligence is not just an abstract concept, but something that is closely tied to physical mechanisms in the brain. This intersection is important because it allows scientists and educators to understand why people learn differently and how various conditions might affect learning and reasoning. Neuroscience has grown rapidly over the past century, providing new tools like functional imaging and computational modeling to study intelligence. When we examine intelligence scientifically, we also begin to understand how factors such as environment, genetics, and experience interact to shape mental abilities. For instance, research shows that enriched environments can lead to stronger neural connections, which may contribute to higher cognitive performance. This connection between biology and behavior has real-world implications, from designing educational programs to creating therapies for brain injuries. It also shows that intelligence is dynamic rather than fixed, changing with development, experience, and health. Researchers today explore how specific brain regions like the prefrontal cortex work together to solve complex problems. They also investigate how communication between regions influences performance on intelligence tests. This chapter introduces key ideas from both psychology and neuroscience to explain how intelligence emerges. It also provides a foundation for understanding how brain research can inform our everyday lives. Throughout the chapter, you will encounter examples of how basic neural processes relate to higher-level reasoning. These examples help bridge the gap between abstract concepts and biological mechanisms. By exploring intelligence from this integrated perspective, we can develop more effective learning strategies and interventions. This perspective also helps us appreciate the remarkable adaptability of the human brain. The study of intelligence through neuroscience enriches our understanding of both fields. It opens up new possibilities for research, education, and clinical practice. As you read further, keep in mind how interconnected these concepts are and how this knowledge can be applied in multiple areas of life.

Neuroscience Foundations

At the heart of intelligence is the neuron, a specialized cell that transmits information throughout the nervous system. Neurons communicate using electrical impulses and chemical signals, which travel across small gaps called synapses. When you learn something new, neurons form new connections or strengthen existing ones, creating pathways that store information. These

networks of neurons, known as neural circuits, are responsible for all our thoughts, memories, and actions. Neuroscientists use tools like functional MRI (fMRI) to see which parts of the brain are active during certain tasks. Electroencephalography (EEG) records electrical activity in the brain and helps track how information flows in real time. By using these methods, researchers can observe how different regions of the brain work together during problem solving. For example, the prefrontal cortex often works with the parietal lobes to manage complex reasoning tasks. The temporal lobes play a key role in understanding language and storing memories. The hippocampus is essential for forming new memories and linking them to existing knowledge. When these areas communicate efficiently, cognitive performance improves. If there are disruptions in these networks, it can affect learning and memory. Research has shown that both genetic factors and environmental influences shape how these neural systems develop. For instance, children who grow up in stimulating environments often show greater synaptic density, which supports better learning. On the other hand, damage to certain brain regions can lead to difficulties in specific cognitive skills. These findings emphasize that intelligence is not just about having a certain brain size or shape but about how well different parts of the brain coordinate their activity. Neuroscience also shows that the brain is plastic, meaning it can change throughout life in response to experience. This adaptability explains why practice and training can improve performance in many areas. As we study these foundations, we see that intelligence emerges from complex interactions within the nervous system. This knowledge not only deepens our understanding of the brain but also guides interventions that can enhance learning and recovery after injury. The study of neurons and neural networks is therefore central to understanding intelligence. It provides a biological framework that complements psychological theories. By combining these perspectives, we can develop more effective educational tools and therapeutic approaches.

Neuroscience Research on Intelligence

Brain Size and Intelligence

For many years, scientists speculated about whether the overall size of the brain was directly related to intelligence. Early research often relied on crude measures, such as weighing brains after death, but these methods offered little insight into how brain structure related to function. Modern imaging techniques like MRI have allowed researchers to measure brain volume in living individuals with far greater accuracy. Studies have found a modest correlation between brain size and IQ, suggesting that larger brains may support more complex processing. However, researchers emphasize that size alone is not a reliable predictor of intelligence. What matters more is the organization and connectivity of neural circuits within the brain. A smaller brain with efficient connections and highly developed regions can perform just as well, or even better, than a larger brain with less efficient organization. Different regions contribute to different types of intelligence, so localized differences in volume or density can be more important than overall size. For instance, greater gray matter density in the prefrontal and parietal regions often correlates with better reasoning and problem-solving skills. These findings highlight that intelligence is multifaceted and cannot be reduced to a single physical measurement. Cultural and environmental factors also play a significant role in shaping cognitive abilities, independent of brain size. Researchers continue to investigate how genetics influence brain development and how experiences like education and training affect brain structure. Brain size might reflect certain developmental processes, but it does not determine destiny. Intelligence emerges from a dynamic interplay between biology, environment, and experience. This understanding counters earlier simplistic ideas about intelligence being innate and fixed. It also underscores the need to consider multiple factors when evaluating human cognitive potential. Modern neuroscience provides a more nuanced picture, showing that intelligence is shaped by both inherited traits and life experiences. This knowledge encourages educators and clinicians to look beyond superficial measures and focus on underlying processes. By integrating brain size data with functional imaging, researchers can better understand how structure supports performance. As research advances, scientists aim to identify patterns of connectivity that are more predictive of learning and reasoning than size alone. This ongoing work reflects the complexity of human intelligence and the power of neuroscience to illuminate it.

White Matter and Connectivity

White matter is composed of myelinated axons, the long fibers that carry signals between different regions of the brain. These axons are covered by a fatty substance called myelin, which speeds up the transmission of electrical impulses. When white matter pathways are well-developed and intact, information flows more quickly and efficiently. Studies using diffusion tensor imaging (DTI) have revealed that individuals with higher intelligence often have more organized white matter tracts. This organization allows for faster communication between regions involved in complex thinking. For example, efficient connectivity between the frontal and parietal lobes supports better problem-solving and reasoning skills. White matter integrity also contributes to working memory, which is critical for learning new information. Disruptions in white matter can slow processing speed and affect performance on cognitive tasks. Researchers have found that training and practice can strengthen white matter pathways, a phenomenon that demonstrates the brain's adaptability. Learning to play a musical instrument or mastering a new language often increases white matter density in relevant areas. This suggests that intelligence is not only influenced by innate traits but also shaped by experience and effort. It also highlights the importance of lifelong learning in maintaining cognitive abilities. White matter research provides evidence that neural efficiency, rather than sheer processing power, underlies many aspects

of intelligence. The speed at which information travels affects how quickly we can solve problems or adapt to new challenges. Furthermore, white matter development is influenced by factors such as nutrition, physical activity, and mental stimulation. Studies on aging show that maintaining white matter integrity can protect against cognitive decline. This research has practical applications in designing interventions to preserve brain health throughout life. It also informs educational strategies that emphasize active engagement and practice. By understanding white matter, we gain insight into the biological basis of learning and intelligence. This knowledge bridges the gap between neuroscience research and real-world applications, from classrooms to clinical settings.

Neuroplasticity

Neuroplasticity refers to the brain's remarkable ability to reorganize itself by forming new neural connections throughout life. This concept has transformed our understanding of intelligence, showing that cognitive abilities are not fixed but can be improved through experience and learning. When we engage in challenging mental activities, our brains adapt by strengthening existing connections and creating new ones. For example, practicing mathematics or learning a new language can lead to measurable changes in brain structure. These changes are often seen in regions associated with memory, attention, and reasoning. Neuroplasticity also explains how people recover functions after brain injuries, as other regions take over tasks once managed by damaged areas. Research demonstrates that neuroplasticity is most active during childhood, but it continues throughout adulthood. This means that adults can still improve their cognitive abilities with the right training and experiences. Activities that promote neuroplasticity include reading, solving puzzles, playing musical instruments, and engaging in regular physical exercise. These activities increase blood flow to the brain, stimulate growth factors, and support the formation of new synapses. The adaptability of the brain provides hope for interventions in neurodegenerative diseases, as therapies can encourage the brain to compensate for lost functions. Neuroplasticity also underscores the importance of education and lifelong learning in maintaining intelligence. It challenges the outdated view that intelligence is determined solely by genetics. Instead, it suggests that effort, environment, and experience play crucial roles. This concept is empowering because it means we can actively influence our cognitive development. Teachers and clinicians use this knowledge to design programs that harness neuroplasticity for better outcomes. For example, cognitive rehabilitation therapy for stroke patients often relies on principles of neuroplasticity. In education, strategies like spaced repetition and active engagement take advantage of the brain's ability to strengthen connections over time. Neuroscientists continue to study the molecular mechanisms behind neuroplasticity to develop new ways to enhance learning and recovery. This ongoing research reinforces the idea that intelligence is dynamic and adaptable. It shows that our brains are not static organs but living systems that grow and change throughout life.

Intelligence Across the Lifespan

Development in Childhood and Adolescence

The human brain undergoes profound changes during childhood and adolescence, shaping the foundation for intelligence and learning. In early childhood, the brain produces an abundance of synapses, which are later pruned to increase efficiency. This synaptic pruning allows neural circuits to become more specialized and refined. Myelination, the process of coating axons with myelin, accelerates signal transmission, enhancing processing speed and cognitive performance. These biological processes align with improvements in attention, memory, and reasoning skills observed as children grow. Educational experiences play a critical role in guiding which connections are strengthened and which are pruned. Children exposed to stimulating environments often develop stronger neural networks, supporting better academic outcomes. Conversely, lack of stimulation or exposure to stress can negatively affect brain development. Adolescence brings further changes, particularly in the prefrontal cortex, which governs executive functions like planning and impulse control. During this period, teenagers may exhibit uneven cognitive development, excelling in some areas while struggling in others. Social interactions also influence brain development, as peer relationships contribute to emotional and cognitive growth. Hormonal changes during puberty interact with brain development, affecting motivation and decision making. The adolescent brain is highly plastic, making it both a period of opportunity and vulnerability. Educational interventions during this time can have lasting impacts on intelligence and learning strategies. Neuroscience research highlights the importance of sleep, nutrition, and physical activity in supporting brain development. Chronic sleep deprivation in teenagers, for example, can impair memory consolidation and attention. Programs that promote healthy lifestyles during adolescence can therefore enhance cognitive outcomes. Understanding these developmental processes helps educators design age-appropriate curricula. It also helps parents create supportive environments that foster learning and curiosity. Research continues to explore how individual differences, such as genetic factors, interact with these developmental milestones. By studying childhood and adolescent brain development, scientists can better understand how to maximize learning potential. This knowledge underscores the importance of early intervention for developmental disorders. Overall, the dynamic changes during these years lay the groundwork for lifelong intelligence. They demonstrate that intelligence is shaped by a complex interplay of biology, experience, and environment.

Aging and Intelligence

As individuals age, their brains continue to change in ways that affect intelligence and cognitive abilities. Some functions, such as processing speed and working memory, often show gradual decline beginning in midlife. However, other aspects of intelligence, such as vocabulary, accumulated knowledge, and emotional regulation, remain stable or even improve. Neuroscience research has revealed that aging brains maintain a surprising degree of plasticity, allowing older adults to learn new skills and adapt to new challenges. Structural changes, such as reduced volume in certain regions, are offset by functional reorganization in others. For example, older adults often recruit additional brain areas to compensate for declining regions when performing cognitive tasks. Lifestyle factors, including regular physical exercise and mental stimulation, have been shown to slow cognitive decline. Engaging in activities like reading, playing chess, or learning a new hobby can enhance neural connections and preserve cognitive abilities. Social engagement also plays a vital role, as maintaining strong relationships supports mental health and cognitive function. Studies suggest that a positive attitude toward aging can itself contribute to better cognitive outcomes. Nutrition and sleep continue to be important, as deficiencies can exacerbate cognitive decline. Research into neurodegenerative diseases like Alzheimer's and Parkinson's has provided insight into the mechanisms of cognitive aging. Early detection and interventions can slow progression and improve quality of life. Scientists are exploring how factors like inflammation and oxidative stress contribute to age-related changes in the brain. Cognitive training programs designed for older adults show promise in enhancing memory and attention. Brain imaging studies reveal that lifelong learning promotes greater connectivity and resilience. This reinforces the message that intelligence is not fixed at any stage of life. Educators and health professionals are developing strategies to support cognitive health in aging populations. Public health initiatives encourage older adults to stay mentally and physically active. Interdisciplinary research is shedding light on how genetics, lifestyle, and environment interact in the aging brain. Understanding these processes helps society prepare for an aging population with unique cognitive needs. It also offers hope that intelligence, in many forms, can flourish well into later life. The study of aging and intelligence ultimately reminds us that the human brain is adaptable throughout the lifespan.

Implications and Future Directions

Integrating Intelligence Research and Neuroscience

The growing integration between intelligence research and neuroscience offers exciting opportunities for education, clinical practice, and technology. By studying how the brain supports various cognitive functions, researchers can design more effective teaching methods tailored to individual strengths. For example, knowing how working memory functions in the brain allows educators to structure lessons that build on prior knowledge and reduce overload. This can lead to classrooms that feel more supportive and responsive to diverse learning needs. Neuroscience research has also shed light on learning disabilities, such as dyslexia and attention-deficit disorders, enabling earlier diagnosis and intervention. With this knowledge, schools can implement targeted programs that give students with these challenges the tools they need to succeed. Beyond education, clinical settings benefit as well. Neuropsychologists use findings about memory networks and brain plasticity to design rehabilitation programs for people recovering from brain injuries. Advances in imaging allow doctors to track recovery and adjust treatments accordingly. Technology plays a role, too, as brain-computer interfaces are developed to help people with severe motor impairments communicate and interact with their environments. These devices rely on understanding how brain signals can be translated into actions. Cognitive training programs, often delivered through apps or games, use principles of neuroplasticity to strengthen specific mental skills. However, applying neuroscience findings comes with ethical considerations. For instance, while brain scans can reveal differences in connectivity, these should never be used to unfairly label or limit someone's potential. Instead, this information should be used to empower individuals with strategies to enhance learning and development. There is also the question of data privacy when dealing with sensitive neurological information. Researchers must work carefully to ensure that technological tools do not reinforce social inequalities or stereotypes. Another implication is the growing need for interdisciplinary collaboration. Psychologists, educators, neuroscientists, and engineers must work together to translate findings into real-world applications. This collaboration ensures that interventions are both scientifically sound and culturally sensitive. Understanding the neural basis of intelligence also opens up questions about how to foster creativity, emotional intelligence, and practical skills. Each of these areas may have distinct neural underpinnings that can be studied and supported. Overall, the future of intelligence research looks bright, but it requires a careful balance between innovation and ethics. As we learn more, the goal is to use this knowledge to improve lives, not limit them. This integration represents a new frontier in understanding the mind and optimizing human potential.

The History of Intelligence Testing

Early Foundations of Intelligence Testing

The story of intelligence testing begins with early efforts to measure human differences, long before modern psychology existed.

Ancient philosophers like Plato and Aristotle speculated about why some people seemed wiser or more capable than others, but they lacked systematic methods. It was not until the 19th century that these questions began to be approached scientifically. Sir Francis Galton, an English polymath and cousin of Charles Darwin, pioneered studies on individual differences. In his book *Hereditary Genius* (1869), Galton argued that intelligence was inherited and attempted to measure mental acuity through sensory and reaction-time tasks. Although his tests were often unreliable, they introduced the idea that intelligence could be quantified. Galton's work laid the foundation for the field of differential psychology, which seeks to understand how and why individuals differ. Building on this, James McKeen Cattell, an American psychologist, coined the term "mental tests" in 1890. He developed assessments that measured reaction times, memory spans, and other basic processes, hoping they would predict academic success. While these early tests did not directly measure intelligence as we understand it today, they represented a shift toward objective evaluation. This period also reflected a growing interest in applying scientific methods to education and policy. However, these tests were limited by the tools and theories available at the time. Many researchers focused on sensory abilities without linking them to higher-order thinking. Despite these limitations, the idea that intelligence could be studied systematically inspired others to refine and expand testing methods. The late 19th century thus set the stage for more practical and valid assessments in the early 20th century. These foundations are important because they show how scientific curiosity, even when imperfect, can lead to significant advancements. They also reveal how concepts of intelligence were shaped by cultural and historical contexts. Understanding this history reminds us that testing tools are not neutral; they reflect the values and knowledge of their time. It is crucial to view early tests as stepping stones rather than final answers. They demonstrate the evolution of thought in psychology and highlight the need for continual revision and improvement. From these beginnings, the field of intelligence testing would grow into a major influence on education and public policy worldwide.

The Birth of the Modern Intelligence Test

A major breakthrough came in 1905 when French psychologist Alfred Binet, working with Theodore Simon, developed the first practical intelligence test. Commissioned by the French Ministry of Education, their goal was to identify children who needed extra help in school. The Binet-Simon Scale included tasks measuring reasoning, comprehension, and problem-solving, which were more directly linked to academic success than previous sensory tests. This test introduced the concept of "mental age," comparing a child's performance to typical age norms. For example, a child who could solve problems typical of older children would be considered advanced. This innovation allowed teachers and psychologists to tailor instruction more effectively. Binet and Simon emphasized that their test was not a fixed measure of ability but a tool to guide education. Their work inspired further developments worldwide. In the United States, Lewis Terman of Stanford University revised and standardized the Binet-Simon Scale, creating the Stanford-Binet Intelligence Scale in 1916. Terman introduced the Intelligence Quotient (IQ), calculated by dividing mental age by chronological age and multiplying by 100. This provided a single number that could be compared across individuals. The Stanford-Binet quickly became widely used in schools, military settings, and clinical contexts. It shaped educational policies and influenced how intelligence was understood for decades. However, even as the test gained popularity, debates continued about what exactly it measured. Critics argued that cultural and language biases could affect scores. Despite these concerns, the Stanford-Binet laid the groundwork for modern intelligence assessments. It demonstrated that intelligence could be measured in a way that informed practical decisions. This period marked a shift from experimental curiosity to widespread application. The success of these tests spurred further research into refining items and reducing bias. It also sparked interest in exploring multiple types of intelligence beyond a single score. The legacy of Binet, Simon, and Terman continues in contemporary testing practices. Their work reminds us that intelligence testing is both a scientific endeavor and a social tool. Its history is a story of innovation, application, and ongoing revision. Understanding this background helps us appreciate the strengths and limitations of current assessments.

Intelligence Testing in the Early 20th Century and Beyond

The early 20th century saw intelligence testing expand rapidly, particularly during World War I. The U.S. Army needed a way to classify large numbers of recruits, leading to the development of the Army Alpha and Beta tests. The Alpha was a verbal test, while the Beta was nonverbal, designed for recruits with limited English proficiency or literacy. These tests were administered to over 1.75 million soldiers, demonstrating the feasibility of large-scale assessment. Results helped place soldiers in roles suited to their abilities, showing practical benefits. However, these tests also fueled public fascination with measuring intelligence. Policymakers began considering how such tools could guide immigration policies, education, and employment. Unfortunately, some misused test results to support eugenic ideas, arguing for restrictive immigration laws and segregation. This misuse serves as an important reminder of the ethical responsibilities involved in testing. Despite these controversies, intelligence testing continued to evolve. In 1939, David Wechsler developed the Wechsler-Bellevue Intelligence Scale, later known as the Wechsler Adult Intelligence Scale (WAIS). Unlike the Stanford-Binet, the WAIS provided separate scores for verbal and performance abilities, offering a more nuanced profile. Wechsler also created versions for children (WISC) and preschoolers (WPPSI), making intelligence testing applicable across the lifespan. During the mid-20th century, factor-analytic approaches advanced theoretical understanding. Charles Spearman's "g factor" suggested a general intelligence underlying all cognitive tasks, while Louis Thurstone proposed multiple primary mental abilities. These debates enriched the field and informed test design. Today, intelligence tests are used in clinical psychology to diagnose learning disabilities and guide interventions. They are also used in

research to study cognition and development. Modern tests strive to be culturally fair and minimize biases that plagued earlier versions. Critics remind us that intelligence is multifaceted, encompassing creativity, emotional understanding, and practical problem-solving. This ongoing dialogue has inspired alternative assessments that go beyond traditional IQ measures. The history of intelligence testing, therefore, is not just about the tests themselves but about how society uses them. It shows the potential for these tools to help or harm, depending on the context and intent. By studying this history, we learn to apply tests responsibly, with cultural sensitivity and awareness of their limitations. Understanding this evolution helps future educators and psychologists make informed choices. It encourages continued innovation in creating assessments that reflect the diversity and complexity of human intelligence.

4.1.1: Overview of Brain Mechanisms in Intelligence, Language, and Cognition

4.1.2: Cognition, Intelligence, and Language as Psychological Adaptations

4.1.3: High Intelligence-Nature or Nurture; Learning Disabilities

4.1.4: Cognition- Categories, Concepts, Schemas and the Brain

4.1.5: Brain Mechanisms and Intelligence

This page titled 4.1: Intelligence is shared under a CC BY-NC 4.0 license and was authored, remixed, and/or curated by Ivette Merced.

4.1.1: Overview of Brain Mechanisms in Intelligence, Language, and Cognition

Learning Objectives

1. Discuss the general relationship across species between brain size, body size, and intelligence, including trends in corticalization and cortical folding
2. Describe the functions of glial cells
3. Describe the locations and functions of each of the lobes of the cerebral cortex
4. Describe contralateral control
5. Discuss general principles that determine the amounts of somatosensory and motor cortex devoted to each part of the body
6. Describe visual agnosia and the location of the brain damage that causes it
7. Describe neuroplasticity and briefly discuss examples of it
8. Discuss what the split-brain experiments tell us about cerebral lateralization of function

Overview

We begin this chapter with a general review of the brain areas involved in complex psychological functions, focusing on the cerebral cortex, including studies of the split brain. Although an introductory psychology course is a prerequisite for this course in Biological Psychology, a refresher will be useful for you, the student, in preparation for the detail to be discussed in subsequent modules of this chapter.

The Cerebral Cortex Creates Intelligence, Language, and Thinking: Overview of the Basics

All animals have adapted to their environments by developing abilities that help them survive. Some animals have hard shells, others run extremely fast, and some have acute hearing. Human beings do not have any of these particular characteristics, but we do have one big advantage over other animals—we are very, very smart.

You might think that we should be able to determine the intelligence of an animal by looking at the ratio of the animal's brain weight to the weight of its entire body. But this does not really work. The elephant's brain is one thousandth of its weight, but the whale's brain is only one ten-thousandth of its body weight. On the other hand, although the human brain is one 60th of its body weight, the mouse's brain represents one fortieth of its body weight. Despite these comparisons, elephants do not seem 10 times smarter than whales, and humans definitely seem smarter than mice.

The key to the advanced intelligence of humans is not found in the size of our brains. What sets humans apart from other animals is our larger cerebral cortex—*the outer bark-like layer of our brain that allows us to so successfully use language, acquire complex skills, create tools, and live in social groups* (Gibson, 2002). In humans, the cerebral cortex is wrinkled and folded, rather than smooth as it is in most other animals. This creates a much greater surface area and size, and allows increased capacities for learning, remembering, and thinking. The increasing amount of cortex in mammals involving folding of the cerebral cortex is referred to as *corticalization*.

Although the cortex is only about one tenth of an inch thick, it makes up more than 80% of the brain's weight. The human cortex contains about 20 billion nerve cells (the entire human brain has somewhere between 100 and 200 billion neurons) and at least 300 trillion synaptic connections (de Courten-Myers, 1999). Supporting all these neurons are billions more glial cells (glia), *cells that surround and link to the neurons, protecting them, providing them with nutrients, and absorbing unused neurotransmitters*. The glia come in different forms and have different functions. For instance, the myelin sheath surrounding the axon of many neurons is a type of glial cell. The glia are essential partners of neurons, without which the neurons could not survive or function (Miller, 2005).

As you recall from the chapter on anatomy of the nervous system, the cerebral cortex is divided into two *hemispheres*, and each hemisphere is divided into four *lobes*, each separated by little "valleys" known as *fissures* (the little hills between fissures are called *gyri,* singular, *gyrus)*.

If we look at the cortex starting at the front of the brain and moving over the top (see Figure 14.1.1), we see first the **frontal lobe** (behind the forehead), which is *responsible primarily for thinking, planning, memory, and judgment*. In addition, in most people the *left frontal lobe contains Broca's area* essential for speech and other language functions (in some left handers, Broca's area may be in the right frontal lobe or language may be less lateralized and instead is spread more equally between the two hemispheres; thus, left handers tend to lose less language function than right handers if they suffer damage to left frontal lobe).

Following the frontal lobe is the **parietal lobe**, *which extends from the middle to the back of the skull and which is responsible primarily for processing information about touch and spatial perception, and parts of which appear to be involved in visualization* (discussed later in this chapter). Spatial perception is one component of intelligence measured on IQ tests. Damage to parts of the *right parietal association cortex* produces *unilateral neglect*, the inability to understand that the left side of your body belongs to you--thus it is "neglected" to the point where a patient may not be able "to find" their left arm, or may dress and groom only the right side of their body.

Then comes the **occipital lobe**, *at the very back of the skull, which processes visual information (the central region of the occipital lobe is called primary visual cortex and has a point-for-point mapping of the retina on its surface; surrounding the primary visual cortex is visual association cortex which is involved in higher order, more complex visual processing and perception, and along with primary visual cortex appears to store long-term visual memories)*.

Finally, in front of the occipital lobe (near the temples and ears) is the **temporal lobe**, *responsible primarily for hearing and language (Wernicke's Area is here in the left temporal lobe in most people and interacts with Broca's area in the left Frontal lobe in language processing)*. Also located in the temporal lobe is the *Inferotemporal (IT) cortex* which is involved in visual recognition. Damage in IT cortex produces *visual agnosia*--people can see and describe visual detail but they can't put the details together to recognize what it is that they are looking at. A small area of the right inferior temporal cortex known as the *fusiform face area (FFA)* appears to be specialized for face processing (Kanwisher & Yovel, 2006). Damage to the FFA produces a related, but more specific disorder, prosopagnosia or face blindness, the inability to recognize familiar faces, even those of close family members, and even one's own face in photographs (see Barton et al., 2002).

Another area involved in facial recognition in humans is the *occipital face area (OFA)* located in the lateral occipital lobe near the occipital gyrus. Brain damage in the OFA results in impaired face recognition. Research suggests that there may be a topographic face map in the OFA where adjacent areas of the human face are represented by adjacent areas of cortex in the OFA (Henriksson, et al., 2015). The FFA and OFA are interconnected and are part of a network for face processing and face recognition in the human inferior temporal and lateral occipital cortices.

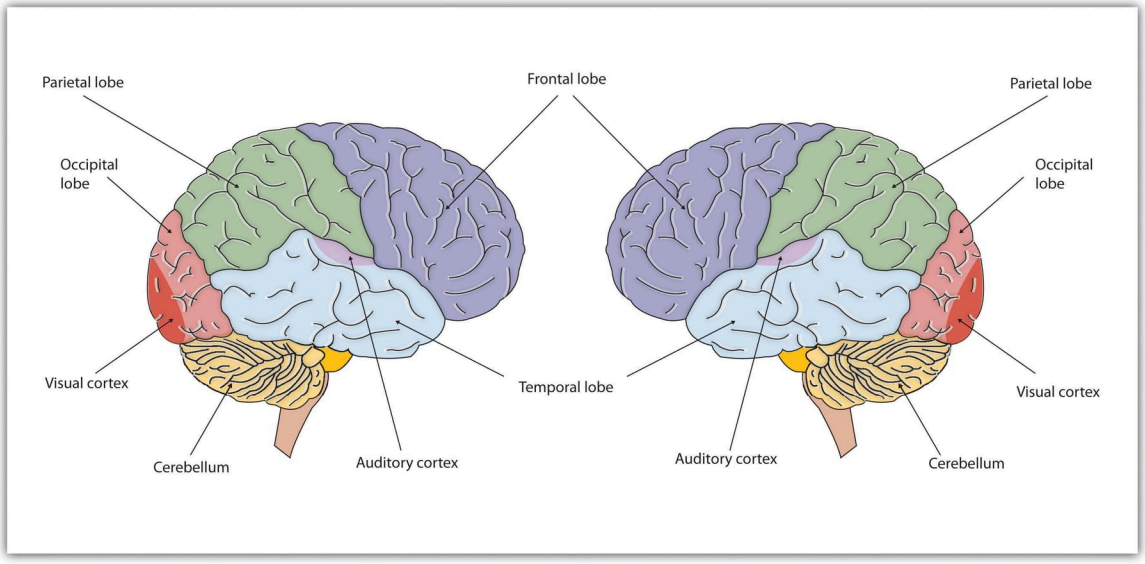

Figure 4.1.1.1: The brain is divided into two hemispheres (right and left), each of which has four lobes (temporal, frontal, occipital, and parietal). Furthermore, there are specific cortical areas within the lobes that control different processes. The FFA in interior

temporal lobe and the OFA in the occipital lobe are specialized for facial processing. Specialized areas of cortex for specific functions illustrate the principle of localization of function within the cerebral cortex.

Functions of the Cortex

When the German physicists Gustav Fritsch and Eduard Hitzig (1870/2009) applied mild electric stimulation to different parts of a dog's cortex, they discovered that they could make different parts of the dog's body move. Furthermore, they discovered an important and unexpected principle of brain activity. They found that stimulating the right side of the brain produced movement in the left side of the dog's body, and vice versa. This finding follows from a general principle about how the brain is structured, called *contralateral control*. The brain is wired such that in most cases the left hemisphere receives sensations from and controls the right side of the body, and vice versa.

Fritsch and Hitzig also found that the movement that followed the brain stimulation only occurred when they stimulated a specific arch-shaped region that runs across the top of the brain from ear to ear, just at the front of the parietal lobe (see Figure 14.1.2 below). Fritsch and Hitzig had discovered the **motor cortex**, *the part of the cortex that controls and executes movements of the body by sending signals to the cerebellum and the primary motor neurons of the spinal cord*. More recent research has mapped the motor cortex even more fully, by applying mild electronic stimulation to different areas of the motor cortex in conscious patients while observing their bodily responses (because the brain has no sensory receptors, these patients feel no pain). As you can see in Figure 14.1.2, this research has revealed that the motor cortex is specialized for providing control over the body; there is a topographic representation of the body surface on the surface of the motor cortex. In fact, the parts of the body that require more precise and finer movements, such as the face and the hands, are allotted the largest areas of motor cortical space. This makes sense since finer movements require more processing and thus more cortical tissue.

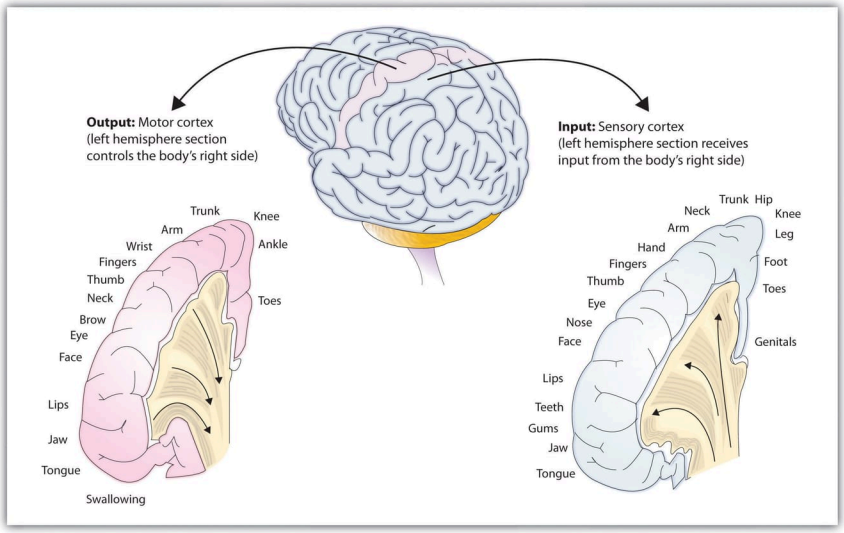

Figure 4.1.1.2: The Somatosensory Cortex and the Motor Cortex.

The portion of the sensory and motor cortex devoted to receiving messages that control specific regions of the body is determined by the amount of fine movement that area is capable of performing. Thus the hand and fingers have as much area in the cerebral cortex as does the entire trunk of the body.

Just as the *primary motor cortex (the precentral gyrus, at the back of the frontal lobe)* sends out messages to the specific parts of the body, the ***primary somatosensory cortex*** *(the post-central gyrus, just behind the central fissure), an area just behind and parallel to the motor cortex, receives information from the skin's sensory receptors and the movements of different body parts*. Again, the more sensitive the body region, the more area is dedicated to it in the sensory cortex. Our sensitive lips, for example, occupy a large area in the sensory cortex, as do our fingers and genitals, whereas the trunk of the body has relatively less area in the sensory cortex devoted to it.

Other areas of the cortex process other types of sensory information. The ***visual cortex*** is *the area located in the* ***occipital lobe*** *(at the very back of the brain) that processes visual information*. If your brain were stimulated, while conscious on the

operating table, by an electrode in the visual cortex, you would see flashes of light or color. Perhaps you remember having had the experience of “seeing stars” when you were hit or fell on the back of your head (this finding suggests that the luminosity and color that we attribute to light are really produced in the brain, when occipital cortex is activated, and that these sensations don't exist in the exterior world outside our heads--luminosity and color are not properties of the world, but are just brain/psychological codes for dark and colorless electromagnetic energies of various wavelengths in the visible spectrum which only become luminous and colored after they are transduced into neuron potentials which activate visual system neurons). The ***temporal lobe***, located on the lower side of each hemisphere, near your temples, *which contains* ***auditory cortex as well as Wernicke's area*** *(on the left temporal lobe of most people) responsible for hearing and language comprehension, respectively*. The inferior temporal lobe (IT cortex) also processes some visual information, providing us, as discussed above, with the ability to recognize and name the objects around us (Martin, 2007).

As you can see in Figure 14.1.2, the motor and sensory areas of the cortex account for a relatively small part of the total cortex. The remainder of the cortex is made up of ***association areas*** of cortex *in which sensory and motor information is combined and associated with our stored knowledge*. These *association areas of cortex* (to be discussed in more detail later in this chapter) are the places in the brain that are responsible for most of the things that make human beings seem human. *The association areas are involved in higher mental functions, such as learning, thinking, planning, judging, moral reflecting, figuring, and spatial reasoning.*

The Brain Is Flexible: Neuroplasticity

The control of some specific bodily functions, such as movement, vision, and hearing, is performed in specified areas of the cortex, and if these areas are damaged, the individual will likely lose the ability to perform the corresponding function. For instance, if an infant suffers damage to facial recognition areas in the temporal lobe (FFA), it is likely that he or she will never be able to recognize faces (Farah, Rabinowitz, Quinn, & Liu, 2000). On the other hand, the brain is not divided up in an entirely rigid way. The brain’s neurons have a remarkable capacity to reorganize and extend themselves to carry out particular functions in response to the needs of the organism, and to repair damage. As a result, the brain constantly creates new neural communication routes and rewires existing ones. Neuroplasticity refers to *the brain’s ability to change its structure and function in response to experience or damage*. Neuroplasticity enables us to learn and remember new things and adjust to new experiences as discussed in chapter 10 on learning and memory.

Our brains are the most “plastic” when we are young children, as it is during this time that we learn the most about our environment. On the other hand, neuroplasticity continues to be observed even in adults (Kolb & Fantie, 1989). The principles of neuroplasticity help us understand how our brains develop to reflect our experiences. For instance, accomplished musicians have a larger auditory cortex compared with the general population (Bengtsson et al., 2005) and also require less neural activity to move their fingers over the keys than do novices (Münte, Altenmüller, & Jäncke, 2002). This is because accomplished musicians through practice have eliminated synaptic connections associated with incorrect movements, making neural control more efficient (see chapter 10 on long-term depression. LTD).

Plasticity is also observed when there is damage to the brain or to parts of the body that are represented in the motor and sensory cortexes. When a tumor in the left hemisphere of the brain impairs language, the right hemisphere will begin to compensate to help the person recover the ability to speak (Thiel et al., 2006). And if a person loses a finger, the area of the sensory cortex that previously received information from the missing finger will begin to receive input from adjacent fingers, causing the remaining digits to become more sensitive to touch (Fox, 1984).

Although neurons cannot repair or regenerate themselves as skin or blood vessels can, new evidence suggests that the brain can engage in neurogenesis, *the forming of new neurons* (Van Praag, Zhao, Gage, & Gazzaniga, 2004). These new neurons originate deep in the brain and may then migrate to other brain areas where they form new connections with other neurons (Gould, 2007). This leaves open the possibility that someday scientists might be able to “rebuild” damaged brains by creating drugs that help grow neurons.

Research Focus: Identifying the Unique Functions of the Left and Right Hemispheres Using Split-Brain Patients

We have seen that the left hemisphere of the brain primarily senses and controls the motor movements on the right side of the body, and vice versa. This fact provides an interesting way to study brain lateralization—*the idea that the left and the right hemispheres of the brain are specialized to perform different functions*. Gazzaniga, Bogen, and Sperry (1965) studied a patient, known as W. J., who had undergone an operation to relieve severe seizures. In this surgery *the region that normally connects the*

two halves of the brain and supports communication between the hemispheres, known as the corpus callosum, is severed. As a result, the patient essentially becomes a person with two separate brains. Because the left and right hemispheres are separated, each hemisphere develops a mind of its own, with its own sensations, concepts, and motivations (Gazzaniga, 2005).

In their research, Gazzaniga and his colleagues tested the ability of W. J. to recognize and respond to objects and written passages that were presented to only the left or to only the right brain hemispheres (see Figure 14.1.3). The researchers had W. J. look straight ahead and then flashed, for a fraction of a second, a picture of a geometrical shape to the left of where he was looking. By doing so, they assured that—because the two hemispheres had been separated—the image of the shape was experienced only in the right brain hemisphere (remember that sensory input from the left side of the body is sent to the right side of the brain). Gazzaniga and his colleagues found that W. J. was able to identify what he had been shown when he was asked to pick the object from a series of shapes, using his left hand, but that he could not do this when the object was shown in the right visual field. On the other hand, W. J. could easily read written material presented in the right visual field (and thus experienced in the left hemisphere) but not when it was presented in the left visual field.

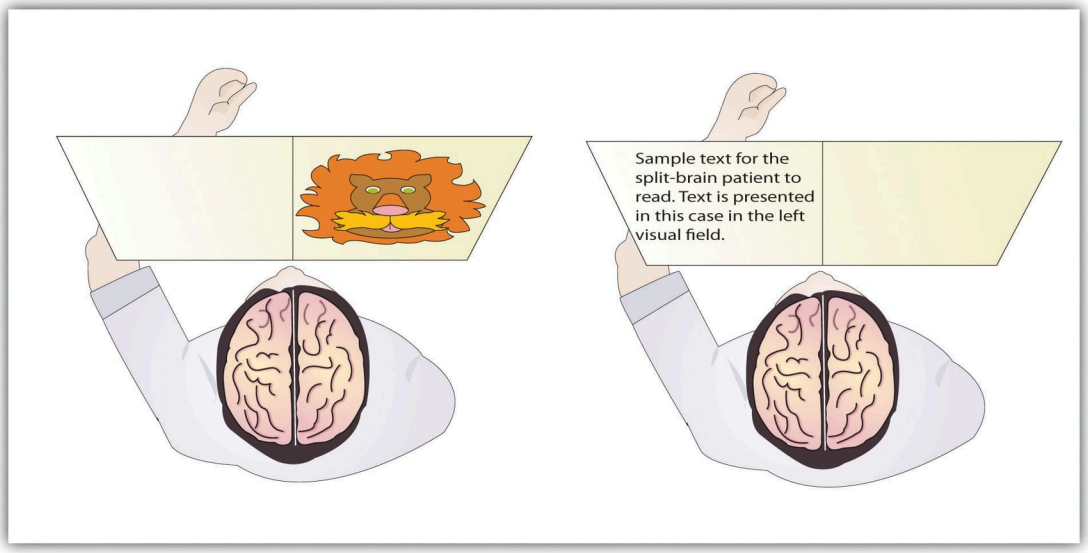

Figure 4.1.1.3: Visual and Verbal Processing in the Split-Brain Patient

The information that is presented on the left side of our field of vision is transmitted to the right brain hemisphere, and vice versa. In split-brain patients, the severed corpus callosum does not permit information to be transferred between hemispheres (as it is in normal persons without brain damage), which allows researchers to learn about the functions of each hemisphere. In the perceptual test on the left, the split-brain patient could not choose which image had been previously presented because the left hemisphere cannot process visual information. In the test on the right side of Figure 14.1.3, the patient could not read the passage because the right brain hemisphere cannot process language.

This research, and many other studies following it, has demonstrated that the two brain hemispheres specialize in different abilities. In most people the ability to speak, write, and understand language is located in the left hemisphere. This is why W. J. could read passages that were presented on the right side and thus transmitted to the left hemisphere, but could not read passages that were only experienced in the right brain hemisphere. The left hemisphere is also better at math and at judging time and rhythm. It is also superior in coordinating the order of complex movements—for example, lip movements needed for speech. The right hemisphere, on the other hand, has only very limited verbal abilities, and yet it excels in perceptual skills. The right hemisphere is able to recognize objects, including faces, patterns, and melodies, and it can put a puzzle together or draw a picture. This is why W. J. could pick out the image when he saw it on the left, but not the right, visual field.

Although Gazzaniga's research demonstrated that the brain is in fact lateralized, such that the two hemispheres specialize in different activities, this does not mean that when people behave in a certain way or perform a certain activity they are only using one hemisphere of their brains at a time. That would be drastically oversimplifying the concept of brain differences. We normally use both hemispheres at the same time, and the difference between the abilities of the two hemispheres is not absolute (Soroker et al., 2005).

Why Are Some People Left-Handed?

Across cultures and ethnic groups, about 90% of people are mainly right-handed, whereas only 10% are primarily left-handed (Peters, Reimers, & Manning, 2006). This fact is puzzling, in part because the number of left-handers is so low, and in part because other animals, including our closest primate relatives, do not show any type of handedness. The existence of right-handers and left-handers provides an interesting example of the relationship among evolution, biology, and social factors and how the same phenomenon can be understood at different levels of analysis (Harris, 1990; McManus, 2002).

At least some handedness is determined by genetics. Ultrasound scans show that 9 out of 10 fetuses suck the thumb of their right hand, suggesting that the preference is determined before birth (Hepper, Wells, & Lynch, 2005), and the mechanism of transmission has been linked to a gene on the X chromosome (Jones & Martin, 2000). It has also been observed that left-handed people are likely to have fewer children, and this may be in part because the mothers of left-handers are more prone to miscarriages and other prenatal problems (McKeever, Cerone, Suter, & Wu, 2000).

But culture also plays a role. In the past, left-handed children were forced to write with their right hands in many countries, and this practice continues, particularly in collectivistic cultures, such as India and Japan, where left-handedness is viewed negatively as compared with individualistic societies, such as the United States. For example, India has about half as many left-handers as the United States (Ida & Mandal, 2003).

There are both advantages and disadvantages to being left-handed in a world where most people are right-handed. One problem for lefties is that the world is designed for right-handers. Automatic teller machines (ATMs), classroom desks, scissors, microscopes, drill presses, and table saws are just some examples of everyday machinery that is designed with the most important controls on the right side. This may explain in part why left-handers suffer somewhat more accidents than do right-handers (Dutta & Mandal, 2006).

Despite the potential difficulty living and working in a world designed for right-handers, there seem to be some advantages to being left-handed. Throughout history, a number of prominent artists have been left-handed, including Leonardo da Vinci, Michelangelo, Pablo Picasso, and Max Escher. Because the right hemisphere is superior in imaging and visual abilities, there may be some advantage to using the left hand for drawing or painting (Springer & Deutsch, 1998). Left-handed people are also better at envisioning three-dimensional objects, which may explain why there is such a high number of left-handed architects, artists, and chess players in proportion to their numbers (Coren, 1992). However, there are also more left-handers among those with reading disabilities, allergies, and migraine headaches (Geschwind & Behan, 2007), perhaps due to the fact that a small minority of left-handers owe their handedness to a birth trauma, such as being born prematurely (Betancur, Vélez, Cabanieu, & le Moal, 1990). Interestingly, there have been a disproportionally large number of U.S. Presidents who have been left-handed, including Gerald Ford, George H.W. Bush, Bill Clinton, and Barack Obama.

Summary

The evolutionarily old brain—including the brain stem, medulla, pons, reticular formation, thalamus, cerebellum, amygdala, hypothalamus, and hippocampus—regulates basic survival functions, such as breathing, moving, resting, feeding, emotions, and memory.

The cerebral cortex, made up of billions of neurons and glial cells, is divided into the right and left hemispheres and into four lobes. The frontal lobe is primarily responsible for thinking, planning, memory, and judgment. The parietal lobe is primarily responsible for bodily sensations and touch. The temporal lobe is primarily responsible for hearing and language. The occipital lobe is primarily responsible for vision. Other areas of the cortex act as association areas, responsible for integrating information. The motor cortex controls voluntary movements. Body parts requiring the most control and dexterity take up the most space in the motor cortex. The sensory cortex receives and processes bodily sensations. Body parts that are the most sensitive occupy the greatest amount of space in the sensory cortex.

The brain changes as a function of experience and potential damage in a process known as plasticity. Neuroplasticity allows the brain to adapt and change as a function of experience or damage. The brain can generate new neurons through neurogenesis.

The severing of the corpus callosum, which connects the two hemispheres, creates a “split-brain patient,” with the effect of creating two separate minds operating in one person. Studies with split-brain patients as research participants have been used to study brain lateralization. The left cerebral hemisphere is primarily responsible for language and speech in most people, whereas the right hemisphere specializes in spatial and perceptual skills, visualization, and the recognition of patterns, faces, and melodies.

4.1.2: Cognition, Intelligence, and Language as Psychological Adaptations

Learning Objectives

1. Explain what is meant by the claim that psychological processes, including intelligence, serve adaptive movement
2. Explain why intelligence and cognition are examples of psychological adaptations
3. Explain why natural selection requires recurrent, across-generation conditions to generate adaptations
4. Describe some of the environmental regularities, including several universal recurrent relational features of the world, that may have been genetically incorporated into brain organization generating intelligence, including general "fluid" intelligence
5. Discuss Spearman's definition of "g"
6. Describe the brain areas that are involved in intelligence, broadly defined as brain systems that guide behavior toward successful adaptation
7. Discuss the role of Shepard's concept of "genetic internalization" of biologically important environmental regularities in the evolution of intelligence
8. Discuss three abstract relational regularities of the world which may have been genetically internalized into the brain operations of general intelligence
9. Describe vector coding
10. Discuss mental models, prospection, and intelligence, and list brain structures most directly involved in the formation of mental models/cognitive maps
11. Describe the neural correlates of differences in intelligence across species and the P-FIT theory of differences in intelligence among humans
12. Describe the Broad Visual Perception Factor and the role it plays in the intelligent control of movement/behavior

Intelligence, Cognition, Language, and Biological Adaptation

by Kenneth A. Koenigshofer, PhD.

Overview

After a general review of cortical functions in the previous section, we now examine higher cognitive functions as modes of achieving biological adaptation to the environment. In a previous chapter, you learned about the neural mechanisms of movement. Let's start this module with the premise that, to be useful, movement must be effectively guided in order for it to be responsive to environmental demands and adaptive opportunities. The senses are the first tier in the systems that guide movement (even some single-celled organisms can sense harmful chemicals in their fluid environment and then use their cilia to swim away from them, showing how even a simple guidance system for movement improves adaptation). Imagine you were one of our evolutionary ancestors; if you couldn't sense an approaching saber-toothed tiger and make accurate judgments about its distance and speed, it is obvious that you would be unable to effectively run or hide from it. If you couldn't feel fear and understand danger, you would not be *motivated* to run or hide. Without senses and perception, it would be impossible for you to organize movements to find food or secure a mate.

However, in addition to the senses, perception, and emotion as guidance systems for movement, higher order functions of the brain, some of which were discussed in the chapter on the mechanisms of movement (e.g. premotor cortex, parietal cortex), are also critically involved in the more advanced control of action. In this chapter, we consider intelligence and cognition as part of the sophisticated systems that guide movement in animals and humans to maximize their adaptation to the environment.

We will also consider other research on intelligence with a very different focus. Early work by psychologists interested in human intelligence took a more practical approach. These psychologists in the first part of the twentieth century focused on the development of methods of measuring intelligence in humans. This approach to the study of psychological attributes is called psychometrics. Though early research emphasized the creation and refinement of intelligence tests, rather than the biological origins and functions of intelligence, psychometric analysis of the performance of large groups of people on intelligence tests

(Spearman, 1904, 1925) ultimately led to theories of the structure of human intelligence (Carroll, 1993; Cattell, 1987). These theories are important to biological psychology because they have influenced much of the modern thinking and research on the genetic and brain mechanisms involved in human thinking and intelligence. Additional details about psychometrics and theories of intelligence can be found in Supplement 1, Traditional Models of Human Intelligence, in this chapter.

More recently, intelligence research by psychologists and neuroscientists has expanded to include the study of brain mechanisms underlying intelligence in humans and in other species. This approach has led to conceptions of intelligence and cognition in a broader biological and evolutionary context. On this view, thinking, intelligence, and language are products of evolution, just like other genetic traits of organisms. Thinking, intelligence, and language exist because they helped ancestral humans meet the challenges presented by the environment, challenges which drove natural selection. In short, thinking, intelligence, and language are biological in origin, biological in function, and, of course, they are generated in a biological organ, the brain.

One of the key evolutionary trends responsible for the evolution of intelligence and cognition was genetic incorporation of information about biologically significant regularities of the world into the circuitry and operations of the brain. As a consequence, the brain is equipped with many "cognitive instincts" and innate implicit knowledge about biologically important, enduring regularities of the terrestrial environment, forming the groundwork for much of our genetically evolved intelligence as a species.

This view contrasts with and rejects the "blank slate" view of the mind/brain assumed in the Standard Social Science Model (SSSM), the set of assumptions that much of psychology and the social sciences were founded upon--the view that humans lacked any innate psychological nature and that the mind and brain were essentially blank at birth, leaving it to learning and culture to form human behavior free of genetics and biological evolution. In this chapter, we take a different point of view--that biology, genes and evolution, are the primary determinants of human cognition and behavior, in interaction with learning and cultural influences, which themselves are ultimately biological in nature.

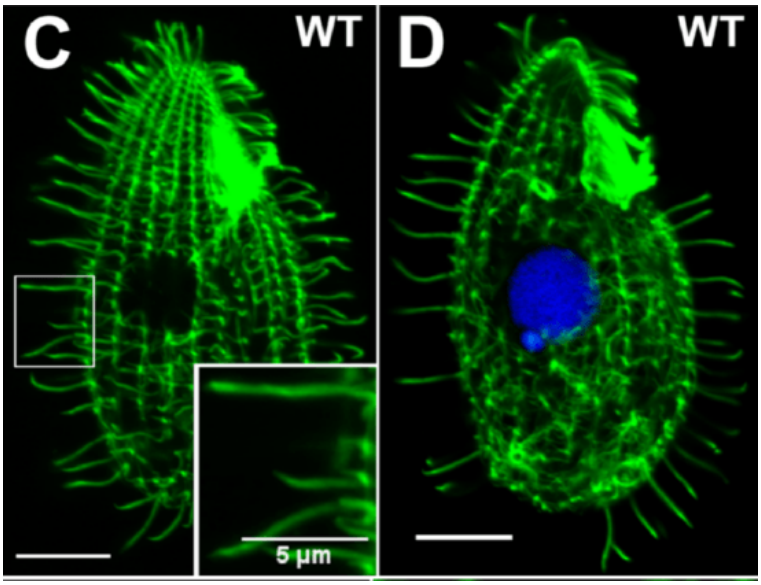

Figure 4.1.2.1: (Left) Lioness hunting in the Serengeti region of Tanzania. Its mechanisms of sensation and perception, emotion, and intelligence are pitted against these same guidance systems for movement found in its prey. Predator-prey interactions may have been an escalating evolutionary impetus for the development of intelligence in both predator and prey. (Right) A single-celled organism featuring its cilia which it uses to move toward favorable parts of its fluid environment and away from harmful regions, thereby facilitating its adaptation. Approach to beneficial elements of the environment and avoidance of and withdrawal from harmful elements is a primary rule governing guidance systems for movement in all motile species. Thinking and intelligence serve the adaptive organization of movement

As argued in the chapter on evolution and genetics, nothing makes sense in psychology except in the light of evolution. This claim is especially relevant for a course in biological psychology. When we consider thinking and intelligence from a biological and evolutionary perspective, it is important to ask what functions they perform for the organism. The brain does all kinds of complex processing, but it is important to understand that for that processing to have any effect on the environment, brain activity must ultimately converge onto motor neurons in the spinal cord ("the final common path") that stimulate the muscles to produce movement--behavior (see the chapter on movement). Like every aspect of our psychology and its corresponding brain activity, the function of thinking and intelligence is to generate adaptive behavior, movement, to successfully meet environmental challenges to survival and reproduction and to exploit opportunities, thereby increasing biological fitness.

Consider plants, for a moment. They don't have intelligence or thinking--they don't need to, because they depend very little upon movement for survival and reproduction--instead, water and their source of energy, sunlight, come to them (plants can move slowly in a limited way; they grow toward sunlight and roots grow toward water sources, but contrast this with all the complex social behaviors modern humans engage in to get food and water--e.g. agriculture, supply chains, plumbing, dams, water companies, etc.). Neither do plants have to flee or hide from predators; they protect themselves with thorns or poisons or simply grow back if partially eaten. Neither do they need to move for reproduction--wind and insects and other animals carry the reproductive cells for them (imagine if this were true for humans! What would happen to human courtship, dating, and romantic love? The purpose of which, from a biological perspective, is to get egg and sperm cells together).

But none of this is true for animals. For animals, including the human animal, movement is key to survival and reproduction, and, as noted above, the movement must be guided to form patterns of action that solve adaptive problems and exploit adaptive opportunities. According to Darwin's theory of evolution, which he explained as "descent with modification," the roots of human cognition and intelligence lie deep in our species' evolutionary ancestry. Evidence for this can be found in Darwin's principle of the "continuity of species" applied to psychology, as shown by the great degrees of

Figure 4.1.2.2: Movement is essential for survival and reproduction in animals. The great Wildebeest migration with over 2 million animals follows the rains to lush new feeding grounds. (Image from Wikimedia Commons; https://commons.wikimedia.org/wiki/F...n_crossing.jpg by Naturaltracksafaris; licensed under the Creative Commons Attribution-Share Alike 4.0 International license. Caption by Kenneth A. Koenigshofer, PhD).

similarity in the guidance and control systems for movement and their underlying brain mechanisms across mammalian species--for example, all mammals have similar brain structures, including limbic structures and cerebral cortex. All species respond to potentially harmful stimuli with threat, attack, or escape. All mammals respond to sexual signals by moving toward and making contact with their source. Each suggests common behavioral control mechanisms evolutionarily conserved across species

But intelligence also exists in non-mammalian species. Intelligence in distantly related species including some birds, such as Corvids (e.g. ravens, jays, crows) and parrots, and in invertebrates such as the octopus and cuttlefish (Adams & Burbeck, 2012; Mather, 2019; Mather & Dickel, 2017), illustrate convergent evolution, suggesting the high adaptive utility of intelligence in diverse ecological niches. Intelligence and thinking, like all psychological processes, evolved to serve the organization of movement to make behavior adaptive, successful, in the Darwinian struggle for survival and reproduction (Koenigshofer, 2011, 2016).

Cognition and Intelligence are psychological adaptations

Intelligence and thinking (i.e. cognition) are psychological adaptations evolved by natural selection over millions of years. A psychological adaptation is a psychological or behavioral trait that has developed through evolutionary processes such as natural and sexual selection and which is encoded into a species' DNA (see Ellis & Ketelaar, 2002). Dicke and Roth (2016) offer a comprehensive definition of intelligence recognizing its role in adaptation to the environment in a wide range of animals and humans:

> According to the majority of behaviorists and animal psychologists, ‘intelligence’ can be understood as mental or behavioral flexibility or the ability
> of an organism to solve problems occurring in its natural and social environment, culminating in the appearance of novel solutions that are not
> part of the animal’s normal repertoire. This includes forms of associative learning and memory formation, behavioral flexibility and innovation rate, as well as abilities requiring abstract thinking, concept formation and insight.

By contrast, Colom et al. (2010) define intelligence simply as "a general mental ability for reasoning, problem solving, and learning."

Figure 4.1.2.3: Because animals cannot photosynthesize, they must move in order to obtain their sources of energy found in plants and other animals--animals which can hide, run, and fight back--unlike the plants' source of energy, the sun. Movement is organized by brain circuitry which has been configured by natural selection over evolutionary time to solve adaptive problems. Here a hyena on the plains of Africa solves the problem of getting sufficient energy to survive and ultimately reproduce its genes. (Image from Wikimedia Commons; https://commons.wikimedia.org/wiki/F...il_breghys.jpg; by Brwynog; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

A typical definition of general intelligence (discussed below) shows how intelligence and general intelligence are terms sometimes used interchangeably, even by psychologists. General intelligence is often defined as "ability to reason deductively and inductively, to think abstractly, use analogies, to synthesize information, and to apply that information to new domains" (Gottfredson, 1997; Neisser et al., 1996).

In spite of some differences in definition among researchers, there is unanimous agreement that intelligence and cognition are properties of brain processes which have been shaped and refined over millions of years of evolution. Once again, Darwin's principle of the "continuity of species" leads us to suspect that there are many similarities between intelligence and cognition in humans and these same processes in animals, especially mammals. To help us understand human intelligence and cognition and their evolutionary origins, many biological psychologists study these processes in other animals, including apes, monkeys, rats, dogs, parrots, and Corvids, such as ravens, jays, and crows. Animals often surprise us with the sophistication of their emotional sensitivity and their intelligence even though they lack language (Huber & Gajdon, 2006; Wasserman, et al., 2006). An interesting anatomical feature of the cerebral cortex is what we might call microprocessors or "chips" in the human cortex. These are columnar structures, known as **cortical columns**, containing approximately 3,000 neurons each. There are approximately 150,000 cortical columns in the human cerebral cortex (Hawkins, et al., 2017) . These structures are very similar from one part of the cortex to another and from one mammalian species to the next and suggest highly generalized computational functions in cerebral cortex, whereas specialized modules or genetically dedicated circuits for processing of emotional and motivational information are localized to subcortical regions of the brain, shared by all mammals (Panksepp & Panksepp, 2000).

Intelligence and cognition (i.e. thinking) are exceedingly complex processes. As a consequence, the brain mechanisms involved in these processes are not well understood. As you can see, even definitions of these processes vary widely in the scientific community. However, all of the definitions above include terms such as reasoning, abstract thinking, insight, or problem solving, processes which themselves are not well defined or clearly understood by psychologists and neuroscientists. This highlights the fact that psychologists and neuroscientists are still in the early stages of gaining a real understanding of how intelligence and thinking work and what neural processes in the brain produce them. Perhaps this is why textbooks in biological psychology have tended to give little or no attention to these processes even though they are perhaps the most wondrous and important products of brain activity.

Psychometrics, the Measurement of Human Intelligence, and "g"

Early in the history of psychology, research about intelligence was not focused upon its evolutionary origins or its adaptive functions. Instead, psychologists concentrated their research efforts on more practical problems such as the measurement of intelligence for classifying students and military recruits. Major study of human intelligence by psychologists began in the early 1900's when psychologists focused on the measurement of intellectual abilities, an approach known as psychometrics. This research approach resulted in the development of intelligence tests and the concept of IQ (intelligence quotient). Additional research in psychometrics, focused on mathematical analysis of performance scores of large populations on IQ tests using a method called factor analysis, which analyzes patterns of correlations between measures. This research led to the finding that people who did well on any particular measure of intellectual performance tended to do well on all such measures. This led

psychologist, Charles Spearman (1904), to hypothesize the existence of a single, unitary "g" factor (g for general) in human intelligence. This g factor referred to a general mental capacity which was hypothesized to be involved to varying degrees in multiple mental abilities including verbal, spatial, mechanical, computational, and other performances. "This *g* factor provides an index of the level of difficulty that an individual can handle in performing induction, reasoning, visualization, or language comprehension tests" and the g factor accounts for "more than half" of the variation among individuals "in a cognitive test or task" (Jung & Haier, 2007, p. 492). The g factor came to be known among psychologists as "general intelligence." Spearman believed that "g" was most closely related to what he called the "eduction [from the Latin root "educere" which means to "draw out"] of relations and correlates," important in inductive and deductive logic, grasping relationships, inferring rules, and recognizing differences and similarities. In the sections below, we examine some key components of intelligence, relevant brain mechanisms, and how intelligence might have evolved.

Conditions required for evolution of psychological adaptations

Understanding the evolutionary origins of intelligence and thinking may offer insights about how they work and about their underlying brain mechanisms. First of all, remember the claim made above that intelligence and cognition are psychological adaptations, or more correctly, a collection of psychological adaptations, each evolved by natural selection to process certain types of information in specific ways. A key principle of how evolution works is relevant here. Evolution by natural selection can only capture information about features of the world that are present generation after generation. This means that any innate brain mechanisms and the innate "instincts" produced by these mechanisms must have been formed as adaptations to regularly recurrent properties of the environment. This is because natural selection requires many generations to work a genetic change in a population (see chapter on evolution and genetics). Without consistent (statistically regular) selection criteria present over many generations, natural selection cannot fashion complex adaptations. For example, if the consistent force of gravity had not been regularly present over generations, land-living vertebrates could not have evolved bones with tensile strength sufficient to adapt to the downward pull of gravity. In this case, these animals would be incapable of movement or even standing. Another example is color vision. The color of many fruits indicates their state of ripeness. Without the ripeness of fruit being regularly signaled by its color, generation after generation, color vision would not have evolved in fruit-eating primates. Stated another way, information about the strength of gravity or about the correlation between wavelength of light and ripeness of fruit could not have been incorporated by natural selection into the evolved adaptations of organisms unless these features of the world were consistently present, and affecting rates of survival and reproduction, generation after generation.

By this reasoning, long-term, across-generation regularities of the world that have adaptive significance should be expected to play a special role in the evolution of the mind/brain (just like they do in the evolution of anatomical and physiological adaptations). As evolutionary psychologists, Tooby and Cosmides (1992, p. 69), state: “Long-term, across-generation recurrence of conditions … is central to the evolution of adaptations." Kaufman et al. (2011, p.213) express a similar idea. They state, "Evolutionary psychologists sometimes argue that a class of situations must be relatively narrow to exert consistent selection pressure, but this claim is insufficiently justified. Any regularity in the environment can exert selection pressure if it poses a challenge or an opportunity to the organism . . ." And as former Stanford psychologist, Roger Shepard, put it, there has evolved "a mesh between the principles of the mind and the regularities of the world" (Shepard, 1987a). This means that the organization of the mind reflects regularities of the world, because of the fact that natural selection operates on conditions that repeat, that are regular, over long periods of time. So, when thinking about the evolution of brain and mind, we should be on the lookout for "instincts" that innately predispose the brain to process environmental inputs using innate principles derived from adaptively significant regularities of the world. In other words, the brain is filled with circuitry that operates by genetically programmed rules derived from information about enduring environmental regularities.

Examples of such long-term regularities or enduring properties of the world are: the widespread presence of environmental stimuli that can damage body tissue; that some things in the environment contain sources of nutrition while others are poisonous; that some potential mates are more likely than others to be healthy and fertile; that snakes and spiders are frequently dangerous; that sugars and fats are concentrated sources of energy; that high status in the social group in social animals gives greater access to resources including mates; and so on. In response to biologically important statistical regularities in the world such as these, neural circuitry has evolved in animal and human brains that causes: withdrawal from harmful stimuli in response to pain; approach toward and consumption of sources of nourishment and avoidance of potential foods that cause illness; powerful innate drives and emotions to mate with sexual partners possessing features indicative of health and reproductive potential (Ellis & Ketelaar, 2002, p. 162; Gangestad & Simpson, 2000); a genetic readiness in humans and other primates to learn fear of snakes and spiders (DeLoache & LoBue, 2009); a startle response to sudden loud noises; status seeking and sensitivity to social standing in social primates; a preference in humans for sugars, salt, and fats; and so on (see Tooby & Cosmides, 2015).

Figure 4.1.2.4: (Left) For most people, spiders like this one induce a strong aversive reaction motivating avoidance and withdrawal behavior, an example of a psychological adaptation evolved to protect us from possible poisoning from this class of stimulus. (Right) Humans have evolved a preference for fats, sweets, and salt, a psychological adaptation from the Pleistocene which can be harmful to health if followed too frequently in the modern urban environment full of fast food restaurants--a very different environment from that of our hunter-gatherer ancestors. (Image on left from Wikimedia Commons, https://commons.wikimedia.org/wiki/F...ia,_Brazil.jpg; by Alex Popovkin, Bahia, Brazil; licensed under the Creative Commons Attribution 2.0 Generic license. Image on right from Wikimedia Commons, https://commons.wikimedia.org/wiki/F..._Bigntasty.jpg; by مانفی in Persian; licensed under the Creative Commons Attribution-Share Alike 4.0 International license. Captions by Kenneth A. Koenigshofer, PhD).

Each of these innate behaviors evolved in response to specific regularities of the world, "recurrence of conditions," that consistently had important adaptive consequences--consequences for survival and reproduction--over countless generations of evolution.

Figure 4.1.2.5: According to evolutionary psychologists, Cosmides and Tooby (2003), forming and maintaining friendships is important to us today because this was one of many adaptive problems that our human ancestors encountered and had to solve in our Pleistocene past. Friendships led to alliances that were important in securing resources within Pleistocene bands of individuals that depended upon one another for survival. For this reason, we are motivated to find friends and having them feels good, reinforcing the behavior. Information processing by the brain necessary for formation and maintenance of relationships is one of the topics studied by biological psychologists interested in intelligence and social cognitive neuroscience. (Image from Wikimedia Commons, https://commons.wikimedia.org/wiki/F...923360765).jpg; by Rod Waddington; licensed under the Creative Commons Attribution-Share Alike 2.0 Generic license. Caption by Kenneth A. Koenigshofer, PhD.).

Evolutionary psychologists have identified some additional recurrent problems that had to be regularly solved by our human ancestors: " . . . winning social support from [group] members, remembering the locations of edible plants, hitting game animals with projectiles, ..., recognizing emotional expressions, protecting family members, maintaining mating relationships, ..., assessing the character [and social valuations] of self and others, causing impregnation, acquiring language, maintaining friendships, thwarting antagonists, and so on" (Cosmides and Tooby 2003, p. 59).

In each case, evolutionary psychologists suspect that brain mechanisms have evolved to contribute to solutions of each of these adaptive problems regularly present generation after generation. On this view, cognition is believed to consist of “many mental rules that are specialized for reasoning about various evolutionarily important domains, such as cooperation, aggressive threat, parenting, disease avoidance, predator avoidance, object permanence, and object movement” (Cosmides & Tooby, 1992, p. 179). But these are not the only kinds of recurrent, across-generation conditions that have been genetically represented by natural selection in brain circuitry. Such regularities can be much more abstract and widely distributed throughout the environment.

Innate (instinctual) Knowledge of Universal Regularities of the World: The Foundations of Intelligence

One approach to understanding the nature and origins of intelligence is the idea that natural selection incorporated information about “general—perhaps even universal—properties” of the world (Shepard, 1992, p. 500) into brain organization over evolutionary time (Shepard, 1992, 1994, 2001). The core idea is that natural selection has selected genes that equip human and animal brains with fundamental information about how the physical world is organized, information that is essential for intelligent adaptation to the environment. This inborn information provides innate "knowledge" about biologically significant, universal properties of the world which have existed continuously for countless generations. This approach also may explain fundamental principles of how our thinking processes are organized and how they evolved.

According to Shepard (1987a, 1992, 1994, 2001), natural selection has favored the genetic incorporation or “internalization” of biologically significant regularities of the world, “whether . . . within a particular species' local niche or throughout all habitable environments. . . . Genes that have internalized these pervasive and enduring facts about the world should ultimately prevail over genes that leave it to each individual to acquire such facts by trial and possibly fatal error” (Shepard, 1994, p.2).

What Shepard means by "genetic or evolutionary internalization" is that natural selection has favored genes that incorporate information into the brain about specific, biologically important, universal regularities of the terrestrial environment. Consequently, information about these enduring environmental regularities, such as the fact that the sun rises and sets approximately every 24 hours, becomes genetically encoded into genes which organize specific brain circuitry or other properties of the brain. In the case of the roughly 24 hour cycle of light and dark, we see daily rhythms of sleep and wakefulness controlled by inborn brain mechanisms and by cycles of melatonin release from the **pineal gland**, a small gland near the center of the brain, which acts on the hypothalamus, involved in the control of these daily cycles. We also see daily cycles of a number of other hormones as well. The release of these hormones is regulated by the **pituitary gland** which itself is under the control of genetically organized circuitry within the **suprachiasmatic nucleus of the hypothalamus**. Animals and humans have many so-called circadian (about a day) rhythms. These rhythms have originated from "genetic or evolutionary internalization" of information about the repeating daily cycle of light and dark into brain organization as a result of natural selection (see chapter on sleep).

Figure 4.1.2.6: A woman sleeping. She does not know that daily cycles of sleep and wakefulness and other circadian rhythms are the result of genetic internalization over the course of evolution of an enduring regularity of the physical environment, the rotation of Earth on its axis (see text below and the chapter on sleep). (Image from Wikimedia Commons; https://commons.wikimedia.org/wiki/F...g_in_Sepia.jpg; by Massimo Danieli; licensed under the Creative Commons Attribution-Share Alike 2.0 Generic license. Caption by Kenneth A. Koenigshofer, PhD.).

Some of these enduring properties of the environment which have been "genetically internalized" by natural selection (Shepard, 1992, 1994, 2001) into the brain's functioning are relatively concrete--such as the approximately 24 hour cycle of light and dark (mentioned above). Others are “three-dimensional, locally Euclidian space” with a "gravitationally conferred unique upward direction," and one-dimensional time with a "thermodynamically conferred unique forward direction" (Shepard, 1992, p. 500). As noted above, circadian rhythms built into us and other species are the result of this "genetic internalization" of the daily light/dark cycle which characterizes the terrestrial environment in all but the polar regions of Earth. The genetic internalization of information about three-dimensional space is evidenced by the presence of "**place cells**" and spatial cognitive maps in the **hippocampus**, as we discussed earlier in Chapter 10 on learning and memory, and involvement of the **parietal cortex** in spatial processing. And one-dimensional time has been internalized into the functional organization of the **cerebellum** where cells which monitor time have been identified (Irvy, et al., 1989; Irvy & Spencer, 2004; Hayashi, et al., 2014). Some additional regularities of the world that have been genetically internalized by evolution may help solidify the point. Objects in the universe tend to have certain shapes, reflectance, and paths of motion and these statistical regularities of the visual world have been "genetically internalized" (Shepard, 1992) by natural selection into the human **visual system** and the visual systems of many other species (Anderson, 2009). Other biologically significant regularities of the world, including regularities of the social environment, leading to evolution of other quite specific components of intelligence (including social intelligence; see sections 18.11 and 18.14) are the recurrent problems of survival and reproduction mentioned above. All of these are examples of how the principles of the mind reflect some of the more concrete regularities of the world (recall the quote above from Shepard).

Natural Selection Favored Representations of Abstract Relational Regularities: Evolution of General Intelligence

In addition to the above relatively concrete regularities of the physical world, there are other enduring and pervasive regularities of the physical environment that are quite abstract and relational and information about these have also been "genetically internalized" into brain operations by natural selection. These relational regularities of the world are **cause-effect**, **similarity, and predictive relations** between objects and events. These relations are so ubiquitous and so familiar to us that often we barely notice them. Yet they are essential to our intelligence. Natural selection has also "genetically internalized" information about these adaptively important relational regularities of the world into our brain organization. As a consequence, our brains are innately predisposed to readily understand cause-effect, to recognize similarity relations which we use to form categories and concepts, and to look for and to find predictive relations among events in the world (Koenigshofer, 2017). This means that we are born with many genetically encoded "instincts" about the abstract, yet fundamental properties of the physical environment. In effect, we inherit some general, universal principles about how the world works. These "cognitive instincts" comprise much of our genetically inherited "general" intelligence ("g," see discussion of "g" above, and also see section 18.11) as a species--properties of the brain derived from eons of evolution by natural selection (Koenigshofer, 2017). These instincts are other ways in which "there has evolved a mesh between the principles of the mind and the regularities of the world" (Shepard, 1987a). Intelligent action depends upon comprehension of causality, similarity, and predictive relations in one's environment.

Causality

Because the world is governed by natural causal laws, **cause-effect** relations between things regularly occur everywhere in the environment and have consistently existed since the beginning of evolutionary time. Such regularities, though abstract and relational, can drive natural selection (Koenigshofer, 2017; see Cosmides & Tooby, 1992, p. 48; Kaufman et al., 2011, p. 213). As a result, this relational property of the world has been genetically internalized, just like information about three dimensional space and the cycles of light and dark, so that our brains (and the brains of many other species) are innately "tuned" to look for and to understand cause-effect in the environment. Penn and Povinelli (2007, p. 98) state: "Animals of all taxa have evolved cognitive mechanisms for taking advantage of causal regularities in the physical world." Evidence for an innate understanding of causal relations in humans comes from experiments showing that children, from a very early age, readily understand cause-effect and use statistical regularities to tease out causes of specific events (see Gopnik, 2010, 2012; Penn & Povinelli, 2007). The inborn predisposition to understand cause-effect as a general property of the world is a central component of human and animal general intelligence and cognition (Koenigshofer, 2017). The famous 18th century British philosopher, David Hume (1748/1988), recognized this fundamental property of thought when he wrote: "All reasonings concerning matter of fact seem to be founded on the relation of Cause and Effect." A modern definition expresses the same idea: "causal reasoning [is] the ability to identify the functional relationship between a cause and its effect (Amodio, 2019).

From the standpoint of biological adaptation, implicit knowledge about causality allows intelligent creatures to navigate and exploit an enormous variety of complex causal relations, to make causal inferences and predictions, which benefit adaptation to the problems and opportunities presented by the environment. A chimpanzee who understands that putting a long stick into a termite hill will cause termites to bite onto the stick gets a lot more juicy termites to eat than a chimpanzee who does not understand this causal relationship (Goodall, 2000). Birds have been observed to toss small pieces of food that float on the surface of a pond to lure fish to the surface where they can be captured more easily. Human understanding of complex causes led to the control of fire, the invention of cooking and agriculture, the construction of shelters and tools, and other innovations making it possible for our species to successfully occupy every region of the planet.

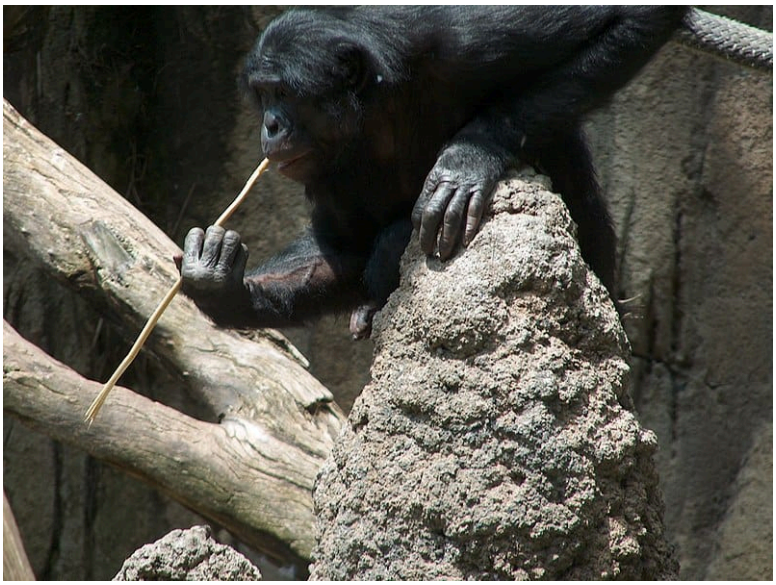

Figure 4.1.2.7: Bonobo chimpanzee termite fishing. (Image from Wikimedia Commons; https://commons.wikimedia.org/wiki/F...r_termites.jpg; by Mike Richey; licensed under the Creative Commons Attribution-Share Alike 3.0 Unported license. Caption by Kenneth A. Koenigshofer, PhD.).

If humans and at least some animals are born with an innate disposition to understand cause and effect, we should expect to find brain structures that seem to be especially involved in perception of and reasoning about cause-effect. Brain imaging studies show that "specific brain networks are involved in the extraction of causal structure from the world" (Fugelsang, et al., 2005, p.45). Cues humans use to determine if two events are causally related include covariation (things occur together), temporal order, contiguity (closeness) in time and space, information about possible causal mechanism in the specific instance of causality being examined, and similarity between cause and effect. Analysis of immediate *visual perception* of causality in humans using fMRI implicates several brain structures including **right middle frontal gyrus**, **right inferior parietal lobule**, **right prefrontal, right parietal, and right temporal lobes** (Fugelsang, et al., 2005). Fugelsang, et al. (2005) also reported that **right parietal cortex** was involved in *spatial cues of causality* (spatial contiguity) and **right temporal cortex** was involved in processing *temporal cues* (temporal contiguity) *of causation*. **Right prefrontal cortex** showed increased activation for both or either type of cue for causation. **Bilateral prefrontal** cortical activation was seen with tasks requiring **logical inference** to make a judgement of causation. These results add to understanding of how the visual system extracts causal information from spatial and temporal cues and further suggests that *causality arising from inference and real world knowledge,* rather than from direct perceptual experience, may correspond to **bilateral activation of** the **prefrontal cortex**.

Fugelsang et al. (2005) state that their findings confirm theories that *extraction of causality is inherent in the visual system*, akin to the innate Gestalt principles of completion of partial contours and perceptual grouping based on similarity or spatial proximity. In addition, "perception of causality appears very early in human life and is culturally invariant" supporting the view that the "visual system may be specially tuned to recover causal structure from the environment" (Fugelsang, et al., 2005, p. 41). Several other studies also support the hypothesis that **extraction of causal structure** is an **innate** property of the brain structures of the visual system (Blakemore, et al., 2001; Fonlupt, 2003; Roser et al., 2005). Perception of causality is immediate like perception of motion or perception of faces suggesting innate mechanisms for perception of causation. Some authors have suggested that the detection of causality may even be served by a specialized brain module for recognizing and understanding causality (Leslie & Keeble, 1987; Scholl & Nakayama, 2002). Furthermore, infants are sensitive to physical causality at only 6 months of age (Leslie & Keeble, 1987; Oakes, 1994).

The exact brain areas activated during detection of causation depends on a number of factors. Judgments of causality that require integration of a working hypothesis with relevant data activate neural tissue in **prefrontal and occipital cortices**. In addition, evaluation of data that is consistent with a *plausible* causal theory, was reported to recruit neural tissue in the **parahippocampal gyrus.** By contrast, **e**valuation of data inconsistent with a plausible causal theory recruited neural tissue in **anterior cingulate, left dorsolateral prefrontal cortex, and precuneus,** suggesting a neural mechanism by which working hypotheses and evidence are integrated in the brain (Fugelsang & Dunbar, 2005). These empirical studies support the theory that, *over the course of evolution, information about cause-effect relations has been genetically internalized into the brain*. Innate understanding of causality is *a highly adaptive component of intelligence* in humans and animals. For example, without an understanding of causality, the planning and execution of goal-directed action on the environment would not be possible.

Similarity

It is a fundamental property of the world that things show similarity to other things in various features and at varying levels of abstraction (i.e. "There is nothing new under the sun."). An apple is similar to other apples and apples are similar to many other fruits. A wolf and a panther are both dangerous predators. All birds have beaks and wings. Prey animals frequent water holes. Both an obsidian knife and an obsidian arrowhead can penetrate a prey animal's flesh. Fast flowing rivers are dangerous to cross. Similarities among things in the world hold important adaptive information. Similarity allows categorization, prediction, and inferences based on generalization. If in the past I have witnessed fast flowing rivers wash people away, then when I encounter another fast flowing river, I can use the similarity to make the prediction that crossing this river could be dangerous, so I adjust my behavior accordingly and perhaps save my life.

This seems so obvious that we can't imagine not behaving so. It would be very stupid, not to be able to take advantage of similarities between past experiences and a current situation, especially when it might mean life or death. And that is exactly the point. It would be stupid, but we and other animals are not stupid, but the reverse, we are intelligent. But where did this ability for generalization come from? It is in our brain so firmly that we readily make such judgments of similarity, and generalize from them to make predictions, and we do this with such ease that we don't even think about it. But in neuroscience, it is those things that we do with greatest ease that most require explanation.

Extraction and exploitation of information such as this, contained in similarities, is an extremely powerful adaptive opportunity which natural selection could not have missed during the course of brain evolution. The fact that generalization and even categorization are found in a wide range of animal species (Soto & Wasserman, 2015) shows that these species are capable of using similarities in the environment to improve adaptation and biological fitness. This suggests that the adaptive information present in similarities drove the evolution of brain mechanisms, from early on, that could efficiently extract this information and put it to adaptive use, at least in birds and mammals, and perhaps in other animal groups as well (e.g. generalization has been found even in some insect species; see below).

Thus, “evolutionary/genetic internalization” (Shepard, 1994, p. 26) by natural selection of similarity, as an abstract, ubiquitous property of the world, provides another innate principle of how intelligence and cognition are organized. Just like we and many other animals have a "cognitive instinct" to understand and to experience the world in terms of cause-effect, we have a cognitive instinct to detect and readily utilize similarities to organize adaptive behavior and improve biological fitness.

Both causality and similarity are properties of how the physical world is put together and both have been incorporated into evolved mechanisms of intelligence in the brain. This makes sense. The brain must organize movement, behavior, in the physical world on our planet and therefore brain mechanisms must be effective in guiding behavior in that physical world. To do so, intelligence must have evolved to reflect and be organized around the general principles of how this physical world works--it operates by these universal principles, cause-effect and the fact that things in the world are naturally similar to other things in ways that provide organisms with information that is important for adaptation.

Genetic internalization of similarity as a general feature of the world created a disposition in human and animals brains to “expect” and to find similarities in the world, to group things by similarity into categories, to readily match new instances to the appropriate category based on similarity, and to infer properties of new instances of a category based on knowledge of properties of the category as a whole. The cognitive processes of generalization, concept formation, categorization, inductive reasoning, categorically based inference, and categorical logic, all emerged as a family of related functional properties of the brain as natural selection fine-tuned the **genetic/evolutionary internalization of similarity** as a fundamental relational regularity in the world (on this basis, it is expected that these cognitive abilities should be correlated). These observations are reflected in “what William James (1890/1950) called ‘the very keel and backbone of our thinking’: sameness. The ability to evaluate . . . similarity . . . is clearly the sine qua non of biological cognition, subserving nearly every cognitive process from stimulus generalization and Pavlovian conditioning to object recognition, categorization, and inductive reasoning” (Penn et al., 2008, p. 111). Note that many of these psychological capabilities are the same ones identified earlier in the definition of general intelligence from Gottfredson (1997).

As noted above, **similarities hold important adaptive information**. Similarities bring order out of chaos. They allow inference and prediction. If you know about one leopard as a member of a category of dangerous things, then you know about many leopards, perhaps all leopards, even those you have yet to encounter. If and when you encounter a leopard again, you already know much about it that can be put to use to organize your response, your behavior, and that knowledge that you gain from an inference about this new leopard, based on the category to which it belongs, may save your life. Evolution has "tuned" our brains to find similarities among things in the world--along with genetic internalization of causation, another exceedingly powerful property of general intelligence as described earlier. As noted above, the inborn disposition of the brain to find and record similarities in the environment guides us (our brains) to form categories and concepts of varying degrees of abstraction which embed adaptive information within them (e.g. all saber-toothed cats are dangerous; pieces of flint are sharp making them a good source of

cutting and scraping tools; all Datura flowers are poisonous; things with feathers that fly are all birds; situations where someone is treated unfairly are all examples of injustice; all atomic particles with a negative charge are electrons, and so on). Categories and concepts are one way in which the brain captures the information contained in similarities in the world and forms knowledge structures that reflect and exploit one form of order in the environment, that order that arises from similarity, thereby improving the guidance of movement, increasing successful adaptation by intelligent action.

Recall that Shepard argued that “the evolutionary internalization of universal regularities” (1994, p. 26) included “three-dimensional, locally Euclidian space,” one-dimensional time with a "thermodynamically conferred unique forward direction," and cycles of light and dark. The genetic internalization of these regular features of the world underlies important components of our ability to understand the world. However, in addition, Shepard has also argued that there has been "evolutionary internalization" of the recurrent fact of the world that "objects having an important consequence are of a particular natural kind . . . however much those objects may vary in their sensible properties . . . " (Shepard, 1992, p. 500). In other words, things can be categorized on the basis of their consequences, regardless of their superficial physical properties. This more abstract form of similarity leads to grouping things which otherwise differ in surface ways but which share the same category of effects, for example, all large predators including bears, wolves, sharks, etc. are dangerous. Other things with very different superficial features may all be good to eat, or poisonous, or have other important adaptive consequences by which they can be grouped. This kind of more abstract categorization, based on similarities in effects, allows a higher level of behavioral guidance by the brain. Some of these categories and the behavioral responses to them may even be innate. For example, feces or spider-like things may innately cause feelings of disgust or fear and lead to withdrawal and avoidance behavior, thereby protecting the organism from potential harm from pathogens or a poisonous bite. The claim that "objects having an important consequence are of a particular natural kind" is basis for Shepard's “universal law of generalization” (Shepard, 1987b), a law which has been verified in diverse species including insects (e.g., see Cheng, 2000).

A quick review is important here. The psychological process of generalization exemplifies a basic property of human and animal minds--that they tend to form groupings, categories, based on similar instances (Broschard, et al., 2021), and then, exploiting these groupings, the mind/brain uses generalization to make inferences or projections about new instances of a category. For example, if you have encountered a number of cats in your past, you will form a grouping in your mind, a category, "cat," and when you see another creature in the future similar to previous cats you have encountered, you can already make a number of inferences about this new instance of the category--e.g. it has claws, it purrs, it eats mice, etc. You can infer these properties even though you have just encountered this particular cat only a few moments before. Because of categorization and generalization, you can make inferences and predictions about this new creature which you have recognized as a member of the category, "cat," based on similarities among all cats. This is an exceedingly important component of our thinking processes and our intelligence. We use this type of process much of the time when we are engaged in "thinking" and "reasoning."

Recognizing similarities among things, and using those similarities to make useful inferences and predictions has exceedingly beneficial effects on survival and sometimes directly upon reproduction. For example, chimpanzee males of lower status have been observed to steal a mating opportunity usually not available to them, when a more dominant male is sufficiently distracted. When a lower status male observes more dominant males fight these males are usually distracted from other matters. If in most situations where dominant males are fighting they are distracted from their watch over their favorite females in the group, and if a lower status male chimp recognizes a similarity between a current fight between dominant males and past such battles, and if, based on the similarity, he infers that during a current fight between dominant males, he likely has a mating opportunity (especially if he is quick), he may successfully mate with a desirable female that he would not otherwise have access to. Males who can make inferences like these based on similarity have a higher reproductive rate than males who cannot make such inferences.

Ancestral humans who recognized similarities between a new animal, never encountered before, and predators encountered in the past, can put this new animal in the category "dangerous predator" and then infer that this new animal is probably also dangerous and should be avoided. The adaptive value of this inference based on similarity is immediate. Imagine an ancestral human who had brain organization incapable of recognizing similarity at all and consequently could not form categories and concepts, and therefore could not make any inferences based on similarity. In this hypothetical case, where similarity to previous predators holds important survival information, clearly survival is at stake, and if one had a brain incapable of exploiting the survival information in similarity then one's chances of seeing another day are vastly reduced and the genes responsible will probably soon be eliminated (an instance of natural selection at work).

Research suggests that category formation depends on the **prefrontal cortex** in humans, and on the pre-limbic cortex in rats (Broschard, et al., 2021). Studies of brain damaged humans also implicate a subcortical involvement of the **striatum**. Specifically, Lagarde, et al. (2015) report involvement of "*a prefrontal-striatal loop in abstract categorization*, and more particularly, the involvement of the head of the **caudate** nuclei and **left frontal lobe** in access to abstract representations in verbal concept formation." To emphasize the point once more, the ability to form groupings, or categories, based on similarity, and to then make inferences about newly encountered instances of the category, is a powerfully adaptive property of the brain's operations.

Categories and concepts based on similarity permit our brains to make inferences about newly encountered instances of the category or concept, like those in the examples above. Categorization, formation of concepts, and inferences based on similarity are key features of general intelligence. All of these cognitive abilities can be understood as arising from the genetic internalization of similarity relations into brain organization by natural selection (Koenigshofer, 2017).

Predictive Relations (Predictive Co-occurrence of Events)

In addition to causality and similarity, it is also an enduring property of the world that some things regularly predict the occurrence of other things (a growling bear predicts an impending attack, sudden heavy rainfall predicts possible flash flooding, an approaching range fire predicts potential danger, a water hole on the plains of Africa predicts that prey animals will be near, and so on). Clearly, **predictive relations** are present everywhere in the environment. It is also clear that predictive relations among things in the world hold exceedingly important adaptive information. This source of adaptive information is far too important for natural selection to have missed it. Thus, we should expect that natural selection must have organized brain systems that capture, not only causality and similarity, but also the *predictive relations* between events in the world. Using Shepard's (1992) terminology, we should expect that over the course of brain evolution, there occurred the "genetic internalization" (Shepard, 1992) of mechanisms that capture predictive relations between events. These mechanisms underlie another central component of general intelligence in humans and many animals.

The brain evolved for prediction (Clark, 2013, 2016; Nave, et al., 2020). The brain can be characterized as "a probabilistic prediction engine" (Nave, et al., 2020, p. e1542). It is not only evolved for prediction, but to implicitly make probability assessments about how likely its predictions about future are to be true. Natural selection for brain organization that captures the adaptive information in predictive relations has predisposed us (i.e. tuned our brains, and the brains of other animals) to find and to exploit the adaptive information held in predictive relations, an exceedingly adaptive property of general intelligence. Predictive relations exist whenever specific events, objects, or situations consistently co-vary or correlate--whenever one thing consistently follows another; for example, think of the CS and US in classical conditioning. After conditioning has occurred, the CS predicts the US. This implicit prediction then controls behavior--the dog salivates immediately after the CS is presented in anticipation of coming food, a response that prepares the dog for the expected arrival of the US (e.g. the dog drools, and this saliva prepares the dog to swallow and digest efficiently if the expected food follows). As discussed in the chapter on learning and memory *classical conditioning* specifically involves the **cerebellum**, whereas associations, in general, between co-occurring events appears to depend on **long-term potentiation (LTP)**, and corresponding changes at synapses in **hippocampus** (Oishi, et al., 2019), **cerebral cortex** (Daw, et al., 2009; De Pasquale, et al., 2014) and other brain regions.

The adaptive significance of this property of general intelligence is hard to overestimate. An innate predisposition built into the brain to search for predictive relations in the environment and to exploit the adaptive information in those relations is an exceedingly powerful cognitive tool for understanding the world. Using this information to make biologically important predictions (a low growl in the nearby brush may be soon followed by an attack from a large predator), to organize behavior serves biological fitness (survival and reproduction of one's genes). To understand the powerful effect on adaptation of an innate disposition to recognize and exploit predictive relations between events in the world, just imagine the crippling effects on survival if this ability were absent in animals and humans. If you had no knowledge of *what follows what* in the environment, the world would seem a chaotic jumble of unrelated events. In such a world, it would be very difficult if not impossible to organize adaptive action to survive the demands of a complex environment. One might speculate, and this is only speculation, that something like this might be how some persons with autism experience the world; perhaps the inability to understand cause-effect or to recognize similarities in order to form categories and make sensible inferences, or inability to recognize predictive relations in the world, or perhaps loss of all three of these abilities might be responsible for some of the symptomology of people who are very severely autistic. The world would seem to lack any order at all without these cognitive abilities. Ordering movement into adaptive patterns would be exceedingly difficult if not impossible.

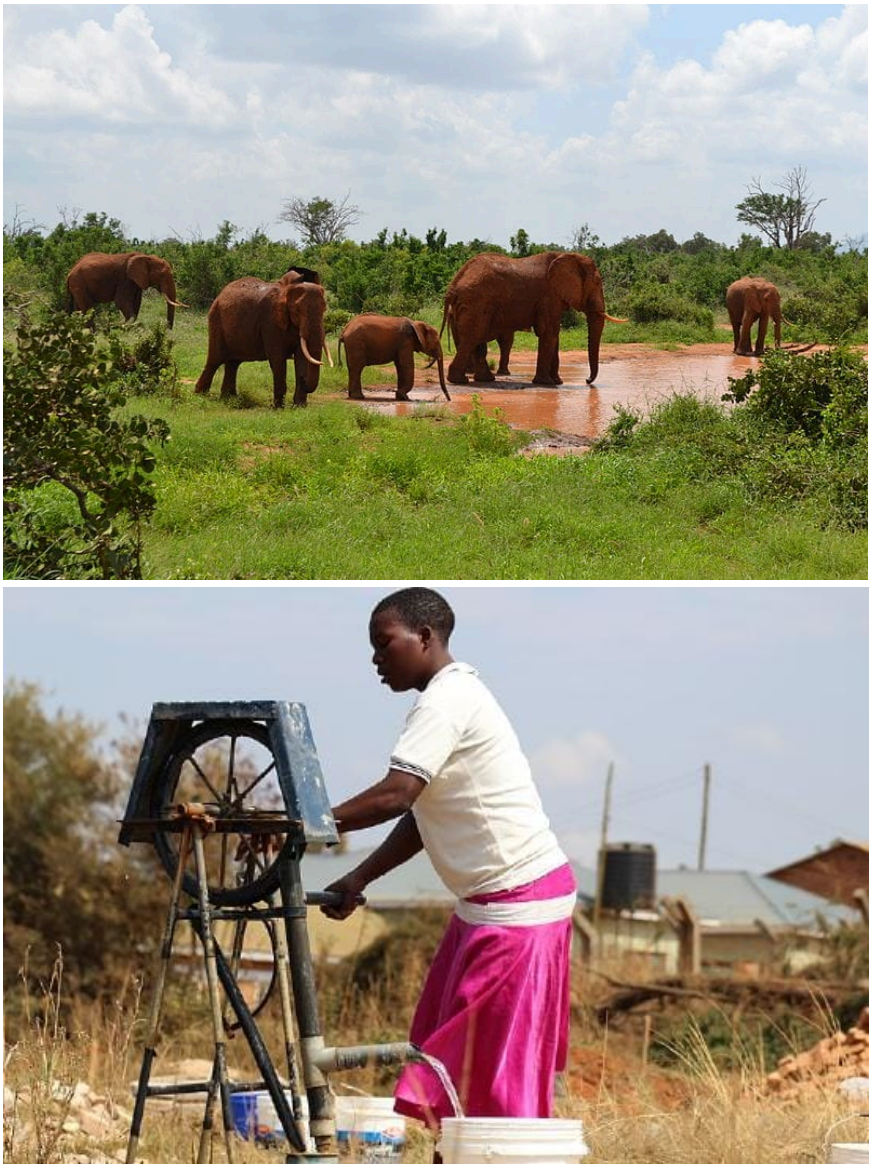

Figure 4.1.2.8: Contrasting behaviors to satisfy water needs in two species. The woman uses invention and technology, two products of human intelligence, to provide a more consistent and higher quality water source. Koenigshofer, PhD).

Intelligence: Cognitive Instincts and "the Infinite Use of Finite Means"

Recall this quote from above: "Evolutionary psychologists sometimes argue that a class of situations must be relatively narrow to exert consistent selection pressure, but this claim is insufficiently justified. Any regularity in the environment can exert selection pressure if it poses a challenge or an opportunity to the organism . . . (Kaufman, et al., 2011, p. 213)

In the case of the abstract relational regularities which drove the evolution of general intelligence, the adaptive opportunity is difficult to overstate. The genetic internalization by natural selection of fundamental information about these abstract relational regularities in the environment has equipped the mind with an exceedingly powerful set of cognitive structures--a set of inborn, general, rule-like principles of how the world works. Deployment of this inborn, implicit “understanding” about causality, similarity, and predictive relations gives general intelligence (g) its adaptive punch because it permits innovative and improvisational solutions to an enormous variety of adaptive problems. This is an example of what Steven Pinker (2007) calls the “infinite use

of finite means," applying a finite set of rules to understand and to solve an enormous variety of adaptive problems and to exploit the diverse opportunities in the environment. We see the power of human general intelligence in the stunning progress in human cultural and technological development from prehistoric times to the present. The existence of **general intelligence** (sometimes called "**fluid intelligence**") contradicts the traditional view sometimes ascribed to evolutionary psychologists that there are specialized modules in the brain for every problem type that ancestral humans had to solve (this is the theoretical assumption of the "massive modularity" of the human mind which leaves no room for more general cognitive processes including general intelligence--see Lloyd & Feldman, 2002; but for an alternative view held by most evolutionary psychologists, "soft modularity," which does allow for some general cognitive processes, see Ellis & Ketelaar, 2002). However, arguably there is no real contradiction if one understands that general intelligence is actually composed of several adaptive specializations that have genetically internalized the abstract properties of causality, similarity, and predictive relations. It is the internalization of these relations, because they are universally present in the world, that gives the mistaken impression of "general process" mechanisms which in fact are actually evolved adaptive specializations to these three specific abstract relations found in the structure of the world (Koenigshofer, 2017).

Genetically internalized information about causality, similarity, and predictive relations as general features of the structure of the world creates a scaffolding of **instinctual knowledge** which **guides** the **learning** of specific details of these relations in **one's own particular environment**, an environment full of specific, perhaps even unique, instances of these pervasive relational regularities of the world (Koenigshofer, 2017). For example, understanding causality as a general principle of the world allowed our ancient ancestors to learn that fire could be used to cook meat making it easier to digest; that setting well-placed fires on grasslands could be used to heard prey animals toward an ambush to facilitate the hunt; that some stones could be shaped into spear heads and tips of arrows; and that skins of animals could be taken and used for clothing. This same instinctual knowledge about causality permitted modern humans to learn how to make and use concrete to lay building foundations; to learn that fertilizers increase crop yields; that rising interest rates cause stock prices to fall; and that sunlight could be converted to useable electricity.

Innate knowledge about cause-effect as a general property of the world allows humans to analyze complex causal relations to solve a wide range of adaptive problems with creativity and innovation unprecedented in the animal kingdom. For example, while most animals seek shelter in vegetation, or in caves, or other features of the natural habitat, humans build castles, houses and skyscrapers. While other animals walk and run or fly to move from one place to another, humans invented the wheel, engines, and steel and now ride in cars, trains, planes, or even a Blue Origin space capsule. While most animals hunt for water and food, humans have invented plumbing, water companies, agriculture and supermarkets. While animals fight with teeth and claws, humans have invented and used spears, guns, and nuclear weapons. These intellectual achievements involve a general understanding of causality, similarity, and predictive relations as well sophisticated understanding of three dimensional spatial relationships, ability for visualization, and culturally transmitted knowledge accumulated and transmitted over generations, primarily and most efficiently by language.

This view that we are born with genes which give our brains innate knowledge about many things in the world is a radical departure from the view that the mind is a **blank slate** at birth. This conception of the mind was promoted by a group of influential 18th century philosophers known as the British Empiricists (such as John Locke). This view of the human mind has been carried forward all the way into 21st century social science and philosophy. Evolutionary psychologists, Cosmides and Tooby (2007), call this old empiricist view of the mind the **Standard Social Science Model (SSSM)**. We now know that this blank slate view of the mind/brain (SSSM) is wrong. For example, as mentioned earlier, Alison Gopnik and her colleagues at Berkeley (Gopnik and Sobel, 2000; Gopnik, et al., 2001; Gopnik, et al., 2004) have found that children, at a very early age, readily discover cause-effect and predictive relations between events in the laboratory, supporting the view that the human brain is genetically predisposed to understand abstract relations such as causality and predictive relations among things in the world (Koenigshofer, 2017). Evolutionary psychologists, Cosmides and Tooby, call the blank slate view of the human mind (the SSSM) "**biologically naive**," "radically defective," and an outdated, theoretical leftover from the days of radical behaviorism.

Cognitive Instincts and Intelligence

As was described in the theoretical account above, the brain has *genetically internalized by natural selection* crucial information about regularities in the world of varying degrees of concreteness and abstraction. This equips us and other animals with inborn, instinctual knowledge about many enduring facts about the environment. Snakes, spiders, and heights have been consistently dangerous to humans generation after generation so natural selection has built this across-generation fact into our brain circuitry in the form of fear circuits readily activated by these stimuli. Certain facial and body forms in the opposite sex are consistently associated over generations with health and high reproductive potential so we have brain circuitry that innately attracts us to these body and facial forms. Three-dimensional space, the forward progression of time, cycles of light and dark, and Shepard's universal law of generalization have been "genetically internalized" into the brain over eons of evolution. And, as we have just

discussed, natural selection has "genetically internalized" information about some quite abstract and universal regularities of the world: causality, similarity, and predictive relations. As a consequence, we are innately predisposed to understand cause-effect, the three-dimensionality of space, the progression of time, similarity relations used to form categories and concepts, to fear snakes and spiders, to seek particular traits in sexual partners, to look for and find predictive relations among events in the world, to understand the minds of others, to protect our young, to form and maintain friendships, and so on. This means that we are born with many genetically encoded "**cognitive instincts**" which make up much of our genetically **inherited intelligence** as a species, the consequence of eons of natural selection.

Details of how natural selection could bring about the genetic internalization of abstract relational regularities of the world (causality, similarity, and predictive relations) are described elsewhere (see Koenigshofer, 2017). Suffice it to say, that adaptive problems and opportunities, though variable or even “novel” in details, are nevertheless invariant in common abstract, relational structure. That recurrent structure provides stable selection criteria over generations for genetic internalization. Since natural selection can only operate over many generations, the specific details of individual cases of each of the abstract relations (cause-effect, similarity, predictive relations) drop out over generations. This leaves only enduring, across-generation, "distilled" abstract relational regularities (independent of specific concrete contents) to act as selection criteria for the genetic internalization of these relational regularities of the world into brain operations. This process has apparently taken place not only in humans, but also in some number of non-human animals as well, since **general intelligence** has also been identified in a variety of non-human **animal species** (Bird & Emery, 2009a, 2009b; Reader, et al., 2011), as well as in humans.

What makes humans so smart?

According to the theoretical views explained above, genetic internalization of these enduring, across-generation, abstract, relational regularities of how the world works drove the evolution of flexible general intelligence in humans and many other animal species. But what makes humans so smart compared to other species on the planet? One key difference between human intelligence and intelligence in non-human animal species is the much higher degrees of **abstraction** that humans are capable of representing, compared to other animals. The ability of the human brain for high levels of abstraction, setting it apart from the brains of other species, is likely due to the greater complexity of circuits in human cerebral cortex compared to other mammals (recall that only mammals have six layered cerebral cortex and approximately 150,000 cortical columns--discussed above--while non-human mammals have significantly fewer). Humans easily detect highly abstract similarities in the environment compared to non-human animals and are capable of forming highly abstract categories and concepts based on these abstract similarities in properties or functions (Koenigshofer, 2017; Penn et al., 2008). For example, Penn et al. (2008) found that the use of causal principles and similarity assessments of high degrees of abstraction is a distinguishing feature of human cognition and problem solving. As they state: “Even preschool-age children understand that the relation between a bird and its nest is similar to the relation between a dog and its doghouse despite the fact that there is little “surface” or “object” similarity between the relations’ constituents” (Penn et al., 2008, p. 111).

Research in molecular genetics suggests one possible explanation for how human ability for high levels of abstraction may have come about. Pollard (2009), comparing human and chimpanzee genomes, found “massive mutations” in humans in the “DNA switches” controlling size and complexity of cerebral cortex, extending the period of prenatal cell division in human cerebral cortex by several days compared to our closest primate relatives. Research using **artificial neural networks** suggests that increasing cortical complexity leads to sudden leaps in ability for abstraction and rule-like understanding of general principles (Clark, 1993), lending further support to the hypothesis that **superior ability for abstraction due to cortical complexity** may be the key component explaining differences in general intelligence between humans and nonhuman animals (see module on artificial neural networks in this chapter).

The frontal cortex is involved in concrete rule learning. **More anterior regions** along the rostro-caudal axis **of frontal cortex support rule learning at higher levels of abstraction.** These abilities for high levels of abstraction may involve **anterior dorsolateral prefrontal cortex** in humans (Kroger et al., 2002; Reber, Stark, and Squire, 1998). Along with human language, the exceptional capacity of the human brain for abstraction may explain the unusual achievements of the human species ranging from agriculture, technology and science, to the invention of complex economies and governments (Koenigshofer, 2016, 2017).

Furthermore, **cultural transmission** of learned information in humans, ranging from books and educational institutions to film and the internet, allows each generation to profit from the accumulated knowledge of prior generations (it might even be said that cultural transmission is a key specialty of the human species). Cultural transmission, along with cooperative problem solving and development of experts in different fields, creates a kind of **group intelligence** not possible in other species. Of course, human language, spoken and written, plays an enormous role in these shared cognitive processes among humans, perhaps explaining at least in part why language evolved. These considerations bring to the forefront the role of culture in human genetic evolution. **Gene-culture coevolution theory** proposes a multidirectional coevolution between genes and culture in which culture

and human created artifacts such as tools, weapons, clothing, and pottery have driven the last 100,000 years of human evolution (Lloyd & Feldman, 2002; Durham, 1991). This theory also assumes an important role for **language in cultural transmission of learned knowledge** and behavior. It also postulates existence of hominin biological changes that facilitated development of sophisticated language in humans (Lloyd & Feldman, 2002).

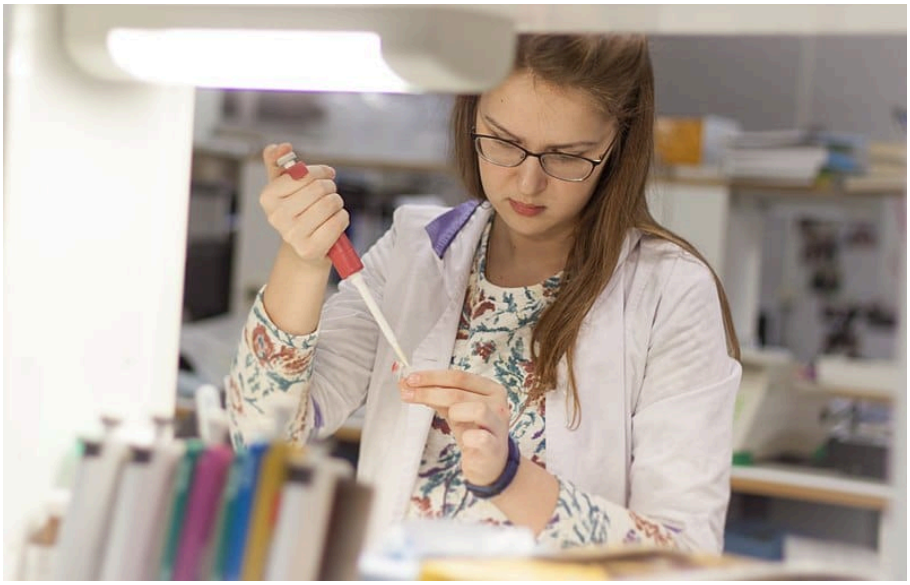

Figure 4.1.2.9: Scientists seek cause-effect, similarity, and predictive relations between variables. Scientific methods are an example of human general intelligence at its best. Alison Gopnik (2010, 2012) at UC Berkeley has found that young children engage in logical analysis of causation, teasing out causes from non-causal factors, in much the same way that scientists do. (Image from Wikipedia, https://commons.wikimedia.org/wiki/F..._reaction).jpg; by Alenakopytova; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

Another factor that may contribute to the superior intellectual capacities of humans is the sophisticated control systems in the human prefrontal cortex. Miller and Cohen (2001) proposed that “cognitive control stems from the active maintenance of patterns of activity in the **prefrontal cortex** that represents goals and means to achieve them. They provide bias signals to other brain structures whose net effect is to guide the flow of activity along neural pathways that establish the proper mappings between inputs, internal states, and outputs needed to perform a given task.” On their view, the prefrontal cortex (PFC) guides the flow of neural activity in relevant brain areas, which allows for cognitive control of behavior. As they state: "depending on their target of influence, representations in the PFC can function variously as attentional templates, rules, or goals by providing top-down bias signals to other parts of the brain that guide the flow of activity along the pathways needed to perform a task" (Miller & Cohen, 2001).

Goldman-Rakic (1996) proposed that the **prefrontal cortex** represents information not currently in the environment, creating a "**mental sketch pad**," to hold visual images in working memory, to represent plans, and to focus attention to intelligently guide thought, action, and emotion. This includes the inhibition of distracting thoughts, actions, and feelings. Although such control does exist to some degree in some non-human animals it is less developed and less influential over behavior than in our own species. The prefrontal cortex is highly interconnected with much of the brain, including extensive connections with other cortical, subcortical and brain stem sites. The **dorsal prefrontal cortex** is especially interconnected with brain regions involved with attention, cognition and action, while the **ventral prefrontal cortex** interconnects with brain regions involved with emotion. According to Striedter (2005), the **prefrontal cortex** (PFC) of humans consists of two functionally, morphologically, and evolutionarily different regions: the **ventromedial PFC** (vmPFC) composed of the ***ventral prefrontal cortex*** and the ***medial prefrontal cortex*** present **in all mammals**, and the **lateral prefrontal cortex (LPFC)**, composed of the ***dorsolateral prefrontal cortex*** and the ***ventrolateral prefrontal cortex***, present **only in primates**.

Mental Models of the World: Capturing Environmental Regularities for Prediction and Planning for Future

Think for a moment about the complexity of the environment that animals like us must adapt to. We live in a world that consists of

inanimate and animate objects, including our own body, that move and change in space and time. Forces that operate on objects can be physical like gravity and the laws of motion, while for people and animals, additional forces acting on them can be social, emotional, or generated by physiological or other needs and motives. The relations among things can be spatial (e.g. the lion is approaching me from my right), temporal (e.g. right after the bell rang a pellet of food appeared), causal/logical (germs cause disease), predictive (one event signals that another event is about to follow), social (interactions among conspecifics), and can reflect similarity (a bear and a wolf are both large predators) and differences (wolves hunt in packs, bears don't), as well as other entities of even greater levels of abstraction.

To successfully navigate this incredibly complex world and its causal and other contingencies, the brain must have accurate neural representations or mental models, inclusive of all of these objects, forces, and relations, in order to guide adaptive behavior. Consequently, evolution has equipped us with a brain that generates **neural representations (mental models or "cognitive maps")** of things (including ourselves, other people, animals, processes, etc.), the relations among them, and the forces that operate on them in three-dimensional space and time (see Behrens, et al., 2018). Many psychologists and neuroscientists have recognized the importance of mental models in the intelligent organization of behavior. "Mental models are psychological representations that have the same relational structure as what they represent. They have been invoked to explain many important aspects of human reasoning, including deduction, induction, problem solving, [and] language understanding, . . . [and they are] also valuable for providing new understanding of how minds perform abduction, a kind of inference that generates and/or evaluates explanatory hypotheses" which focus on explaining causal mechanisms (Thagard, 2010, p. 447). "[T]hese models underlie deductive, inductive, and abductive reasoning yielding explanations" that permit us to understand the world (Khemlani, et al., 2014) and then to use this understanding to predict, to plan, and to manipulate objects and events in the environment to human advantage. In an important sense, the use of mental models to generate adaptive behavior encompasses much of what we mean by intelligence.

Neural Coding and Mental Models

Mental models are thought to be **generated by the activities of large populations of neurons** in the brain. One theory of how this is done proposes that complex ideas, concepts, perceptions, memories and other mental structures are represented by specific patterns of neural firing, over different regions of brain, in enormous numbers of neurons, each "tuned" to fire to a specific feature or to a specific value of a feature or property of the world (recall Hebb's idea of "cell assemblies" discussed in the chapter on learning and memory). Neuroscientists know that this sort of coding of properties exists in many parts of the brain. For example, recall from the chapters on vision and other sensory systems that individual neurons in the visual cortex are "tuned" (i.e. have receptive fields) to specific visual properties such as the orientation of linear borders and their direction of movement, while some neurons in somatosensory cortex, for example, respond to specific angles of specific joints of the skeleton to code limb positions, while other respond to tactile stimulation of specific areas (dermatomes) of skin, while still other neurons in auditory cortex fire to a specific narrow range of frequencies. Paul Churchland, at the University of California, San Diego, postulates that complex stimuli such as human faces or even highly abstract concepts and ideas such as scientific theories may be neurally represented in the brain by complex patterns of firing in enormous populations of neurons, each tuned to fire neuron potentials to specific features and magnitudes of features found in the world or generated by creative recombination of features in imagination.

This kind of coding can be conceptualized as long strings of numbers (each number is referred to as a "scalar," and the entire string of scalars is called a "coding vector") in which each number (scalar) in the string (the vector) corresponds to the firing rate of a specific neuron in a large population of neurons involved in the coding of a perception, a concept, an idea, or a complex set of ideas such as a scientific theory. This means that **coding vectors** for a single idea might be exceedingly long, containing thousands or millions of scalars in a single coding vector, each such scalar representing the firing rate of one of thousands or even millions of neurons involved in the coding of a single concept, idea, or complex of interrelated ideas (see Churchland, 1985, 2013).

Consistent with this view, the coding capacity of a single human brain with its 100 to 200 billion neurons is staggering, well within the parameters suggested by Churchland. As Thagard (2010, p. 450) explains: "A population of neurons represents something by its pattern of firing. The brain is capable of a vast number of patterns: assuming that each neuron can fire 100 times per second, then the **number of firing patterns** of that duration is $(2^{(100)})^{100000000000}$, a number **far larger than** the **number of elementary particles in the universe**, which is only about 10^{80}. A pattern of activation in the brain constitutes **a representation of something** when there is a stable causal correlation between the firing of neurons in a population and the thing that is represented, such as an object or group of objects in the world."

According to mental model theory, the enormous coding capacity of the human brain permits the human mind to represent concepts, ideas, theories, and other components of human knowledge of great subtlety and complexity, including theories in

science about hidden causes of things not directly observable (Churchland, 1985, 2013). "[M]ental models operating at various degrees of abstraction are invaluable for high-level reasoning. . . you can build simplified but immensely useful models of past and future events, as well as of events that your senses do not enable you to observe. Hence science uses abductive inference and conceptual combination to generate representations of theoretical (i.e. non-observable) entities such as electrons, viruses, genes, and mental representations" (Thagard, 2010, p. 457).

Using Churchland's concept of **vector coding**, each neural representation of a perception, a concept, an abstract relation, a thought, or other mental activity could be conceptualized as a specific, very long, coding vector, perhaps consisting of thousands or millions of scalars corresponding to the firing rates in an equal number of neurons which are involved in the coding of that particular mental activity. By this reasoning, mental models of the world would involve patterns of firing over space (neural space; i.e. areas of brain) and time (temporal patterning) in enormous numbers of neurons, corresponding to coding vectors of vast length changing their scalar values and composition moment to moment. This is hard to imagine, but perhaps this is the scale on which neural coding of mental events, such as concepts, relations, ideas, and so on takes place--millions upon millions of neurons firing in ever changing spatial-temporal patterns of neural activity distributed across many regions of brain at any one time.

Brain Mechanisms, Mental Representations, Relational Reasoning and Intelligence

Research suggests that reasoning requires coding involving neurons in **prefrontal cortex**. "Reasoning depends on the ability to form and manipulate mental representations of relations between objects and events. . . [and] the integration of multiple relations between mental representations . . .[However,] patients with **prefrontal damage** exhibited a selective and catastrophic deficit in the integration of relations. . . . The integration of relations may be the fundamental common factor linking the diverse abilities that depend on prefrontal function, such as planning, problem solving, and fluid intelligence" (Waltz et al., 1999, p. 119; **fluid intelligence** is another term for **general intelligence**, and is separate from one's store of learned knowledge). These results suggest that although mental models may involve many different brain areas acting together, the **prefrontal cortex** appears to play a special role in high level abstract reasoning requiring the integration of multiple relations. This may explain why **damage in prefrontal cortex** "leads to selective decrements in performance on tasks involving hypothesis testing, categorization, planning, and problem solving, all of which involve relational reasoning" (Waltz et al., 1999, p. 119).

In addition, because the ability to anticipate and prepare for future events improves chances of survival, evolution has favored **brains that** can **predict** future events (Clark, 2013; Nave, et al., 2020; Koenigshofer, 2017) including the future consequences of our own actions. Thus, according to mental model theory, intelligence involves formation by the brain of **mental/neural models or mappings** of the **physical and social worlds** and how they work. This idea is similar to **Tolman's concept of "cognitive maps,"** in which he envisioned mental mappings of the environment even in rats learning a maze (Tolman, 1948). This concept has even been extended to understand the coding of social relationships (Schafer & Schiller, 2020). On this view, **intelligence** involves enormously complex neural representations, models, or mappings of the environment and how it operates, including its causal relations, from which it is possible to make causal inferences and to generate causal explanations. There is evidence that mental models involved in causal inference may depend upon localized regions of cortex. According to Khemlani, et al. (2014) "**mental models for causal inference** are implemented within **lateral prefrontal cortex.**" Furthermore, planning future actions has also been associated by researchers with **lateral prefrontal and parietal cortex**. "**Lateral prefrontal cortex**, the **anterior** extent of the **inferior parietal lobule**, **dorsal anterior cingulate**, and **anterior insula** comprise regions of an extended **frontoparietal** control system" (Spreng, et al., 2015).

Recall Shepard's idea that there has evolved "a mesh between the principles of the mind and the regularities of the world." As discussed above, a primary characteristic of intelligence is that it predisposes animals and humans to discover and exploit regularities in the environment of varying degrees of abstraction. Similarities between things in the world help organize knowledge by the formation of categories (see module that follows on categories, concepts, and schemas). Inference from categories to specific instances of a category is one way to predict future outcomes (if this happens, then that is likely to follow), including the prediction of the effects of one's own future actions (if I do this, then that is likely to follow). Both of these kinds of predictions are examples of what we mean by "reasoning." The latter is critical for planning and the achievement of long-term goals.

Prediction allows us to plan ahead, to problem solve, and to achieve long-term goals, functions which depend upon **prefrontal cortex (PFC)**. For example, one function of the prefrontal cortex may be to gather facts, memories, and information from various brain regions and then coordinate and organize this divergent information into a workable whole in working memory in the PFC in order to solve a puzzle or find a solution to a problem (D'Esposito & Postle, 2015). However, an alternative theory is that the **PFC** is involved in **selective attention** to information which is localized in posterior brain regions such as **occipital and parietal cortex**. According to this view, the memories for relevant information are stored in the same regions activated during the initial sensory processing prior to memory formation (i.e. memories are stored in the sensory cortex). Information may flow in

both directions from posterior regions of cortex to the PFC and from PFC to posterior regions of cortex during a visual cognitive task such as categorizing visual stimuli (Lara & Wallis, 2015). Some studies of sensorimotor processing have shown similar bidirectional interactions within the **frontoparietal network** (Siegal et al., 2015), a brain network which has been identified, using brain functional MRI (fMRI) and Positron Emission Tomography (PET), as a primary neural substrate relevant to **intelligence** (Colom et al., 2010; Hearne, et al., 2016; Jung & Haier, 2007).

The connection of *parietal and frontal cortex* to intelligence has been formalized in the **Parieto-Frontal Integration Theory (P-FIT) of intelligence** (Jung & Haier, 2007). According to Jung and Haier (2007), the P-FIT model of intelligence proposes that the **dorsolateral prefrontal cortex**, the **inferior and superior parietal lobule**, the **anterior cingulate**, and areas within the **temporal and occipital lobes** are crucially involved in intelligence. *White matter* regions (consisting of tracts of myelinated axons) such as the **arcuate fasciculus** are also involved (more details about this theory follow in a later module). This theory attempts to relate these brain areas and their functioning to individual differences among people in intelligence, as measured by standard intelligence tests (see module that follows on the measurement of human intelligence).

Representations of Space and Time as Components of Intelligence

As already discussed, similarity relations, predictive relations (event covariation), and cause-effect relations (Koenigshofer, 2017) are not the only environmental features which have been genetically internalized into brain operations by natural selection. In addition, as discussed above, there are fundamental properties of time and three-dimensional space (see Shepard, above) and a large number of other relatively concrete regularities of the world which have also been incorporated into the mental/neural models or cognitive maps of the environment created within our brains. Thus, we, like other animals, have specialized regions of the brain dedicated to time perception and others devoted to creation of three-dimensional representations of the space around us. Recall from above, the **"place cells"** discovered in the **hippocampus** of the rat. These are "tuned" to fire action potentials when the rat is in a particular place in its environment; recall that other cells in the **cerebellum, hippocampus, and entorhinal cortex** appear to be involved in representation of the passage of time (Irvy, et al., 2002; Schafer & Schiller, 2020). Natural selection favored brain circuitry capable of exploiting these universal regularities or invariants in the structure of the world, along with more specific regularities of the physical and social environments acquired through learning, allowing us to generate quite sophisticated mental models of how the world operates. These brain systems form neural groundwork for thinking and intelligence in humans and animals.

"From Reflex to Reflection" in the Control of Action

The better our mental/neurological models of the world are, the more accurately we can anticipate future events and thus prepare for them. The better we are able to prepare for future events, whether only moments or years ahead, the more successful, the more adaptive, our behaviors are likely to be. These mental models or cognitive maps are part of the sophisticated guidance systems that shape behavior into adaptive patterns. This allows humans and animals to meet the challenges, and to maximize the opportunities, presented by the environment. The result? Increased biological fitness measured by the successful reproduction of genes (Dawkins, 1976).

In fact, we can see an important evolutionary trend: the brain's increasing ability to anticipate future, beginning with reflexes (e.g. sexual reflexes anticipate coitus) and then classical conditioning, found even in simple animals, in which the organism learns to anticipate or expect the UCS (such as meat in Pavlov's experiments) a few seconds after the CS (the bell). Natural selection for prediction and the anticipation of future ultimately led to evolution of the ability for advanced mental planning and prediction in human thinking (Clark, 2013; Koenigshofer, 2017), sometimes involving anticipation of events decades or even centuries into the future (e.g. you may anticipate a well paying, interesting career years from now after you have completed college, and that mental image keeps you focused day to day on your goal and the intermediate steps to achieve it; scientists predicted global warning decades ago; Leonardo da Vinci in the 1400's anticipated invention of the helicopter by hundreds of years; Jules Verne anticipated space travel long before the first human space flight; the founders of the U.S. Constitution formed principles of governance which anticipated political behavior of people hundreds of years in the future to this day). This general trend in evolution toward increasing capacity of brains to guide behavior by anticipation of the future can be summarized in the phrase "from reflex to reflection" (Koenigshofer, 2011, 2016).

Recent research has identified a number of brain structures involved in mental representations of future states of the world, specifically of one's own personal future, goals, and plans, essential for intelligent control of behavior. **Prospection** is the ability to mentally represent the future. To reach a future goal it is essential to make plans which organize a sequence of actions leading to achievement of the future goal. Behaviors controlled by mental anticipation of *imagined future*s can be called *prosponses* to distinguish them from *responses* to stimuli in the present or recent past (such as a CS in conditioning) (Koenigshofer, 2016).

According to Spreng et al. (2015), *autobiographical planning* involves personal plans directed toward real-world goals. These researchers found that autobiographical planning involves "synchronized activity of **medial temporal lobe memory structures as well as frontal executive regions**, . . . specifically, of the **default** and **frontoparietal control networks**. [The **default network** consists of] the **medial prefrontal cortex** (PFC), **medial parietal cortex**, **including posterior cingulate cortex** (PCC) and **retrosplenial cortex** (RSC), the **posterior inferior parietal lobule** (IPL), **medial temporal lobes** (MTL) [**including hippocampus, amygdala, and parahippocampal** regions], and **lateral temporal cortex**. . . [This network is activated] by self-generated thought and active across multiple functional domains including memory, future-thinking, and social cognition" (Spreng et al., 2015).

Earlier research revealed that the default network may be "a common 'core' network that" . . . "underlies both remembering and imagining." Functional MRI (fMRI) studies "reveal striking overlap in the brain activity associated with remembering actual past experiences and imagining or simulating possible future experiences" (Schacter, et al., 2012, p. 677-678). Clinical observations are consistent with this hypothesis from fMRI studies. For example, *amnesic patients have difficulty imagining the future*. Another study of amnesic patients with **hippocampal damage** revealed impairments when these patients were asked to *imagine* novel experiences (Schacter, et al., 2012). The abilities for imagining (see section below) and future-thinking are very important components of human intelligence.

How the World Works and Intelligent Control of Movement

Considering the complexity and variety of the many objects, forces and relations interacting in the physical and social worlds, it is not surprising that intelligence involves the integration of many brain areas acting together. As mentioned earlier, representation of three-dimensional space, including the position of one's own limbs, is dependent upon regions within the **parietal lobe** and one's location in local space is coded by **hippocampal "place cells."** Visual representation of objects depends upon the visual cortex in the **occipital lobe**, while visual recognition requires the **inferotemporal lobe** (lower temporal lobe, also known as **IT cortex**).

Human social interactions require other brain areas. A relatively new specialty called **social cognitive neuroscience** studies the brain systems involved in the information processing involved in social interactions, including some subcortical structures, several of which are part of the **limbic system**. Other researchers study neurocognitive adaptations underlying **intuitive (or "folk") psychology**, which humans use for inferring **social causality** in other humans, helping us understand their motives and predict their likely future actions. Others study **intuitive (or "folk") physics**, for innately inferring **physical causality** among inanimate objects in one's environment helping us anticipate future events (Baron-Cohen, et al., 2001; Kubricht et al., 2017). As already mentioned, developmental psychologists are studying young children's ability to use statistical regularities in the environment to discover the cause-effect relations between physical events (see Gopnik et al., 2001; Gopnik, 2012; Gopnik & Wellman, 2012).

To form mental models of the world to guide intelligent behavior, all of this information and information from additional sources must be combined. Rabini, et al. (2021) provide evidence that the **precuneus area** (see Figure 14.1.6) of the **parietal lobe**, which underwent a *significant enlargement in fairly recent human evolutionary history*, is critically involved in the mental combination of different mental concepts, in part, to create new more complex concepts and ideas, and perhaps to help generate integrated mental models of the environment. Among other things, the **precuneus** region (what is often referred to as the **superior lobule of the parietal lobe** which equates with the outer extension of the **anterior and posterior precuneus**) of the parietal lobe may have set the stage for the evolution of complex language and thinking by its involvement in the *linking of concepts and ideas into increasingly complex ones* in sophisticated human thought and complex cognition (Rabini, et al., 2021).

Planning for future ultimately involves action in the world and testing out the accuracy of one's mental models against feedback from the world. As Geertz (2016, p. 185) states:

> The process of comparing models with perceptual input from the wider world is known today as “prediction error monitoring” (Frith 2007: 132ff.; Frith & Frith 2010). Our experience of the world is in fact our experience of the brain’s simulation of the world. The brain constantly predicts what is going on in the physical world, the body and, especially, the social world. These simulations are tested against the input of neurological mappings, perceptual input and social mappings. When it detects errors in its predictions, the brain attempts to improve its predictions.

Nave et al. (2020) express similar ideas. But attempts to improve predictions based on feedback from the world is only half the story. Not only does the brain attempt to improve its predictions, but it also directs the modification of behavior, based on feedback from the environment, to make corrections in action needed to keep behavior on track toward the achievement of an imagined goal. Continuous feedback from the environment about the effects of one's own behavior guides behavior toward imagined goals, with needed corrections along the way. For example, if you imagine going to law school and your grade on a

midterm exam in one of your pre-law courses is below average, then this feedback from the environment that does not match your mental model of what is required to get accepted into law school can cause you to modify your study habits. This type of monitoring of the match or mismatch between an imagined goal and the actual effects of one's actions with respect to the goal, an important feature of intelligent action, involves interaction between the **prefrontal cortex** and the **hippocampus.** As Numan (2015, p. 323) states:

> Action plans are essential for successful goal-directed behavior, and are elaborated by the prefrontal cortex. When an action plan is initiated, the prefrontal cortex transmits an efference copy (or corollary discharge) to the hippocampus where it is stored as a working memory for the action plan (which includes the expected outcomes of the action plan). The hippocampus then serves as a response intention-response outcome working memory comparator. Hippocampal comparator function is enabled by the hippocampal theta rhythm allowing the **hippocampus** to compare expected action outcomes to actual action outcomes. If the expected and actual outcomes match, the hippocampus transmits a signal to **prefrontal cortex** which strengthens or consolidates the action plan. If a mismatch occurs, the hippocampus transmits an error signal to the prefrontal cortex which facilitates a reformulation of the action plan, fostering behavioral flexibility and memory updating.

This sort of monitoring of the effects of one's actions comparing those effects to the effects desired to reach a goal is an essential part of the guidance systems for movement in complex animals, especially in humans, and is a central feature guiding intelligent action.

Above, we referred to *cognitive instincts*. Another of these instincts is emotional/motivational--what we commonly refer to as curiosity. As argued above, we are innately predisposed to understand cause-effect and to seek causal explanations of the world, "curiosity." As Thagard (2010, p.458-9) states: "abductive inference . . . leads people to respond to surprising observations with a search for hypotheses that can explain them. . . Brains make mental models through complex patterns of neural firing and use them in many kinds of inference, from planning actions to the most creative kinds of abductive reasoning." Understanding causality is not much use if you are not equipped with brain mechanisms which drive the motivation to know why things happen in your environment; that drive to explain, is the drive to identify causes. Knowing the causes of things allows better prediction, which leads to understanding of how to manipulate the environment to adaptive advantage--intelligence put to action.

General Intelligence: Adaptive Specializations to Abstract Relational Regularities

As described above, some of the most biologically important features of the world, of the environment, are abstract and relational. Recall that Spearman believed that *g* was most closely related to the "drawing out" of "relations and correlates," abstract regularities of the world important in inductive and deductive logic, grasping relationships, inferring rules, and recognizing differences and similarities. Also discussed above, several of these broad, abstract properties of the world were central to the evolution of general intelligence and these have been genetically internalized into brain organization over the course of evolution. As previously noted, these include: 1) Causation: things/events in the world are governed by natural causal laws, and thus, causal relations among its elements are everywhere. Causality in the world holds important adaptive information. Innate knowledge about causality, by its genetic internalization, gives the mind ability to discover and exploit the biologically important information in causal relations, thereby improving adaptation; 2) Similarity relations: things/events in the world have similarities to one another in multiple dimensions and at varying degrees of abstraction (e.g. "there is nothing new under the sun"). Similarities hold important adaptive information extracted by the grouping of things into categories and concepts of varying degrees of abstraction; 3) Predictive covariation of events: things/events in the world covary or co-occur with one another in predictable ways, offering opportunity for prediction, and serving as an important cue to causality (Gopnik, et al., 2001; Gopnik & Wellman, 2012), both highly significant for successful adaptation. Genetic internalization of knowledge about these abstract relational regularities (causality similarity, and predictive relations) set the groundwork for the evolution of categorization, concept formation, generalization, causal and categorical logic and inference, and analogical reasoning, all of which are potent components of cognition and general intelligence (Koenigshofer, 2017).

From this perspective, **general intelligence** (Spearman's "g;" see discussion above and section 18.11) evolved as a **collection of adaptive specializations** (specific psychological adaptations to a particular class of environmental feature, relation, or adaptive problem; see Gallistel, 1995) **to** these universal, **abstract relational regularities (causality, similarity, and predictive relations)** of the world which repeatedly appear, generation after generation, in virtually all situations, adaptive problems, and adaptive opportunities in the environment. The adaptive information in causality, similarity, and predictive relations among events was far too significant to be missed by natural selection. Specialized brain mechanisms evolved to extract and utilize the information in these abstract relational regularities--forming the foundations of general intelligence in us and many

other animals. The high levels of general intelligence that evolved in our species gave us ability to discover and understand general principles of how the world works that could be applied to a wide range of environmental problems and adaptive opportunities. General intelligence, becoming highly developed in recent human evolution (probably within the past 100,000 years; see Mellars, 2005), has allowed our species, unlike any other, to create the scientific method, systems of government and law, machines to do our work, modern medicine, agriculture, cities and nations, and space travel. Highly developed general intelligence combined with our capacities for cooperation and cultural transmission, both facilitated by language, set us apart from all other animals.

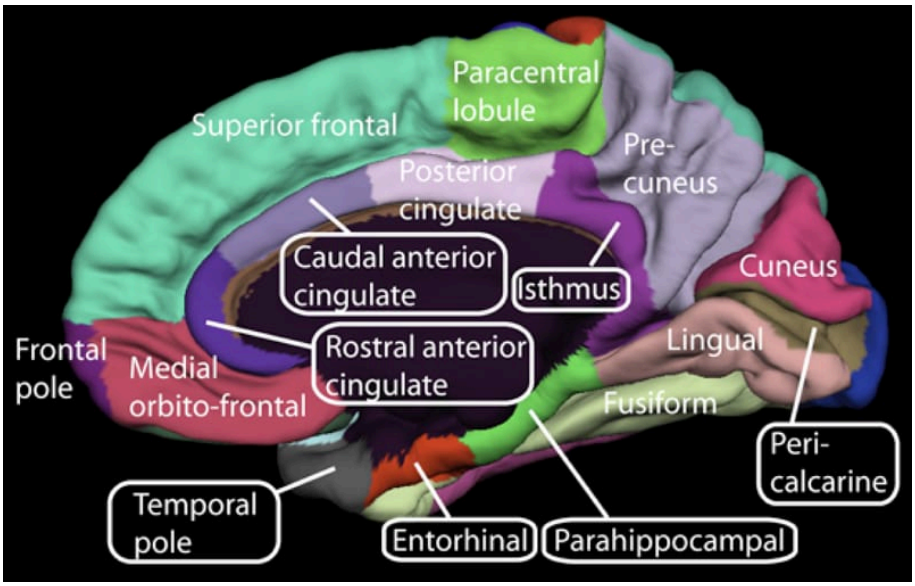

Figure 4.1.2.10: Artist's depiction of midline cross-section of human brain showing some of the structures involved in generating some components of intelligence (see text above); the hippocampus proper, buried in temporal lobe cortex, is not shown because it is located behind the plane of the midline view shown here. Koenigshofer, PhD).

General Intelligence in Humans and Non-human Animals: Neural Correlates

Historically, psychologists have focused on ways of measuring intellectual abilities that are important for success in school. Traditional IQ tests were designed to measure these abilities. As discussed above, one important observation from research based on these intelligence tests is that measures of different intellectual skills are correlated: individuals that do well in one type of intellectual ability tend to do well in all types. These positive correlations among measures of different types of intellectual activity are known among psychologists as "the positive manifold." The "positive manifold" has been interpreted by many psychologists as strong statistical evidence (from the mathematical method, factor analysis; Spearman, 1904) for the general intelligence factor, "g," which exists in addition to more specific intelligences such as verbal fluency and visual-spatial abilities (see models of human intelligence in the next module).

Perhaps unexpectedly, recent research shows that general intelligence (ability to recognize "relations and correlates," according to Spearman,1904, 1925, who originated the concept) is found to some degree in many mammals and even in some birds (Emery & Clayton, 2004). Recent research shows that degrees of general intelligence among mammals is most strongly associated with "the **number of cortical neurons, neuron packing density, interneuronal distance and axonal conduction velocity**—factors that determine general information processing capacity (IPC), as reflected by general intelligence" (Dicke & Roth, 2016). These researchers compare IPC in various species. They report that: "The highest IPC is found in humans, followed by the great apes, Old World and New World monkeys. The IPC of cetaceans and elephants is much lower because of a thin cortex, low neuron packing density and low axonal conduction velocity. By contrast, corvid [rooks, crows, ravens] and psittacid birds [parrots] have very small and densely packed pallial neurons and relatively many neurons, which, despite very small brain volumes, might explain their high intelligence."

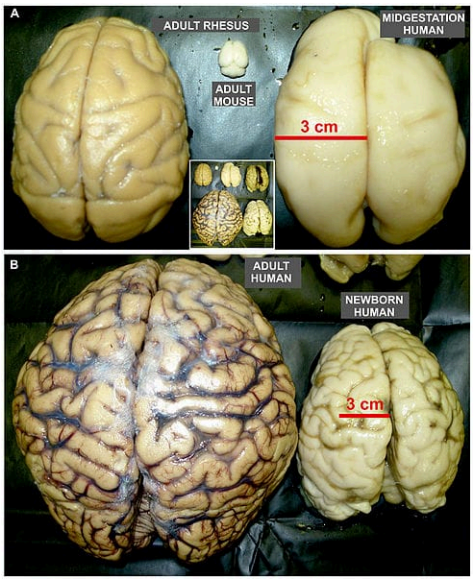

Figure 4.1.2.11: Size proportion of mature rodent and non-human primate brain as well as developing and mature human brains. Dorsal view of adult mouse (A), rhesus monkey (A), and human brain (B), as well as human fetal brain around mid-gestation (A) and at term (B). (A) The size of human fetal brain already at mid-gestation has reached the size of the adult rhesus monkey brain. Nevertheless, adult rhesus monkey brain is almost 100 times larger than brain of adult mouse. (B) The adult human brain is around 3–4 times larger than newborn brain which size reaches the size of adult chimpanzee brain. Note that the pattern of gyrification (cerebral gyri--the hill portions of the cortical folds) in human newborn brain is close to the one observed in adult. The inlet in the middle of the figure is the integrative photo of all brains shown in A and B that demonstrate their actual proportions (the right brain in the upper row of insertion is from fetus at the beginning of third trimester of gestation). Image and caption from Wikimedia. https://commons.wikimedia.org/wiki/F...00050-g004.jpg; by Ana Hladnik, Domagoj Džaja, Sanja Darmopil, Nataša Jovanov-Milošević and Zdravko Petanjek; licensed under the Creative Commons Attribution 3.0 Unported license).

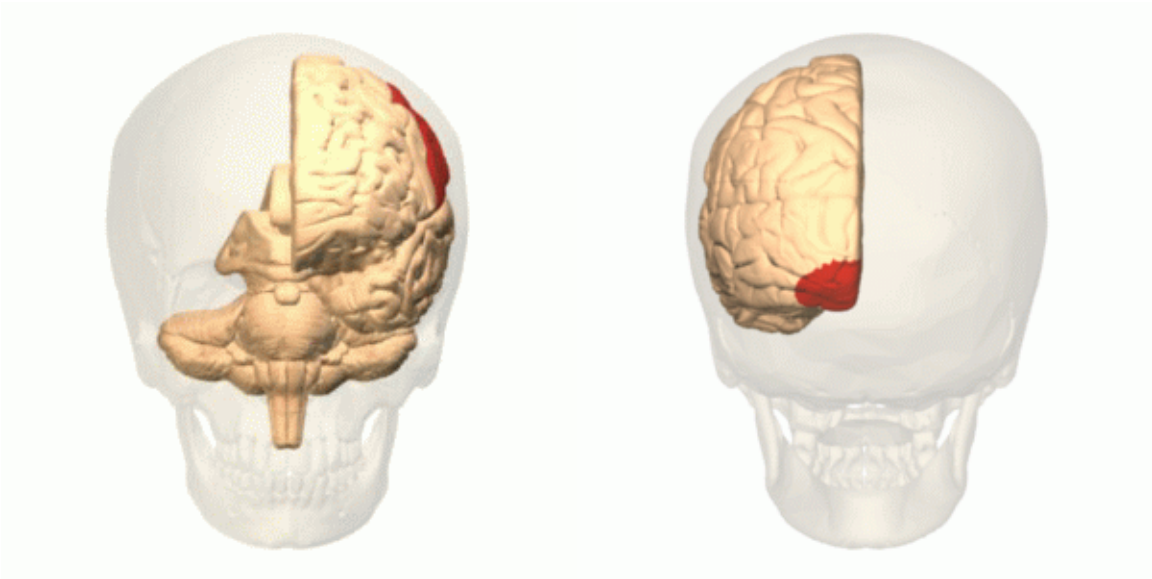
An approach to individual differences among humans in intelligence involves **efficiency of neural processing--**higher IQ people show greater processing efficiency (Haier et al., 1992; Van Den Heuvel et al., 2009). Brain imaging studies show that higher IQ individuals show lower brain activation (as indicated by glucose metabolism) than lower IQ individuals when completing the same cognitive task, indicating that individuals with higher intelligence, as measured by IQ tests, do information processing more efficiently, with less expenditure of metabolic energy by the brain, compared to lower IQ individuals whose brains work harder (their brains expend more metabolic energy) at solving the same problem. Haier, et al. (1992, p. 415-416) conclude: "Intelligence is not a function of how hard the brain works but rather how efficiently it works."

Brain processing efficiency may be related to any number of factors: inherited brain circuitry configurations which are more "streamlined" as a result of more efficient neural pruning during brain development (Koenigshofer, 2011, 2016); better conduction over pathways connecting multiple regions of brain; "more long-distance connections that ensure a high level of global communication efficiency within the overall network" (Van Den Heuvel, et al., 2009, p. 7619); less engagement of brain areas not required to solve a particular problem or complete a particular cognitive task (Haier, et al., 1992); and/or as Hearne, et al. (2016) conclude, "higher global network efficiency is related to higher general intelligence measures" with "a key role for connections between **prefrontal and frontal cortices** comprising the **dorsal attention network**" and with activity also in "**posterior cingulate/precuneus** . . . the **superior parietal cortex (fronto-parietal network)** and the **occipital cortices (visual network)**. Resting state functional connectivity between bilateral prefrontal cortices encompassing the dorsal attention network and the **right insula (salience network)** was also associated with intelligence scores."

In humans, **general intelligence** is heritable and is dependent upon **many genes interacting** together (Bouchard, 2014). One can wonder whether some of these many genes determining intelligence might hold information about some of the environmental regularities in the world discussed above, including relational regularities such as causality and similarity. This is an area of research wide open for researchers in behavior genetics or cognitive genetics.



When considering human intelligence, the role of language is a significant factor. Much of human thinking involves the use of words. As Dicke and Roth (2016) state, "The evolution of a syntactical and grammatical language in humans most probably has served as an additional intelligence amplifier, which may have [also] happened in songbirds and psittacids" [parrots] as a consequence of convergent evolution--the evolution of similar characteristics in unrelated or distantly related species because of

common selection pressures. As mentioned above, the **precuneus** of the parietal lobe may have played a significant role in the evolution of language by having involvement in the combination of ideas and concepts from different semantic domains (Rabini, et al., 2021).

Studies of brain damaged patients supply further insight into brain mechanisms involved in abstract concept formation and thinking dependent upon language. Patients with one type of **frontotemporal** dementia (FTD) are particularly impaired "in verbal concept formation (i.e. categorization based on abstract similarities between items). . . [with] especially the **left frontal lobe**, thought to be involved in abstract word processing (Lagarde, et al., 2015, p. 456).

Another Component of General Intelligence: Visual Imagery and Imagination

Another important component of general intelligence is ability to visualize--to form and manipulate visual images in imagination. Psychologists who study human intelligence using and analyzing intelligence tests label this the *Broad Visual Perception factor* (*Gv*), “which is an ability to generate, retain, retrieve and transform visual images” (Kvist and Gustafsson, 2008, p.422-423). This is one of the sub-factors of *g* (general intelligence) in Carroll’s (1993) widely accepted three-level model of human intelligence (see module on measuring human intelligence which follows). This visualization ability may have developed as an adaptation or perhaps as an "exaptation" (recruitment of an adaptation to a different function; see Gould and Vrba, 1982). On this view, portions of the visual system, including parts of **visual, motor, and frontal and parietal association cortex**, were recruited over evolutionary time to permit the formation and manipulation of visual images used to mentally test out probable effects of future behaviors before committing to them in the real physical world. Much of what we call "thought" is of this form (Koenigshofer, 2011, 2016, 2017). Note that some studies described above found activity in the **cortical visual areas and frontal and parietal cortical areas** to be **associated with intelligence**. Other studies, discussed above in the section on mental models, implicate the "default network" in both imagination and memory.

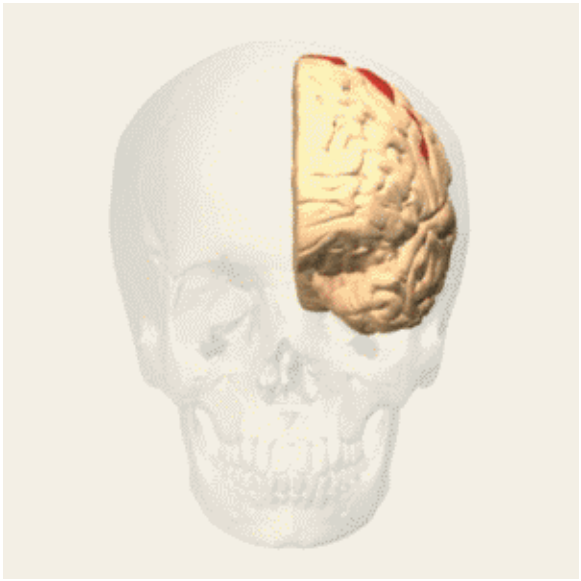


Figure 4.1.2.12: (Left) Left Parietal Lobe; (Center) Left Primary Visual Cortex; the Visual association cortex (not colored) immediately surrounds primary visual cortex; (Right) Left Primary Motor Cortex; premotor cortex (not colored) is located just anterior to primary motor cortex. (Images from Wikimedia Commons; https://commons.wikimedia.org/wiki/F..._animation.gif; https://commons.wikimedia.org/wiki/F..._animation.gif; https://commons.wikimedia.org/w/inde...=Go&type=image; by Polygon data were generated by Database Center for Life Science (DBCLS); licensed under the Creative Commons Attribution-Share Alike 2.1 Japan license; caption by Kenneth A. Koenigshofer, PhD).

There is experimental evidence for this claim. For example, brain imaging studies show that when humans imagine a particular movement, the same brain region that becomes active during the actual movement also becomes active during the imagined movement, even though no actual movement occurs. In both cases, the activated brain area shows nearly the same fMRI image (Ganis, et al., 2004; Kanwisher, 2009; Kosslyn, et al., 2006) suggesting that similar circuits are involved in imagining a movement and actually carrying out the movement. Similar results using fMRI have been reported for visual perception and mental imagery in the "mind's eye" with the greatest overlap in activation patterns for perception and imagery in imagination occurring in the **frontal and parietal cortex** (Ganis, et al., 2004). Mental testing of planned actions in the mind's eye (guided by innate, implicit "knowledge" of cause-effect, predictive event covariation, and similarity relations) is highly adaptive because it is safe, fast, and efficient (Koenigshofer, 2017). Testing out possible behaviors and their likely effects in imagination can eliminate harmful or even fatal choices in the real world. In addition, mental testing of possible behavioral choices takes much less time and much less caloric expenditure than testing out behaviors by trial and error in the real physical world (think about mentally searching for your car keys until you find them mentally vs. actually moving to search your house, car, and garage to try to find them--the savings in time and in calories is clear). Because of these adaptive advantages, it is likely that there has been strong selection for neural mechanisms supporting visual imagination--a major component of human general intelligence and an integral part of what is generally referred to as "thinking" (Koenigshofer, 2011, 2016, 2017).

Experimental Support for Mental Imagery

Image Scanning

Seminal research in visual imagery was provided by Kosslyn's image-scanning experiments in the 1970s. Using the mental representation of a ship, subjects were instructed to shift their mental focus from one part of the ship to another. The reaction time of the subjects increased with distance between the two parts of the imagined ship, which indicates that we actually create a mental picture of scenes while trying to solve small cognitive tasks such as scanning the mental image of an object. Interestingly, Marmor and Zaback (1976) found that this visual ability can be observed also in people who are congenitally blind. Presuming, that the underlying processes are the same as in sighted subjects, it could be concluded that there is a deeper encoded system that has access to more than just the visual input.

Mental Rotation Task

Other advocates of visual spatial representation theory, Shepard and Metzler, developed the mental rotation task in 1971. Two spatially complex objects are presented to a participant at different angles and his/her job is to decide whether the objects are identical or not. The results show that the reaction times increases linearly with the rotation angle of the objects. The participants mentally rotate the objects in order to match the objects to one another. This method is called "mental chronometry".

This experiment was crucial for demonstrating the importance of imagery within cognitive psychology, because it showed the similarity of imagery to the processes of perception. For a mental rotation of 40° the subjects needed two seconds on average, whereas for a 140° rotation the reaction time increased to four seconds. Therefore, it can be concluded that people in general have a mental object rotation rate of 50° per second.

Spatial Frameworks

As mentioned above, researchers generally believe that mental models are perceptually based as indicated by fMRI studies which show extensive overlap between fMRI images of the perception of an object and its visualization. Indeed, people have been found to use spatial frameworks like those created for texts to retrieve spatial information about observed scenes (Bryant, 1991). Thus, people create the same sorts of spatial memory representations no matter if they read about an environment or see it themselves.

Size and the visual field

If an object is observed from different distances, it is harder to perceive details if the object is far away because the objects fill only a small part of the visual field. Kosslyn did an experiment in 1973 in which he wanted to find out if this is also true for mental images, to show the similarity of the spatial representation and the perception of real environment. He told participants to imagine objects which are far away and objects which are near. After asking the participants about details, he supposed that details can be observed better if the object is near and fills the visual field. He also told the participants to imagine animals with different sizes near by another. For example an elephant and a rabbit. The elephant filled much more of the visual field than the rabbit and it turned out that the participants were able to answer questions about the elephant more rapidly than about the rabbit. After that the participants had to imagine the small animal besides an even smaller animal, like a fly. This time, the rabbit filled the bigger part of the visual field and again, questions about the bigger animal were answered faster. The result of Kosslyn's experiments is that people can observe more details of an object if it fills a bigger part of their mental visual field. This provides evidence that mental images are represented visual-spatially.

Visual Imagery, Intelligence, and the Frontoparietal Network

Significantly, visual imagery in the mind's eye can also be employed to mentally test novel combinations of causes and effects, similarity relations, and predictive relations (covariations) to discover new knowledge about hidden causes of events in the world, eventually leading to the creation of sophisticated scientific models of how the world works—human general intelligence at its best (Koenigshofer, 2017). For example, the famous theoretical physicist, Albert Einstein, used mental imagery extensively to do "thought experiments" that played a large role in his formulation of the theories of general and special relativity. Brain imaging studies using fMRI implicate **parietal cortex** in the use of imagination (Nair et al., 2003). Bruner (2010, p. S84) suggests that "the **parietal lobe system** 'forms a neural image of surrounding space' (Mountcastle, 1995 p. 389)," and perhaps of one's potential future action in that space. Significantly, parietal cortex has strong linkages with **prefrontal cortex** forming a **frontoparietal network:** the **inferior parietal lobule** (further subdivided into the **supramarginal gyrus**, the **temporoparietal junction**, and the **angular gyrus**, see Figure 14.2.8) is primarily connected with **dorsolateral prefrontal cortex** (Bruner, 2010; see Figure 14.2.7), associated, in part, with abilities for abstract thought, while upper parietal regions, according to Bruner, are associated in the scientific literature with functions such as abstract representation, internal mental images, "imagined world[s],. . . and thought experiment" (i.e., imagination). Significantly, a number of other research groups using fMRI brain imaging techniques in humans also find evidence of a critical role of the **frontoparietal network** in human intelligence and general cognitive ability (Colom, et al., 2010; Jung & Haier, 2007; Sripada, et al., 2020; Vendetti & Bunge, 2014; Wendelken, et al., 2017; Yeo et al., 2016).

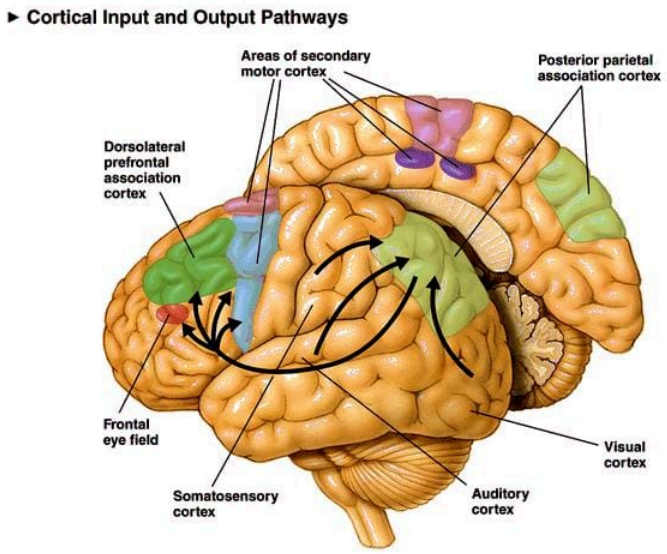

Figure 4.1.2.13: Connections of posterior parietal association cortex with dorsolateral prefrontal association cortex. (Image from Wikipedia; https://commons.wikimedia.org/wiki/F...ietal_Lobe.jpg; by Paskari; licensed under the Creative Commons Attribution-Share Alike 2.5 Generic, 2.0 Generic and 1.0 Generic license. Caption by Kenneth A. Koenigshofer, PhD.).

The emergence during human evolution of this visualization ability may help account for the development of modern human cognition, first appearing some 60,000-100,000 years ago (Mellars, 2005). Speculatively, superior abilities for imagination of the type described above might account, at least in part, for human competitive advantage over Neanderthals (Koenigshofer, 2017) perhaps contributing to Neanderthal extinction about 30,000 years ago (Watson and Berry, 2009). Consistent with this view, morphological studies suggest enhanced **parietal lobe** development in modern humans compared to Neanderthals (Bruner, 2010); by contrast, recent studies show little relative enlargement of the frontal lobes in humans compared to apes (Barton and Venditti, 2013). At least one post-mortem anatomical study of Einstein's brain suggested unusual enlargement of the **inferior parietal lobules** in parietal lobes along with a number of other atypical features in the **occipital lobes**, and throughout the cerebral cortex (Chen et al., 2014; see Carrillo-Mora et al., 2015). Another study of Einstein's brain by Falk et al. (2013, p. 1304) reports "Einstein's brain has an extraordinary prefrontal cortex, which may have contributed to the neurological substrates for some of his remarkable cognitive abilities. The primary somatosensory and motor cortices near the regions that typically represent face and tongue are greatly expanded in the left hemisphere. Einstein's parietal lobes are also unusual and may have provided some of the neurological underpinnings for his visuospatial and mathematical skills, as others have hypothesized. Einstein's brain has typical frontal and occipital shape asymmetries (petalias) and grossly asymmetrical inferior and superior **parietal lobules**" with relative enlargement of the left inferior parietal module. Chen et al., referred to above, found exceptional enlargement of both **inferior parietal lobules** (which include the **supramarginal gyrus and angular gyrus** (Figure 14.2.8), involved in multiple functions including number processing, "mentalizing," and spatial cognition) in Einstein's brain compared to controls. Einstein was famous for his use of visualization to explore his ideas in theoretical physics through "thought experiments" in his "mind's eye." Additional evidence regarding Einstein's exceptional parietal lobes was provided by studies of cortical glial cells. A study by Diamond et al. (1985) of Einstein's brain found that the only cortical area of the four cortical areas examined with a greater number of glial cells per neuron, compared to controls, was the **left posterior parietal cortex**, a finding interpreted by the authors to mean that this area of Einstein's brain must have been exceptionally active during his lifetime.

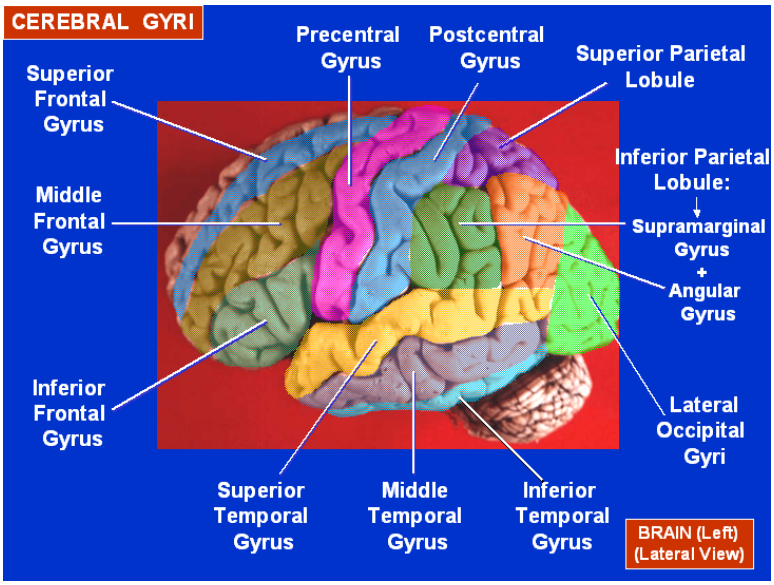

Figure 4.1.2.14: Cortical gyri, including the left inferior parietal lobule composed of the supramarginal and angular gyri. This capacity for visualization permitting mental trial and error likely occurs to some degree in non-human animal species as well. Kohler's (1925/1959) classic work showing the use of "insight" by chimpanzees in problem solving offers evidence for this hypothesis, assuming that insight involves mental trial and error. Additional evidence suggesting mental trial and error in imagination in a variety of animals is provided by experiments showing insight in some orangutans, gorillas, and chimpanzees (Mendes, et al., 2007; Hanus, et al., 2011) and in rooks--birds in the same Corvid family as ravens and crows (Bird & Emery, 2009a, 2009b).

One key feature of more traditional approaches to the study of human intelligence is that they emphasize aspects of human intelligence and thinking, such as language and computation, that are especially important for life in complex modern society. As described in the next module, some psychologists have hypothesized multiple kinds of human intelligence. Others focus primarily on how to measure intelligence, and still others study individual differences in intelligence among people. Because these psychologists tend to be interested in practical application of their tests in school and work settings, they tend to give relatively little attention to theories about the evolutionary origins or biological functions of intelligence. Nevertheless, intelligence tests are very useful predictors of success in environments such as school, military, and work settings. All involve measurement of mental skills important to successful adaptation to the demands of the physical and social environments typical of modern, industrialized societies.

Summary

Intelligence and cognition are complex psychological adaptations involving many different areas of the brain interacting together. Intelligence in the broadest sense involves the formation of sophisticated mental models of the world and how it works. These models include representations of things, events, and the predictive, similarity, and causal relations among them, as well as representations of space and time. Mental models of the physical and social environments permit prediction of future events, providing powerful evolutionary advantage. Mental models include the formation of categories, based on similarities, which allow inferences based on assignment of newly encountered things and events to previously formed categories. Mental models exploit the innate disposition to understand cause-effect relations in the environment, leading to knowledge about what causes what. This knowledge allows manipulation of causes to affect future environmental outcomes toward better adaptation. General intelligence emerges during evolution from genetic internalization of universal, abstract relational features of the world including cause-effect, event covariation, and similarity, each of which plays a role in thought and reasoning about the environment (Koenigshofer, 2017). Spearman (1904, 1925) discovered and was first to describe general intelligence, which he believed consisted of ability to recognize "relations and correlates" in the environment. Another aspect of general intelligence is ability to visualize, to form and manipulate visual images in imagination. This ability may have developed as an exaptation or recruitment of portions of the visual and motor systems, including parietal association cortex. This would allow some visual and motor circuits to form internally generated mental images that can be mentally manipulated to test out probable effects of possible future

behaviors before committing to them in the physical world. Because this ability to visualize outcomes in the "mind's eye" is much safer and saves time and calories compared to testing outcomes in actual physical behavior, it is likely that there has been strong selection pressure for ability to manipulate mental images to plan future action. This component of intelligence provides a powerful mechanism for maximizing the adaptive outcomes of behavior and therefore provides enormous selective advantage--a strong impetus for its evolution as a central feature of intelligence (Koenigshofer, 2017).

4.1.3: High Intelligence-Nature or Nurture; Learning Disabilities

Learning Objectives

1. Describe how genetics and environment affect intelligence
2. Explain the relationship between IQ scores and socioeconomic status
3. Describe the difference between a learning disability and a developmental disorder

Overview

A young girl, born of teenage parents, lives with her grandmother in rural Mississippi. They are poor—in serious poverty—but they do their best to get by with what they have. She learns to read when she is just 3 years old. As she grows older, she longs to live with her mother, who now resides in Wisconsin. She moves there at the age of 6 years. At 9 years of age, she is raped. During the next several years, several different male relatives repeatedly molest her. Her life unravels. She turns to drugs and sex to fill the deep, lonely void inside her. Her mother then sends her to Nashville to live with her father, who imposes strict behavioral expectations upon her, and over time, her wild life settles once again. She begins to experience success in school, and at 19 years old, becomes the youngest and first African-American female news anchor (“Dates and Events,” n.d.). The woman—Oprah Winfrey—goes on to become a media giant known for both her intelligence and her empathy.

High Intelligence: Nature or Nurture?

Where does high intelligence come from? Some researchers believe that intelligence is a trait inherited from a person’s parents. Scientists who research this topic typically use twin studies to determine the heritability of intelligence. The Minnesota Study of Twins Reared Apart is one of the most well-known twin studies. In this investigation, researchers found that identical twins (100% of their DNA is identical) raised together and identical twins raised apart exhibit a higher correlation between their IQ scores than siblings (50% of their DNA in common) or fraternal twins (50% of their DNA in common) raised together (Bouchard, Lykken, McGue, Segal, & Tellegen, 1990). The findings from this study reveal a genetic component to intelligence (Figure 10.3.1). At the same time, other psychologists believe that intelligence is shaped by a child’s developmental environment. If parents were to provide their children with intellectual stimuli beginning from before they are born, it is likely that they would absorb the benefits of that stimulation, and it would be reflected in intelligence levels.

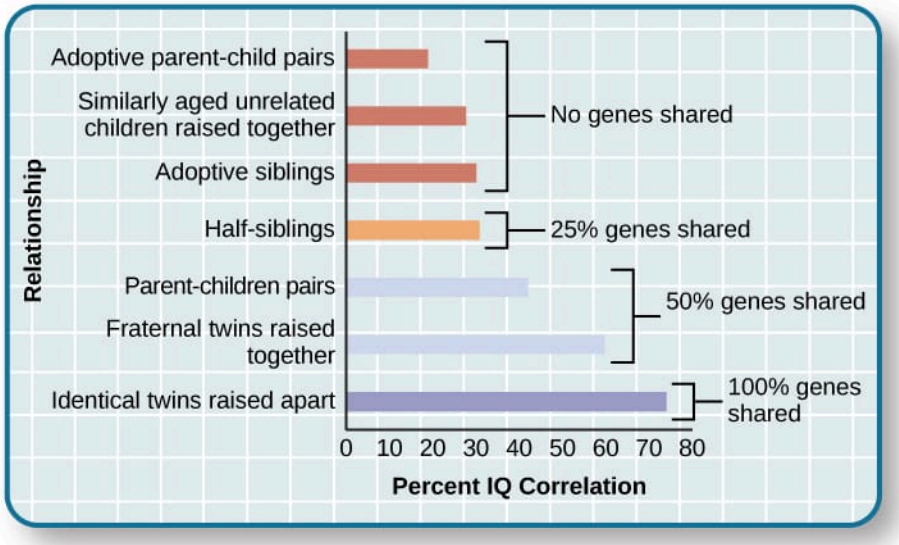

Figure 4.1.3.1: The correlations of IQs of unrelated versus related persons reared apart or together suggest a genetic component to intelligence.

The reality is that aspects of each idea are probably correct. One study suggests that genetics seem to be in control of the level of intelligence, environmental influences are also involved (Bartels, Rietveld, Van Baal, & Boomsma, 2002). Certainly, there are behaviors that support the development of intelligence, but the genetic component of high intelligence can not be ignored. As with all heritable traits, however, it is not always possible to isolate how and when high intelligence is passed on to the next generation.

Range of Reaction is the theory that each person responds to the environment in a unique way based on his or her genetic makeup. According to this idea, your genetic potential is a fixed quantity, but whether you reach your full intellectual potential is dependent upon the environmental stimulation you experience, especially in childhood. Think about this scenario: A couple adopts a child who has average genetic intellectual potential. They raise her in an extremely stimulating environment. What will happen to the couple's new daughter? It is likely that the stimulating environment will improve her intellectual outcomes over the course of her life. But what happens if this experiment is reversed? If a child with an extremely strong genetic background is placed in an environment that does not stimulate him: What happens? Interestingly, according to a longitudinal study of highly gifted individuals, it was found that "the two extremes of optimal and pathological experience are both represented disproportionately in the backgrounds of creative individuals"; however, those who experienced supportive family environments were more likely to report being happy (Csikszentmihalyi & Csikszentmihalyi, 1993, p. 187).

Another challenge to determining origins of high intelligence is the confounding nature of our human social structures. It is troubling to note that some ethnic groups perform better on IQ tests than others—and it is likely that the results do not have much to do with the quality of each ethnic group's intellect. The same is true for socioeconomic status. Children who live in poverty experience more pervasive, daily stress than children who do not worry about the basic needs of safety, shelter, and food. These worries can negatively affect how the brain functions and develops, causing a dip in IQ scores. Mark Kishiyama and his colleagues determined that children living in poverty demonstrated reduced prefrontal brain functioning comparable to children with damage to the lateral prefrontal cortex (Kishyama, Boyce, Jimenez, Perry, & Knight, 2009).

The debate around the foundations and influences on intelligence exploded in 1969, when an educational psychologist named Arthur Jensen published the article "How Much Can We Boost I.Q. and Achievement" in the Harvard Educational Review. Jensen had administered IQ tests to diverse groups of students, and his results led him to the conclusion that IQ is determined by genetics. He also posited that intelligence was made up of two types of abilities: Level I and Level II. In his theory, Level I is responsible for rote memorization, whereas Level II is responsible for conceptual and analytical abilities. According to his findings, Level I remained consistent among the human race. Level II, however, exhibited differences among ethnic groups (Modgil & Routledge, 1987). Jensen's most controversial conclusion was that Level II intelligence is prevalent among Asians, then Caucasians, then African Americans. Robert Williams was among those who called out racial bias in Jensen's results (Williams, 1970).

Obviously, Jensen's interpretation of his own data caused an intense response in a nation that continued to grapple with the effects of racism (Fox, 2012). However, Jensen's ideas were not solitary or unique; rather, they represented one of many examples of psychologists asserting racial differences in IQ and cognitive ability. In fact, Rushton and Jensen (2005) reviewed three decades worth of research on the relationship between race and cognitive ability. Jensen's belief in the inherited nature of intelligence and the validity of the IQ test to be the truest measure of intelligence are at the core of his conclusions. If, however, you believe that intelligence is more than Levels I and II, or that IQ tests do not control for socioeconomic and cultural differences among people, then perhaps you can dismiss Jensen's conclusions as a single window that looks out on the complicated and varied landscape of human intelligence.

Learning Disabilities

Learning disabilities are cognitive disorders that affect different areas of cognition, particularly language or reading. It should be pointed out that learning disabilities are not the same thing as intellectual disabilities. Learning disabilities are considered specific neurological impairments rather than global intellectual or developmental disabilities. A person with a language disability has difficulty understanding or using spoken language, whereas someone with a reading disability, such as dyslexia, has difficulty processing what he or she is reading.

Often, learning disabilities are not recognized until a child reaches school age. One confounding aspect of learning disabilities is that they often affect children with average to above-average intelligence. At the same time, learning disabilities tend to exhibit comorbidity with other disorders, like attention-deficit hyperactivity disorder (ADHD). Anywhere between 30–70% of individuals with diagnosed cases of ADHD also have some sort of learning disability (Riccio, Gonzales, & Hynd, 1994). Let's take a look at two examples of common learning disabilities: dysgraphia and dyslexia.

Dysgraphia

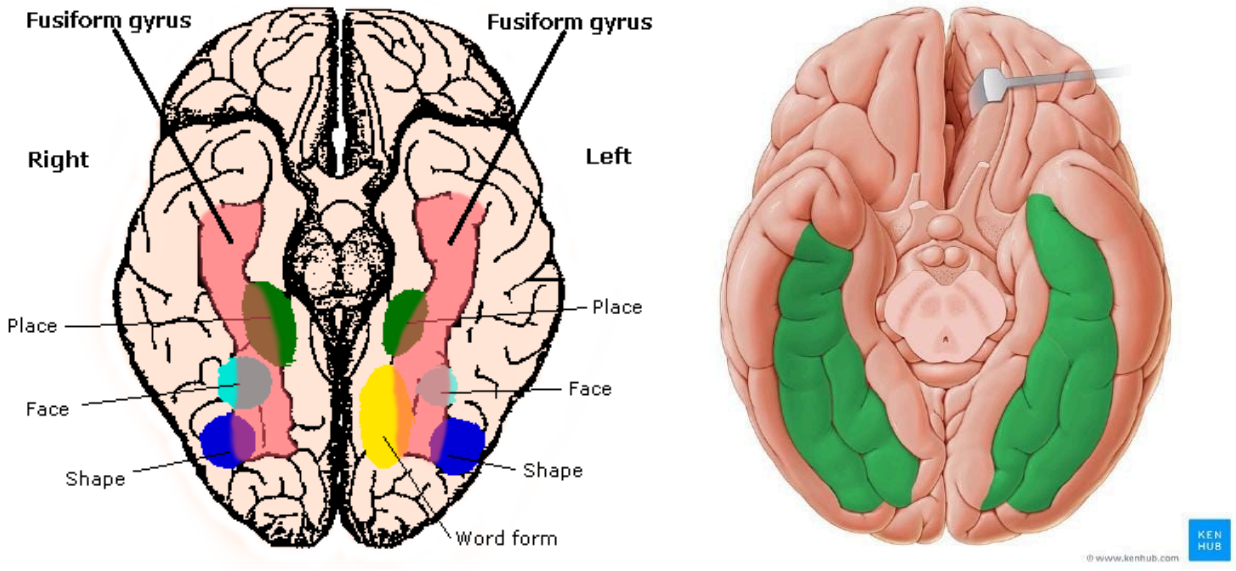
Children with dysgraphia have a learning disability that results in a struggle to write legibly. The physical task of writing with a pen and paper is extremely challenging for the person. These children often have extreme difficulty putting their thoughts down on paper (Smits-Engelsman & Van Galen, 1997). This difficulty is inconsistent with a person's IQ. That is, based on the child's IQ and/or abilities in other areas, a child with dysgraphia should be able to write, but can't. Children with dysgraphia may also have problems with spatial abilities.

Dyslexia

Dyslexia is the most common learning disability in children that causes difficulties in learning to read. An individual with dyslexia exhibits an inability to correctly process letters. The neurological mechanism for sound processing does not work properly in someone with dyslexia. As a result, dyslexic children may not understand sound-letter correspondence. A child with dyslexia may mix up letters within words and sentences—letter reversals, such as those shown in Figure 10.3.2, are a hallmark of this learning disability—or skip whole words while reading. A dyslexic child may have difficulty spelling words correctly while writing. Because of the disordered way that the brain processes letters and sound, learning to read is a frustrating experience. Some dyslexic individuals cope by memorizing the shapes of most words, but they never actually learn to read (Berninger, 2008).

The Brain, Dyslexia, and Dysgraphia

Developmental dyslexia is a heritable neurodevelopmental disorder that impairs reading in individuals with normal intelligence and educational opportunities. Reading requires the coordination of many brain systems. This "reading circuit" includes language mechanisms in Broca's and Wernicke's areas in the frontal and temporal lobes, respectively, as well as systems involved in vision, working memory, attention, movement and cognition. Processing of printed words takes place within "the visual word form area" located in the fusiform gyrus (also involved in object and face recognition) of the left hemisphere.



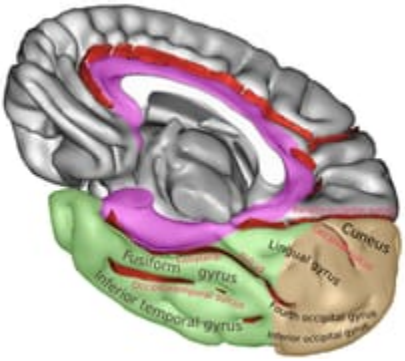


Figure 4.1.3.2: Fusiform gyrus viewed from bottom of human brain. Note an area for "word form" located in the left fusiform area. (Images from Wikimedia Commons, Fusiform gyrus, retrieved 10/19/21).

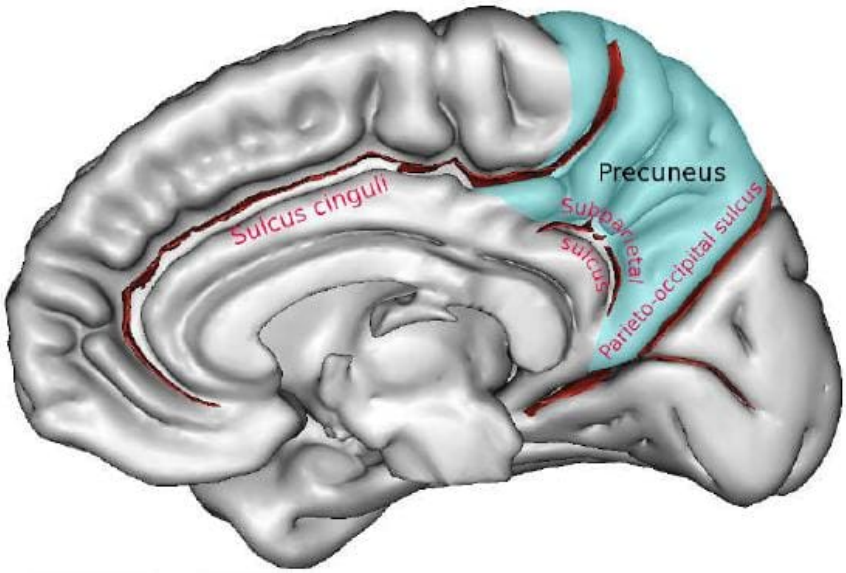

Next, a large circuit in the left hemisphere is activated. This circuit includes the **supramarginal gyrus** (mapping of spelling and other writing conventions to language sounds), the **superior temporal gyrus** (phonological sound processing), the **inferior parietal lobule** and the **angular gyrus** (word-meaning processing) and the **inferior frontal gyrus** (phonological sound and semantic meaning processing, working memory). In addition, **subcortical regions** implicated in long-term and working memory, procedural learning and rapid sequential auditory processing (thalamus, basal ganglia and hippocampus) also appear to be involved in reading.

In addition, there is strong evidence for a role of the **visual magnocellular (M) system** in reading and research suggests a

significant role of deficits in the visual magnocellular (M) system in **developmental dyslexia** (DD). The M and parvocellular (P) pathways are major parallel visual system streams feeding to lateral geniculate nucleus (visual area) of the thalamus, then onto primary visual (striate) cortex, and then to the extrastriate regions of the occipital lobe (i.e., the 'dorsal' and the 'ventral' visual streams). The **ventral stream (the "what" pathway)** which involves the inferior temporal cortex is associated with color, form perception, and the discrimination and recognition of objects). The **visual magnocellular or dorsal system (the "where" pathway**; depth and motion perception) contributes to rapid recognition and sequencing of letters by quickly focusing the **ventral attention network** (VAN) on the letter to be identified. Finally, left and right fronto-parietal (attentional) networks critically modulate visual and auditory word pathways by selective attention in both temporal and spatial dimensions. The **visual magnocellular system (the "where" pathway) is related to the fronto-parietal attentional network**. Previous neuroimaging studies have revealed reduced or absent activation within the visual M pathway in DD. Considering the complexity of the circuitry involved in reading, it is likely that a wide range of patterns of neurological deficit in the above mentioned brain areas may contribute to reading difficulties in different individuals (Mascheretti, et al., 2021).

Dysgraphia appears to involve disorder in some **brain areas** which are **not involved in dyslexia**. Richards, et al. (2015) used fMRI to study structural white matter integrity and functional connectivity in children with dysgraphia and dyslexia and found significant differences between control group and both the dysgraphic and dyslexic groups in functional connectivity. Left **occipital temporal gyrus**, supramarginal gyrus, **precuneus**, and **inferior frontal gyrus** were used in these analyses because these brain areas were shown in an analysis of prior research to be related to written word production. Dysgraphia and dyslexia differ in white matter integrity, fMRI functional connectivity, and white matter–gray matter correlations.

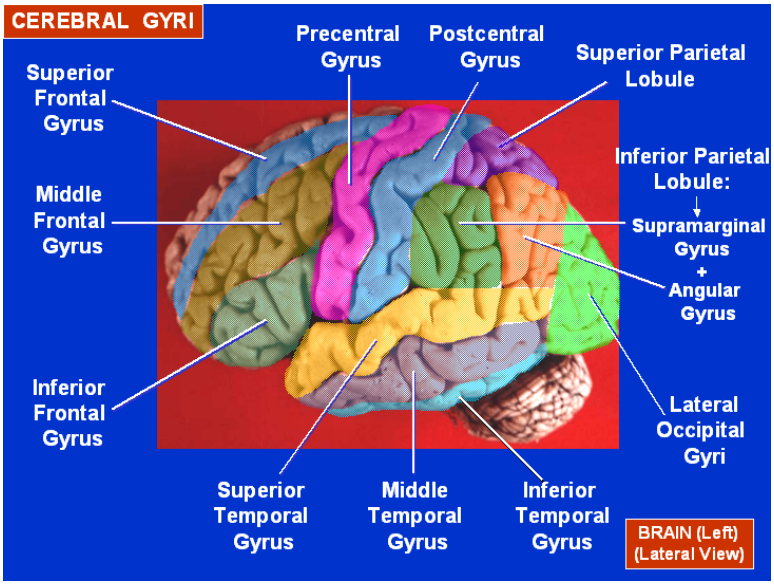

Figure 4.1.3.3: (top left) Fusiform gyrus (also known as the lateral occipitotemporal gyrus) viewed from bottom of human brain. (top right) Midline view featuring the Precuneus (multiple functions including memory, sensory/perceptual integration, mental imagery strategies) and several other midline sulci. (bottom) Left hemisphere of human brain showing Inferior Frontal gyrus in the Frontal lobe and the Supramarginal gyrus in the Parietal lobe. Decreased white matter integrity and impaired functional connectivity among these structures is associated with dysgraphia. (Images from Wikipedia Commons, Fusiform gyrus, Precuneus, Inferior Frontal gyrus; retrieved 10/19/21. Caption by Kenneth A. Koenigshofer, PhD, including reference to Science Direct, Precuneus; Richards, et al., 2015).

Summary

Genetics and environment affect intelligence and the challenges of certain learning disabilities. The intelligence levels of all individuals seem to benefit from rich stimulation in their early environments. Highly intelligent individuals, however, may have a built-in resiliency that allows them to overcome difficult obstacles in their upbringing. Learning disabilities can cause major challenges for children who are learning to read and write. Unlike developmental disabilities, learning disabilities are strictly neurological in nature and are not related to intelligence levels. Students with dyslexia, for example, may have extreme difficulty learning to read, but their intelligence levels are typically average or above average.

Review Questions

1. Where does high intelligence come from?
    1. genetics
    2. environment
    3. both A and B
    4. neither A nor B
2. Arthur Jensen believed that _____.
    1. genetics was solely responsible for intelligence
    2. environment was solely responsible for intelligence
    3. intelligence level was determined by race
    4. IQ tests do not take socioeconomic status into account
3. What is a learning disability?
    1. a developmental disorder
    2. a neurological disorder
    3. an emotional disorder
    4. an intellectual disorder
4. Which of the following statements is true?

1. Poverty always affects whether individuals are able to reach their full intellectual potential.
2. An individual's intelligence is determined solely by the intelligence levels of his siblings.
3. The environment in which an individual is raised is the strongest predictor of her future intelligence
4. There are many factors working together to influence an individual's intelligence level.

Critical Thinking Questions

What evidence exists for a genetic component to an individual's IQ?

Describe the relationship between learning disabilities and intellectual disabilities to intelligence.

Personal Application Question

Do you believe your level of intelligence was improved because of the stimuli in your childhood environment? Why or why not?

4.1.4: Cognition- Categories, Concepts, Schemas and the Brain

Learning Objectives

1. Describe cognition.
2. Discuss concepts and prototypes.
3. Explain schemas and how they contribute to the adaptive organization of behavior and its efficiency.
4. Discuss the brain structures involved in category formation.
5. Describe the types of characteristics of things which affect where in the brain their categories are stored.
6. Describe the roles of similarity, prototypes, and typicality in categorization.
7. Explain prosopagnosia.
8. Describe the fuzzy nature of concepts.
9. Explain category hierarchies.
10. Discuss the representation of concepts and knowledge.

Overview

Cognitive psychology is dedicated to examining how people think, including interactions among human thinking, emotion, creativity, language, and problem solving, and how we organize thoughts and information gathered from our environments into meaningful categories. As discussed earlier, the generation of categories, based on similarity, is an example of an ability that has arisen from the genetic internalization, by natural selection, of an enduring fact of the world. That fact is that things in the world are similar to other things, in various properties, and in varying degrees of abstraction (see Section 14.2). A brain unable to form categories would be crippled; every experience would seem unrelated to every other, and the brain's ability to find order in the world would not exist. Much of thinking involves the formation and use of categories. Inferences about the properties of new instances of a category based on knowledge about the category is an essential component of intelligence and thinking in humans and in a number of other animal species. The high level of abstraction that the human brain is capable of provides humans with categories of very high degrees of abstraction, giving great cognitive power to our species compared to other animals. Human concepts can range from classification based on simple concrete properties such as shape or color to high order abstract properties leading to concepts such as mammal, illegal, commerce, electrostatic force, or beauty. **Corticostriatal loops** involving connections between a number of cortical areas and the striatum, composed of several nuclei of the basal ganglia, appear to be crucially involved in category formation in humans.

Concepts and Prototypes

The senses serve as the interface between the mind and the external environment, receiving stimuli and translating it (transducing it via sensory receptors) into nervous impulses that are transmitted to the brain. The brain then processes this information and uses the relevant pieces to create thoughts, which can then be expressed through language or stored in memory for future use. When thoughts are formed, the brain also pulls information from emotions and memories, powerful influences on both our thoughts and behaviors.

Concepts are *abstract representations* or *cognitive structures* formed from classes or *groupings of things*, events, or relations *based on common properties*. Concepts can be about concrete things such as the concepts "car," "bird," or "swimming," or about complex and abstract things, like "justice" or "success". In psychology, for example, Piaget's stages of development are abstract concepts. Some concepts, like tolerance, are agreed upon by many people, because they have been used in various ways over many years. Other concepts, like the characteristics of your ideal friend or your family's birthday traditions, are personal and individualized. In this way, concepts touch every aspect of our lives, from our many daily routines to the guiding principles behind the way governments function.

A **prototype** is the *best example* or representation *of a concept*. For example, for the category of civil disobedience, your prototype could be Rosa Parks. Her peaceful resistance to segregation on a city bus in Montgomery, Alabama, is a recognizable example of civil disobedience. Or your prototype could be Mohandas Gandhi, sometimes called Mahatma Gandhi. Mohandas

Gandhi served as a nonviolent force for independence for India. Prototypes apply to more concrete concepts as well. In your mind, is the prototype bird a penguin, an eagle, a sparrow, or is there some other type of bird that is the best example of the concept, bird? Which of the birds listed in the previous sentence is *most typical of the category* "birds"? Is "typical" simply a function of frequency of occurrence?

Schemas

A **schema** is a mental construct consisting of a cluster or collection of related concepts (Bartlett, 1932). In other words, a schema is a collection of knowledge and beliefs about some entity or situation that directs behavior and guides expectations. Schemas help organize knowledge and often help us predict event sequences and attributes of things we encounter in the world. For example, the schema "library" suggests the presence of books, desks, shelves, and a quiet place to study. It also suggests a sequence of actions including searching the stacks, selecting a book, and taking the book to a librarian at a check out desk before leaving the library with the book. There are many different types of schemas, and they all have one thing in common: schemas are a method of organizing information that allows the brain to work more efficiently. When a schema is activated, the brain makes immediate assumptions about the person or object being observed and using this *information contained in the schema* to organize behavior.

There are several types of schemas. A **role schema** makes assumptions about how individuals in certain roles will behave (Callero, 1994). For example, imagine you meet someone who introduces himself as a firefighter. When this happens, your brain automatically activates the “firefighter schema” and begins making assumptions and generating *expectations (predictions)* that this person is brave, selfless, and community-oriented. Despite not knowing this person, already you have unknowingly made judgments and formed expectations about him. Notice how the *schema is predictive* in the sense that it allows you to form expectations about something in the future, in this case, what behaviors this person might be expected to engage in. A common feature of many forms of cognition, including schemas, is *projections or expectations about probable events in future time*.

Schemas also help you fill in gaps in the information you receive from the world around you. While schemas allow for more efficient information processing, there can be problems with schemas, regardless of whether they are accurate most of the time: Perhaps this particular firefighter is not brave, he just works as a firefighter to pay the bills while studying to become a children’s librarian. *Schemas involve generalization--inference based on* prior experience with *similar* things in the past. Like schemas, all forms of *generalization* permit *prediction* allowing us to fill in gaps in our direct knowledge including what might be expected to occur in the future. Although there is always the chance that our predictions or inferences based on generalization might be wrong, nevertheless, *schemas and generalizations from them are powerful forms of cognition*. They permit us to form *expectations from incomplete information* about the future and thus allow us to prepare and plan for what is to come next. This *anticipatory property of cognition* is *highly adaptive* and likely has been powerfully *selected* for during the course of *brain evolution*.

An **event schema**, also known as a **cognitive script**, is a knowledge structure about a sequence of events. An event schema can lead to a set of behaviors that can feel like a routine. Think about what you do when you walk into an elevator. First, the doors open and you wait to let exiting passengers leave the elevator car. Then, you step into the elevator and turn around to face the doors, looking for the correct button to push. Like all *schemas*, event schemas are learned from *environmental regularities* we experience in the world.

Event schemas can vary widely among different cultures and countries. For example, while it is quite common for people to greet one another with a handshake in the United States, in Tibet, you greet someone by sticking your tongue out at them, and in Belize, you bump fists (Cairns Regional Council, n.d.) Because event schemas are automatic, they can be difficult to change. Imagine that you are driving home from work or school. This event schema involves getting in the car, shutting the door, and buckling your seatbelt, and putting the key in the ignition, and driving a particular route. How many times have you driven your route home only to remember as you pass your turn that you were intending to stop at the store first?

Concepts, Prototypes, Schemas, and Evolution of General Intelligence

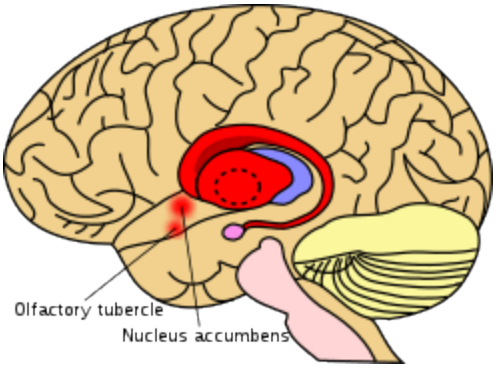
Concepts, prototypes, and schemas all rely upon abstract, higher order features of the world which the brain captures and utilizes when it forms these *knowledge structures*. For example, concepts and prototypes are knowledge structures which *capture* ***similarities*** among individual instances of things (e.g. all birds have beaks, feathers, and wings). As discussed in an earlier section, the *brain* appears to be *innately organized* to find similarities and to *generate higher order representations based on similarity*. This leads to formation of concepts, categories, and predictions or expectations based on partial information. Also, as previously discussed, the brain has evolved to readily recognize and represent ***cause-effect*** and the ***predictive relations***

(correlation or covariation) of environmental events (Koenigshofer, 2017), leading to the formation of event schemas, as well as knowledge about the predictive and causal relations among events in the world--*all* of these help generate *sophisticated* ***knowledge*** *and understanding of one's environment*, facilitating adaptive organization of behavior and *increasing biological fitness*.

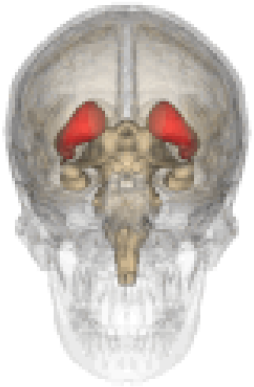
Perhaps one of the strongest examples of human *thinking and intelligence* is *scientific discovery*, a process which demonstrates abilities for *categorization*, often of a *highly abstract* nature, and *causal understanding*, talents which are evident in humans at an early age. As one researcher and his colleagues state,

> "Causal induction, i.e., identifying unobservable mechanisms that lead to the observable relations among variables, has played a pivotal role in modern scientific discovery, especially in scenarios with only sparse and limited data. Humans, even young toddlers, can induce causal relationships surprisingly well in various settings despite its notorious difficulty" (Zhang, et al., 2021, p. 1).

Combined, these innate, evolved properties of the brain help the brain develop understanding of the relations among things in the world, thereby guiding adjustments in behavior for successful adaptation to the environment. Recall from earlier sections that these abilities comprise central components of **general intelligence** (the recognition "of relations and correlates," according to Spearman, 1904, 1925), found not only in humans, but in many animals ranging from crows and ravens to the great apes (see Koenigshofer, 2017). Although it is likely that the abilities that underlie general intelligence are distributed widely in the brain, the **frontal and parietal lobes** of the cerebral cortex appear to be especially important in *human general intelligence* (Bruner, 2010). Also recall that one *additional component of general intelligence* is the *ability to imagine possible future behaviors and their probable outcomes* in visual-like mental images, an ability which may involve **visual and motor cortex and parts of the parietal lobe** involving, as discussed in an earlier module, a **frontoparietal network**. This ability to imagine, as already noted, may play an important role in *response selection and planning* for the future, *key features of human cognition and intelligence* (Koenigshofer, 2017).

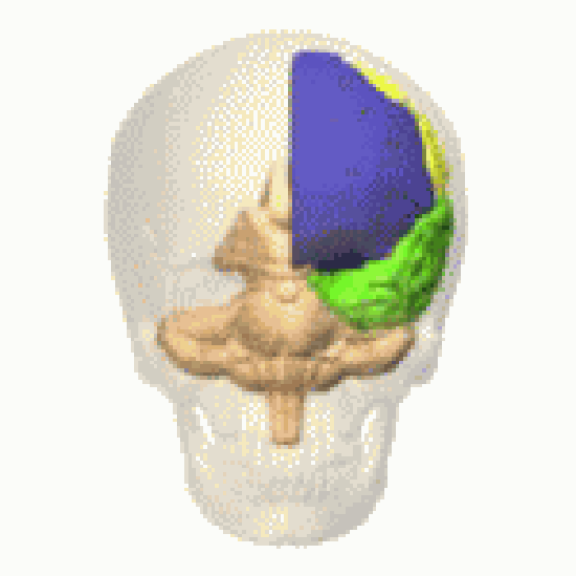


Brain Mechanisms in Category Formation



How the brain forms categories, and the brain areas involved, is not yet settled. However, evidence from studies of brain damage and brain imaging sheds light on the issue.

One thing is certain. Category formation is essential to cognitive processes. According to Seger and Miller (2010), the *ability to form groupings* of things and events into categories is a *fundamental property of "sophisticated thought*." Intelligence depends upon the ability to form meaningful categories. Disruption of this key feature of thinking and intelligence leads to behavioral and cognitive pathology. The importance of category formation is suggested by Seger and Miller (2010). Without the ability to form categories, "the world would lack any deeper meaning. Experiences would be fragmented and unrelated. Things would seem strange and unfamiliar if they differed even trivially from previous examples. This situation describes many of the cognitive characteristics of neuropsychiatric disorders such as autism" (Seger & Miller, 2010, p. 203).



Category formation, as discussed in earlier sections, reflects a fundamental fact of the world--that things and events in the world are similar to other things and events. Ability of the brain to exploit this fundamental property of the world to allow inference from the properties of a known category to new instances of the category has enormous, favorable consequences for survival and reproduction. A general principle is operating here. Natural selection has organized brain systems to reflect biologically significant regularities of the world (Koenigshofer, 2017; Shepard, 2001). This is consistent with the view expressed earlier that *intelligence and thinking* evolved as sophisticated *guidance systems* which produce neural models or *cognitive maps* of the world for the production of adaptively successful behavior.

The ability to form categories is dependent upon many brain areas which interact during the learning of categories. According to Seger and Miller (2010), these areas include the **visual cortex**, the **prefrontal cortex**, the **parietal cortex**, the **basal ganglia**, and the **medial temporal lobe**, including "interactions within and between **corticostriatal loops** connecting cortex and basal ganglia and between the basal ganglia and the medial temporal lobe." This provides "a balance between acquisition of details of experiences and generalization across them" to form and use categories (Seger & Miller, 2010, p. 203). According to Seger and Miller (2010), the **inferotemporal (IT) cortex** is likely a participating brain area in visual categorization given that it contains the **fusiform face area (FFA)**, rich in **face cells**, active during learning of new face categories. Furthermore, **IT cortical neurons** in trained monkeys fire selectively to trees or fish with relatively little variation of firing within categories, suggesting that these neurons within the IT cortex **encode specific categories of stimuli**.

Mahon and Caramazza (2009) reviewed research on categorization involving brain imaging and brain damage. They note that one generalization from this research is that "object domain and sensory modality jointly constrain the organization of knowledge in the brain." In other words, **localization of particular items of knowledge in the brain depends on the object category (e.g. faces, tools) and also upon which sensory system (e.g. visual, auditory) is involved in representing the knowledge**. Specifically, studies of the effects of brain damage on verbal categorization have been interpreted by some researchers to indicate that broad categories of objects (object domains) may be represented separately in different cortical regions. Research with brain damaged patients with damage in different brain areas has revealed "disproportionate or even selective impairments" for one category compared to other categories. This supports the view that *different categories of objects are represented in different areas of brain*. Cases of verbal category impairments have been found for the categories "animals," "fruit/vegetables," "conspecifics" (other humans), and "non-living things." For many patients, the deficits included failure to understand knowledge about the concepts, not just in naming them. For example, patients with impairment of the category "animals" could not answer simple questions about the features of specific animals, such as "Does a whale have legs" (Mahon and Caramazza, 2009, p. 28). Another patient had deficits in conceptual knowledge about people as evidenced by a severe inability to name famous people, even though this patient did not have **prosopagnosia** (inability to recognize familiar faces, such as family members or even one's own face in a photograph, while still being able to recognize a familiar person by other sensory modalities such as by voice).

According to Mahon and Caramazza, in addition to the theory that different categories may be localized in different modality-specific regions of brain (e.g. visual areas, somatosensory areas), other theories of categorical knowledge have been proposed, including the idea that **category formation is "constrained by evolutionarily important distinctions such as animate, inanimate, conspecifics, and tools," or** that **categories are based on "statistical regularities in the co-occurrence of object properties in the world,"** implying wide distribution of neural representations of specific categories in the brain.

According to Mahon and Caramazza (2009), Damasio et al. (1996) found that inability to name pictures of famous people was related to "**left temporal pole lesions**," while impairment for naming animals occurred "with (more posterior) lesions of **anterior left ventral temporal cortex**." Additional studies confirmed that impairments naming animals occur with lesions of **anterior temporal cortex**. Studies by Damasio and colleagues and others found deficits for recognizing and naming tools with lesions to the **posterior and lateral temporal cortex,** overlapping the left posterior middle temporal gyrus. fMRI studies reveal that "nonliving things, and in particular tools, differentially activate the **left middle temporal gyrus**" as does mechanical motion. "Living **animate things** such as faces and animals elicit differential neural responses in the **lateral fusiform gyrus**, whereas **nonliving things** (tools, vehicles) elicit differential neural responses in the **medial fusiform gyrus**." Interestingly, brain areas involved in emotional processing and *theory of mind* (attribution of mental states in others) are part of the neural network activated during processing of information about living animate things (Mahon & Caramazza, 2009).

Ishibashi et al. (2016) reviewed "neuroimaging studies . . . to identify tool-related cortical circuits dedicated either to general tool knowledge or to task-specific processes. The results indicate the following: (a) Common, task-general processing regions for tools are located in the **left inferior parietal lobule** (LIPL) and **ventral premotor cortex**; and (b) task-specific regions are located in **superior parietal lobule** (SPL) and **dorsal premotor area** for imagining/executing actions with tools and in **bilateral occipito-temporal cortex** for recognizing/naming tools."

An approach to cognition known as **embodied cognition** hypothesizes that abstract concepts necessarily involve experience with previous sensorimotor interactions involving the whole body and thus may include encoding by sensory and motor areas of the brain. For example, we speak of an idea that we are not grasping as being "over our head," and we speak of affection in terms of

warmth as represented in the fact that affection often is expressed in ways that allow us to feel the physical warmth of the body of another for whom we have affection. The concept of justice is often represented by a scale in balance. So, on this view, abstract concepts are often expressed in terms that are analogous to sensory and motor experiences of a body embedded in a concrete physical world.

Summary

In this section, you were introduced to topics within cognitive psychology, which is the study of cognition, or the brain's ability to think, perceive, plan, analyze, and remember. Concepts and their corresponding prototypes help us quickly organize our thinking by creating categories into which we can sort new information. We also develop schemas, which are clusters of related concepts. Some schemas involve routines of thought and behavior, and these help us function in various situations without having to "think twice" about them. Schemas show up in social situations and routines of daily behavior. Concepts, prototypes, and schemas arise from fundamental dispositions of the brain to form knowledge structures based on similarity, causal relations, and correlations or predictive covariations of events. Natural selection favored brain organization capable of exploiting these abstract properties of the world leading to the evolution of general intelligence. General intelligence equipped humans and many other species with capacity to solve a wide range of adaptive challenges. In humans especially, this involves reasoning, planning, and imagination of possible future actions and their probable outcomes (Koenigshofer, 2017).

4.1.5: Brain Mechanisms and Intelligence

Learning Objectives

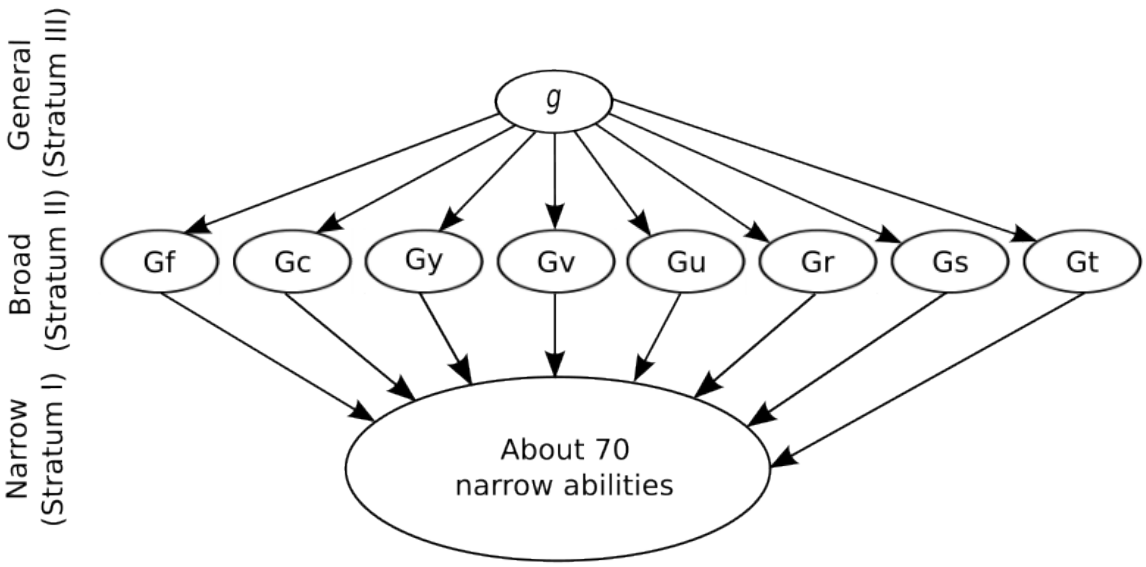
1. Describe the brain structures included in the P-FIT model of the biology of intelligence.
2. Describe the Default-Mode Network (DMN) and its relationship to the biology of intelligence.
3. Discuss the type of attention that is probably involved when someone is taking an I.Q. test and how this is related to interpretation of brain imaging studies of the brain networks involved in human intelligence.

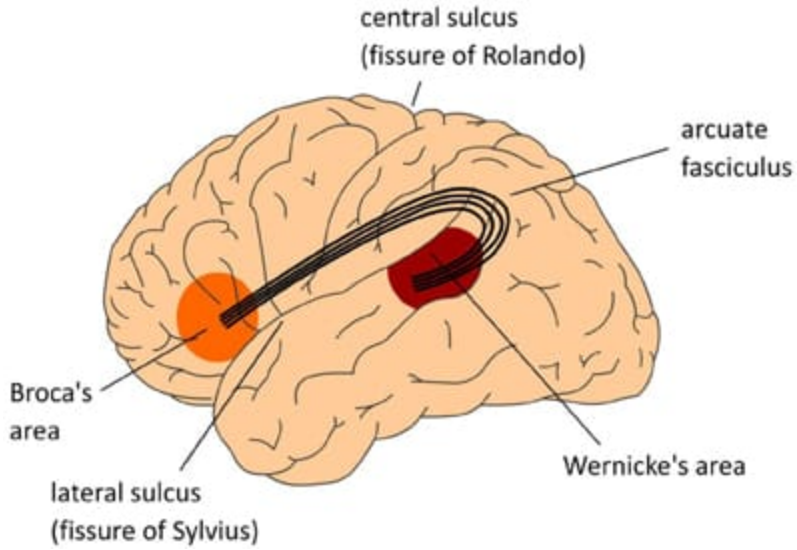
Overview

According to Hearne, et al. (2016, p.1), "Human intelligence can be broadly defined as the capacity to understand complex ideas, adapt effectively to the environment and engage in complex reasoning[1]. Measures of intelligence can be related to performance on virtually any cognitive task, from sensory discrimination[2] to challenging cognitive tasks such as the identification of patterns in the Raven's Progressive Matrices test[3]. Importantly, scores on intelligence tests can accurately predict various life outcomes, including academic success[4], job performance[5] and adult morbidity and mortality[6]." In spite of the adaptive importance of intelligence in human life, the brain mechanisms involved in intelligence are not well understood. However, research makes it increasingly clear that complex functions such as cognition and intelligence involve many brain areas acting together in interconnected neural networks comprised of multiple brain areas. Furthermore, interactions between different networks of brain areas are also important if we are to understand how the brain creates cognition and intelligence. Functional magnetic resonance imaging (fMRI) has been used to investigate the relationship between individual differences in intelligence and brain activity during cognitive activities such as working memory and reasoning. As discussed in prior modules of this chapter, brain imaging studies implicate neural interactions in a **fronto-parietal network** underlying many of the functions associated with human intelligence. These observations have resulted in the influential **Parieto-Frontal Integration Theory** of intelligence (P-FIT) which identifies a number of interacting brain structures associated with individual differences in human intelligence including frontal and parietal lobes and other structures. Additional research (Hearne, et al., 2016) shows that individual differences in intelligence between people are also associated with the degree of neural interaction between the fronto-parietal network and the **default-mode network**. Greater connectivity between these two neural networks when the brain is at rest (i.e. in the absence of any specific cognitive task) is correlated with higher intelligence scores in individuals compared to those with lesser connectivity between the fronto-parietal and default mode networks. Interactions with a **dorsal attention network** (DAN) must also be considered for a more complete understanding of the complex network interactions involved in cognition and intelligence.

Brain Mechanisms and Intelligence

Because of the complexity and number of interacting factors in human intelligence, understanding the brain mechanisms in human intelligence is a monumental task for researchers. The figure below showing Carroll's influential model of human intelligence is a reminder of the large number of interacting abilities involved. The various factors and abilities shown are derived mathematically using *factor analysis* based on analysis of patterns of correlations in the performances of large numbers of people on measures of intelligence such as standard I.Q. tests (e.g. Wechsler Adult Intelligence Scale, WAIS).





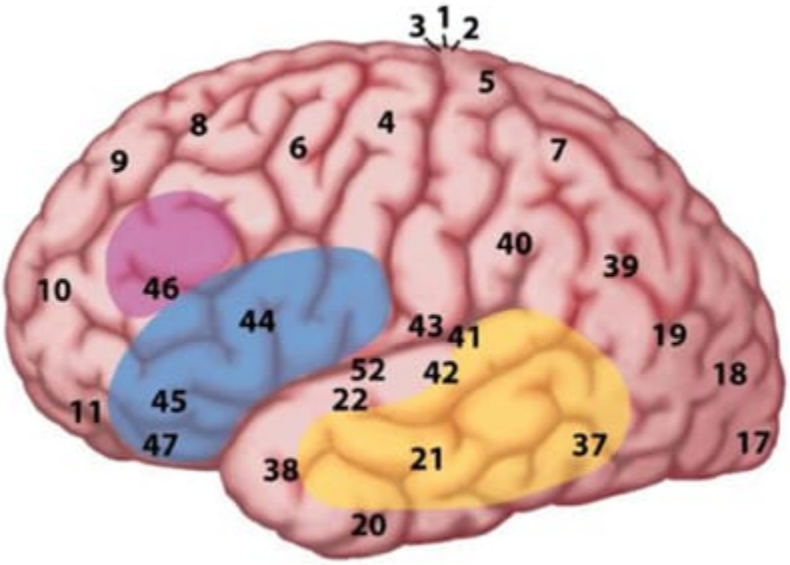


Figure 4.1.5.1: At the top of Carroll's three-stratum model of human intelligence is the g-factor, general intelligence. Notice the large number of Stratum I abilities which comprise the factors in g and the more specific g-factors in Stratum II. Abbreviations: fluid intelligence (Gf), crystallized intelligence (Gc), general memory and learning (Gy), broad visual perception (Gv), broad auditory perception (Gu), broad retrieval ability (Gr), broad cognitive speediness (Gs), and processing speed (Gt). (Image and abbreviations from Wikimedia Common; File:Carroll three stratum.svg; https://commons.wikimedia.org/wiki/F...ee_stratum.svg; by Victor Chmara; made available under the Creative Commons CC0 1.0 Universal Public Domain Dedication).

In spite of this complexity, neuroscientists using brain imaging methods have identified brain regions associated with differences in measured I.Q. or other measures of general intelligence. As mentioned earlier in this chapter, Jung and Haier (2007) reviewed brain imaging studies and identified a set of brain areas correlated with individual differences in intelligence and reasoning among people. They called this set of interconnected brain regions the **fronto-parietal network** and dubbed their model the **Parietal-Frontal Integration Theory (P-FIT)**. "The P-FIT model includes, by Brodmann areas (BAs): the **dorsolateral prefrontal cortex** (BAs 6, 9, 10, 45, 46, 47), the **inferior** (BAs 39, 40) **and superior** (BA 7) **parietal lobule**, the **anterior cingulate** (BA 32), and **regions within** the **temporal** (BAs 21, 37) and **occipital** (BAs 18, 19) **lobes**. White matter regions (i.e., **arcuate fasciculus**) are also implicated" (Jung and Haier, 2007, p. 135).

The arcuate fasciculus interconnects regions of temporal and parietal cortex with frontal cortex (see Figure 14.8.2). This bundle of axons connects Wernicke's and Broca's areas, in temporal and frontal lobes, respectively, which are involved in language comprehension and language production (see modules on language later in this chapter). Surprisingly, this does not mean that language ability is necessary for cognition and intelligence.

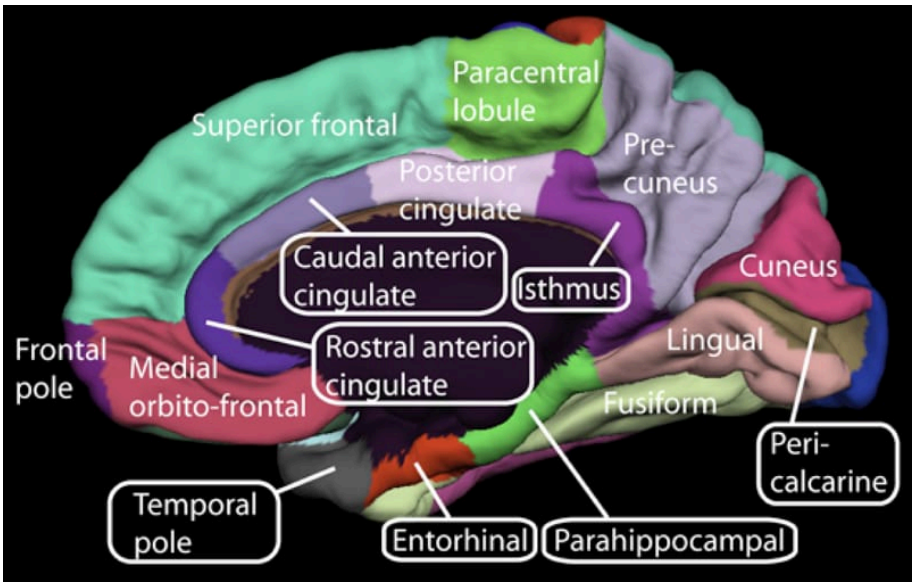

Figure 4.1.5.2: (Left): The Arcuate Fasciculus. Lateral view of left hemisphere. (Center): The center figure also displays a lateral view

of the left hemisphere. The numbers indicate Brodmann areas (BA). These are areas with differences in the cytoarchitectonics (i.e., composition of cell types). The memory areas are in the temporal cortex (in yellow) including the angular gyrus in parietal cortex. Broca's area (Brodmann areas 44 and 45) and adjacent cortex (Brodmann areas 47 and 6) in the frontal lobe involved in language. Control operations recruit another part of the frontal lobe (in pink), and the Anterior Cingulate Cortex (ACC; not shown in the center figure), as well as areas involved in attention. (Right): Medial view of cerebral cortex showing major gyri. (2008) Mapping the Structural Core of Human Cerebral Cortex. PLoS Biol 6(7): e159. doi:10.1371/journal.pbio.0060159[1]; licensed under the Creative Commons Attribution 2.5 Generic license).

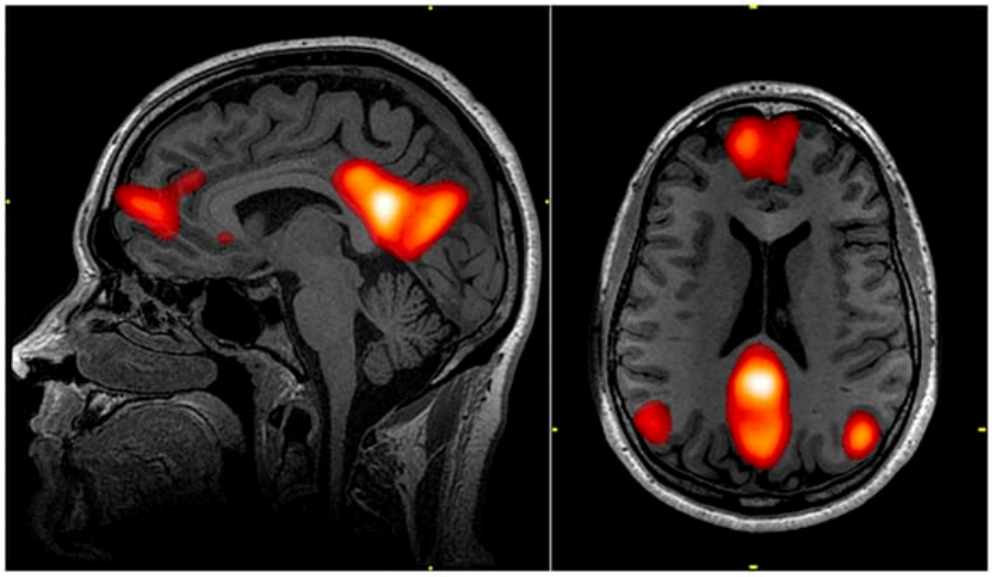
For example, "patients with even severe damage to the language network can retain high intelligence and the ability to perform challenging cognitive tasks, like arithmetic (Varley et al., 2005) and causal reasoning (e.g., Varley and Siegal, 2000; see Fedorenko and Varley, 2016, for a review)" (Assem, et al., 2020, p. 139). This finding strongly suggests that **cognitive tasks like arithmetic and causal reasoning do not depend upon language or language networks.** This finding is consistent with the theory that causal reasoning is a component of general intelligence evolved by "genetic internalization" of causality, similarity, and predictive relations into functional organization of the brain, and that general intelligence is found in many non-human animal species even though they lack language (Koenigshofer, 2017).

Using fMRI, Duncan (2010, 2013) has identified a frontal and parietal pattern of neural activity associated with diverse cognitive tasks and general fluid intelligence. Duncan calls this pattern "multi-demand" (MD) because this activation pattern is a "salient part of the brain's response to many different kinds of cognitive challenge. . . . [T]his multiple-demand (MD) pattern extends over a specific set of regions in **prefrontal and parietal cortex**, in particular: cortex in and around the **posterior** part of the **inferior frontal sulcus** (IFS), [cortex' in the **anterior insula** and the adjacent **frontal operculum** (AI/FO), in the **pre-supplementary motor area** and adjacent **dorsal anterior cingulate** (preSMA/ACC), and [cortex] in and around the **intraparietal sulcus** (IPS). A smaller region of accompanying activity is **sometimes** seen in **rostrolateral prefrontal cortex** (RPFC)" (Duncan, 2010, p. 172). A similar pattern of activation is seen in tasks associated with **general fluid intelligence**. Furthermore, "recent lesion data suggest that deficits in fluid intelligence are specifically associated with damage to the MD network (Duncan, 2010, p. 172).

Using fMRI, Gray, et al. (2003) found that individual differences in general fluid intelligence (gF) were associated with differences in activation of attentional mechanisms in the **lateral prefrontal and parietal cortex** during a working memory task. These results are consistent with the P-FIT model of intelligence and suggest that at least some of the differences in measured intelligence among people may be due to differences in brain networks that mediate attention.

According to Assem, et al. (2020, p. 131), "A distributed frontoparietal Multiple Demand (MD) network [Duncan, 2010, 2013] has long been implicated in intelligent behavior, and its damage has been associated with lower intelligence and difficulties in problem solving. . . [It] has been linked to our ability to engage in goal-directed behaviors, solve novel problems, and acquire new skills. . . . Damage to this network as a result of stroke, degeneration or head injury leads to poorer executive abilities (attention, working memory, and inhibitory control) and lower fluid intelligence (Glascher et al., 2010; Roca et al., 2010; Woolgar et al., 2010) . . . and aberrant functioning of this network has been reported in a variety of neurological and psychiatric disorders."

Emphasizing interactions between various brain networks in human intelligence, Hearne, et al. (2016, p. 7) state: "How the brain self-reorganizes to achieve optimal configurations of functional networks across individuals with varying levels of intelligence is an open question. Recent neuroimaging work has suggested that transient cooperation between different neural systems, including **fronto-parietal**, **cingulo-opercular and default-mode networks**, is integral to **complex cognitive tasks** such as reasoning[42,43], memory recollection[44] and working memory performance[39,45]. Future studies should test the notion that individual differences in intelligence rely on dynamic, context-specific, reconfigurations of local activity and connectivity within a diffuse system comprising fronto-parietal, cingulo-opercular and default-mode regions[46]."



Hearne, et al. (2016, p. 1) "revealed a novel contribution of across-network interactions between **default-mode and fronto-parietal networks** to individual differences in intelligence at rest (i.e. in the absence of any specific cognitive task). Specifically, [they] found that greater connectivity in the resting state was associated with higher intelligence scores." The **default-mode network** includes the medial prefrontal cortex, posterior cingulate cortex, and the inferior parietal lobule. Other structures

sometimes considered part of this network are the middle temporal lobe and the precuneus.

What is the significance of connectivity between networks at rest, when no specific cognitive task is being performed? The answer to this question reflects another method used by neuroscientists to understand the functional and neuroanatomical relationships between networks of interconnected brain areas. Dixon et al. (2017) describe the method this way: "Resting state functional connectivity has emerged as a powerful, non-invasive tool for delineating the functional network architecture of the human brain." In other words, connectivity between brain networks at rest helps neuroscientists determine how various brain networks are "wired" together and how they functionally interact with one another to produce cognition and intelligence.

In this light, remember that Hearne, et al. (2016, p.1) found that "greater connectivity in the resting state [between default-mode and fronto-parietal networks] was associated with higher intelligence scores." To help us understand why this might be so, we have to know something about the suspected role that the default-mode network plays in cognition. Dixon, et al. (2017, p.632) explain it this way: "The default network (DN) is involved in a variety of internally-directed processes, including self-reflection, autobiographical memory, future event simulation, conceptual processing, and spontaneous cognition . . . and exhibits decreased activation during many cognitive tasks that demand external perceptual attention." The finding of decreased activation during cognitive tasks requiring attention to input from the external environment suggested to some researchers that there might be **two competing mutually inhibiting networks**, one for **internal reflection**, and **the other**, **a "task positive" or "task-related"** network **for attention to** the **external world**. However, later research found "co-activation and positive functional connectivity between the DN and the frontoparietal control network (FPCN)—a component of the “task positive” network—during some task conditions, including mind wandering, spontaneous thought, autobiographical future planning, creativity, memory recall, working memory guided by information unrelated to current perceptual input, social working memory, and semantic decision making. . . . On the other hand, studies have generally found anticorrelation [increase in activity in one network is associated with a decrease in the other] between the DN and other components of the “task positive” network, particularly the dorsal attention network (DAN)" (Dixon, et al., 2017, p. 633).

The **“dorsal attention network” (DAN) or “frontoparietal network”** directs visual attention and short-term memory processes . . . Moreover, this network is distinct from a cingulo-opercular cognitive control network (CCN). Yet, no consensus has been reached regarding the precise components of the DAN. On the basis of task-based and resting-state fMRI studies, the DAN in humans is typically defined to include all or some of the following four regions: (1) intraparietal sulcus (IPS)/ superior parietal lobule; (2) superior pre-central sulcus (sPCS) containing the homolog of primate frontal eye fields; (3) inferior pre-central sulcus (iPCS), alternately known as inferior frontal junction; and (4) the motion-sensitive area MT complex (MT) . . . [Moreover,] subcortical structures, such as superior colliculus and pulvinar, are often implicated in attentional functions" and parts of the cerebellum are also involved in the DAN" (Brissenden, et al., 2016, p. 6083-4).

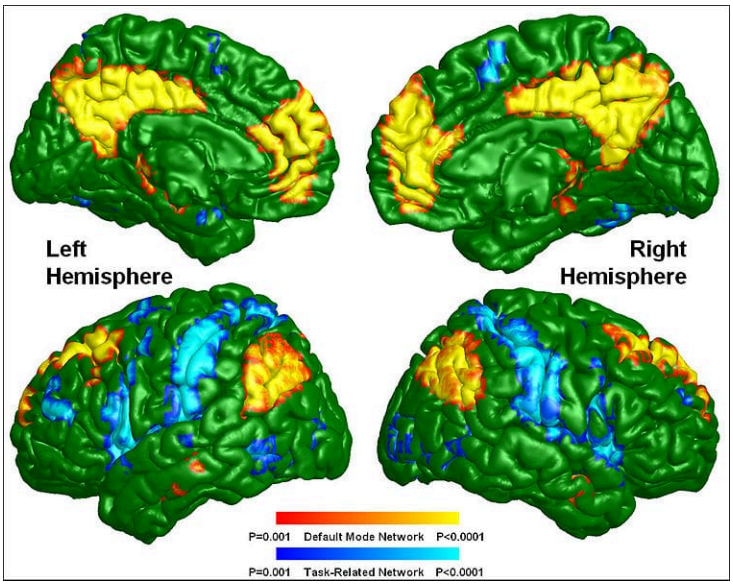


Figure 4.1.5.3: (Left): The Default Mode Network, midsagittal and horizontal cross-section views. (Right): Default Mode Network contrasted with Task-Related Network. On a green background, the default mode network is highlighted in warm colors (red and yellow) and the task-related network is highlighted in cold colors (blue and light blue). Top, medial views. "[A]ttention is a selection mechanism that serves to choose a particular source of stimulation, internal train of thoughts, or a specific course of action for priority processing . . . However, in certain situations attention is necessary to supervise goal-directed action . . . [and] is necessary for detecting errors, and controlling behavior in dangerous and novel or unpracticed conditions. Thus, attention mechanisms are also central to the generation of voluntary behavior, which often involves inhibition of automatic responses. . . . [Furthermore, attention can be] mostly driven by external stimulation or . . . [by] endogenous processes such as voluntary intentions or expectations. . . . [or] attention can also be directed to an object because of its relevance to our current goals" (Rueda, et al., 2015, p.183). Additionally, sustained attention on a task (such as taking an I.Q. test) must be maintained during distraction. Sustained, focused attention is clearly involved in a person's performance on many measures of intelligence. Rueda, et al. (2015) identify **three types of attention networks: 1) alerting**, such as attention to a sudden loud noise (mediated by norepinephrine); **2) orienting**, shifts of attention from one location to another, involving **parietal and frontal cortices** and which uses acetylcholine; and **3) executive attention**, attention required to deal with distraction and incongruous (conflicting) information especially if incompatible with the task, goal, or problem at hand; executive attention involves **anterior cingulate and prefrontal cortices**, and is modulated by levels of brain dopamine and serotonin.

The close association of attention with ability to concentrate during working memory and problem solving raises the possibility of a confound between attention and intelligence in some of the brain imaging studies supporting the P-FIT and similar models of the biology of intelligence discussed above. In other words, the networks identified with intelligence may turn out to be more accurately defined as attention networks. If so, some of the brain imaging research in intelligence may be accessing attentional networks, rather than intelligence networks. In this case, variations in I.Q. associated with the functioning of these networks may primarily reflect differences among people in attentional mechanisms which then affect performance on I.Q. tests. Attention and working memory, though certainly essential to problem solving, reasoning, and intelligent action, do not capture the reasoning processes themselves. When interpreting research in this area, it is important to be aware of the specific features of the cognitive tasks under study. For example, does any particular imaging study use control procedures that can separate effects of attention and working memory from the reasoning processes of intelligence themselves? It may turn out that this separation is so difficult to accomplish that, in actual practice, the overlap between attention networks and intelligence networks may be hard to tease out.

However, attentional networks have been identified such as the *dorsal attention network* (DAN) and a cingulo-opercular cognitive control network (CCN) (and others mentioned above), and the extent to which these do not overlap the networks associated with general fluid intelligence, researchers may be closer to identifying networks involved in reasoning and intelligence as distinct from the mechanisms of attention.

In the meantime, we do know that variations among people in I.Q. and other measures of intelligence are correlated with differences in their brain activity in the fronto-parietal network (as proposed by the P-FIT model and Duncan's MD network), and with the degrees of functional connectivity at rest between this network and the default-mode network. However, additional research is needed to clarify the underlying reasons for these correlations between measures of intelligence and levels of activity in these brain networks and their connectivity.

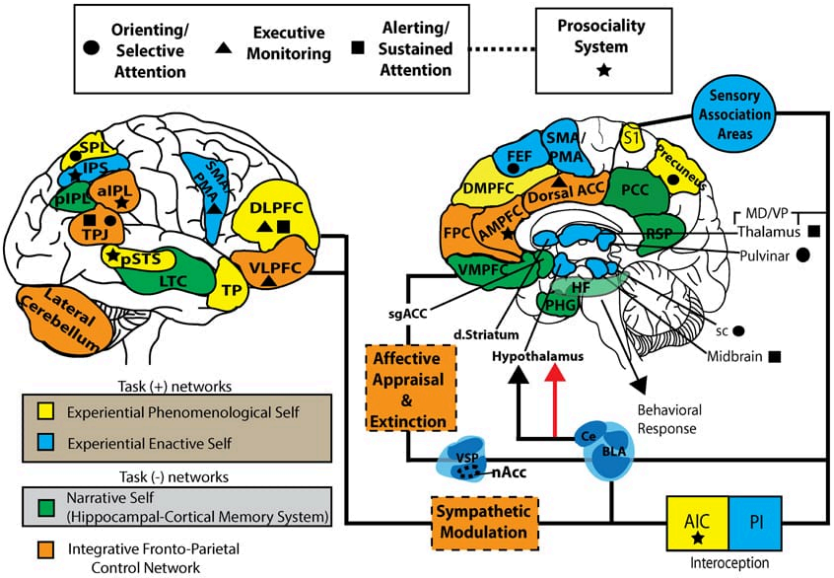

Figure 4.1.5.4: One model of the complex interactions between various brain areas involved in cognitive control of behavior generating various neural models of the intelligent self in interaction with the internal (mental) and external (sensory) worlds (the foregoing caption by the author of this module, Kenneth A. Koenigshofer, Ph.D.). (The following caption is from the authors of this image). This working model represents a parcellation of task positive (self-specifying: EPS and EES), task negative (NS), and integrative fronto-parietal control networks. Cellular Basis of Differences in Human Intelligence

Most of the research on the neurological basis of intelligence in humans has focused either on 1) gene loci associated with individual differences in intelligence or 2) is based on using whole brain imaging to identify brain regions correlated with individual differences in intelligence. Some studies show common genes for differences in brain volume and differences in intelligence, while others suggest that genes that facilitate growth of neurons are associated with higher IQ (see section below on genes and intelligence). Functional and structural MRI studies highlight correlations between specific areas of cortex, including frontal and temporal lobes, and measures of g, general intelligence (see discussion of g in prior modules in this chapter). Higher order association cortex in frontal and temporal lobes contains large numbers of pyramidal neurons with large and complex dendritic branching that might account for individual differences in cortical thickness, synaptic integration, and perhaps IQ (Goriounova, et al., 2018). These neurons and their connections are "the principal building blocks for coding, processing, and

information storage in the brain and give rise to cognition (Salinas & Sejnowski, 2001). Given their vast number in the human neocortex, even the slightest change in efficiency of information transfer by neurons may translate into large differences in mental ability" (Goriounova, et al., 2018, p. e41715).

As shown in Figure 14.5.5 (below), Goriounova, et al. (2018) found that IQ scores are positively correlated with cortical thickness of the temporal lobe, the length of pyramidal neuron dendrites, and complexity of dendritic branching. "Thus, larger and more complex pyramidal neurons in temporal association area may partly contribute to thicker cortex and link to higher intelligence" (p. e41721).

These same researchers also found evidence that larger temporal lobe pyramidal neurons generated action potentials faster than smaller ones and that faster action potential (AP) onset generates better temporal tracking of high frequency inputs leading to more efficient information coding and transfer in larger temporal lobe pyramidal neurons. They report that "human cortical pyramidal neurons from individuals with higher IQ scores generate faster APs" and therefore "neurons from individuals with higher IQ scores are better equipped to process synaptic signals at high rates and at faster time scales, which is necessary to encode large amounts of information accurately and efficiently" (Goriounova, et al., 2018, p. e41724). These researchers state that their results help explain why faster reaction times in even simple tasks (as a measure of mental processing speed) are consistently associated with higher general intelligence measured by IQ scores on intelligence tests and other measures of Spearman's g (see discussion of g, general intelligence factor, in prior modules of this chapter).

They also note that "Pyramidal cells are integrators and accumulators of synaptic information. Larger dendrites can physically contain more synaptic contacts and integrate more information. Indeed, human pyramidal neuron dendrites receive twice as many synapses as in rodents (DeFelipe et al., 2002) and corticocortical whole-brain connectivity positively correlates with the size of dendrites in these cells" (Goriounova, et al., 2018, p. e41726). Goriounova et al. (2018) claim that larger and more complex dendritic arrays in larger pyramidal neurons are accompanied by increases in integration in cortical areas. "Human pyramidal cells in layers 2 and 3 [of the cerebral cortex] have 3-fold larger and more complex dendrites than in macaque or mouse" which "suggest evolutionary pressure on both dendritic structure and AP waveform and emphasize specific adaptations of human pyramidal cells in association areas for cognitive functions" (p. e41727). They reason, therefore, that larger pyramidal neurons, with more extensive dendritic branching and faster onset of action potentials, are necessary for higher order cortical processing associated with human cognition. Based on this conclusion, they suggest that differences among individuals in "neuronal complexity" might associate with differences among people in mental ability (Figure 14.8.5).

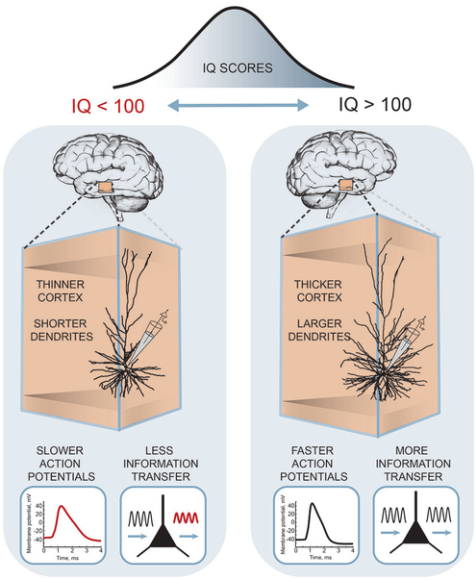

Figure 4.1.5.5: A cellular basis of human intelligence. Higher IQ scores associate with larger dendrites, faster action potentials during neuronal activity and more efficient information tracking in pyramidal neurons of temporal cortex. The figure is based on the results from Goriounova et al.(2018). (Image from Wikimedia Commons; File:Cellular basis of IQ.png; https://commons.wikimedia.org/wiki/F...asis_of_IQ.png; by Natalia A. Goriounova and Huibert D. Mansvelder; licensed under the Creative Commons Attribution 4.0 International license).

Summary of Other Brain Features Correlated with Differences in Human Intelligence

The following table summarizes characteristics of the brain associated with individual differences among humans in general intelligence, as measured by IQ and other psychological tests of intelligence. Based on Goriounova and Mansvelder (2019).

==========

Table 14.5.1: Neurological features (unshaded rows) associated with intelligence (rows 3 and 4 are continuations of rows 1 and 2).

==========

NEUROLOGICAL TRAIT	overall brain volume	cortical thickness in frontal, parietal and temporal association cortex	rapid increase in cortical thickness in childhood with rapid decrease in cortical thickness by early adolescence as pruning of excess synapses occurs increasing processing efficiency	efficiency of processing in distributed cortical areas (frontal, parietal, temporal) as measured by lower neural activity and lower brain metabolic energy required for mental task performance by high I.Q. individuals
CORRELATION OF NEUROLOGICAL TRAIT WITH INTELLIGENCE AS MEASURED BY PSYCHOLOGICAL TESTS (r =, when stated by Goriounova & Mansvelder)	positive, r= between .24 to .33 (correlated with overall brain volume)	positive correlations with IQ (top of this column above, i.e. cortical thickness)	both changes (rapid increase followed by rapid decrease) in cortical thickness positively correlated with high I.Q.	positive correlations with general "fluid" intelligence
NEUROLOGICAL TRAIT (continued)	cortical structure and cortical thickness in lateral areas of temporal lobes and in temporal pole	prefrontal cortex: structure, function and connectivity	functional integrity of white matter (pathways composed of myelinated axons interconnecting brain regions), especially between right frontal and temporal cortex; mental retardation associated with severe damage to white matter	left hemisphere gray matter volume and white matter (myelinated axons) connectivity between left posterior orbital frontal cortex (OFC) and rostral anterior cingulate cortex (rACC)
CORRELATION OF NEUROLOGICAL TRAIT WITH INTELLIGENCE AS MEASURED BY PSYCHOLOGICAL TESTS (continued)	positive correlation with general "crystallized" intelligence dependent on verbal abilities, semantic working memory and acquired knowledge (correlated with structure and cortical thickness of temporal lobes and temporal pole)	positive correlation especially with reasoning ability (i.e. correlated with prefrontal structure, function, and connectivity)	positive correlation with intelligence (i.e. correlated with white matter integrity)	positive correlations with general "fluid" intelligence, "g" (see section 18.11)

==========

Summary Conclusions from Table 14.5.1 (above): "**Conclusions on Gross Brain Distribution of Intelligence:** intelligence is supported by a distributed network of brain regions in many, if not all, higher-order association cortices, also known as parietal-

frontal network (Jung and Haier, 2007). This network includes a large number of regions—the dorsolateral prefrontal cortex, the parietal lobe, and the anterior cingulate, multiple regions within the temporal and occipital lobes and, finally, major white matter tracts. Some limited division of function can be observed, implicating frontal and parietal areas in fluid intelligence, temporal lobes in crystallized intelligence and white matter integrity in processing speed. Although brain imaging studies have identified anatomical and functional correlates of human intelligence, the actual correlation coefficients have consistently been modest, around 0.15–0.35" (Goriounova and Mansvelder, 2019). Note that the amount of variation (variance) in a variable accounted for by its correlation with another variable is equal to the correlation coefficient squared. For example, in this case, a correlation of 0.35 means that only .35 x .35 = .1225 (12.25%) of the variation in intelligence among individuals studied is attributed to its correlation with anatomical and functional features of the brains studied in brain imaging studies, according to Goriounova and Mansvelder (2019). Thus, in the best case, they find that about 88% of the variance in intelligence among individuals studied is accounted for by observed differences among individuals in anatomical and functional features of the brains of those studied using brain imaging. Perhaps the brain imaging is detecting brain regions involved in only some components of intelligence (perhaps attention?) while missing others such as processing of similarity or causal relations, for example.

Genes and Intelligence

Attempts to find single genes that determined intelligence completely failed. The conclusion was that intelligence must be a highly polygenic trait. However, most of the genes that affect intelligence are in non-coding regions of DNA that do not code for protein structure but are instead regulatory genes (which turn on and off other genes) that are involved in generation of cortical neurons during brain development. Different genes correlated with intelligence primarily affect prenatal brain developmental processes including "the proliferation of neural progenitor cells and their specialization, the migration of new neurons to the different layers of the cortex, the projection of axons from neurons to their signaling target and dendritic sprouting" (Goriounova and Mansvelder, 2019).

Genes also affect cell-cell interactions. "Many of the identified genes that play a role in neurodevelopment might contribute to synaptic function and plasticity. Brain function relies on highly dynamic, activity-dependent processes that switch on and off genes. These can lead to profound structural and functional changes and involve formation of new and elimination of unused synapses, changes in cytoskeleton, receptor mobility and energy metabolism. Cognitive ability may depend on how efficient neurons can regulate these processes . . . some candidate genes . . . are specifically involved in axon guidance during neuronal development" (Goriounova and Mansvelder, 2019). This may suggest that efficiency in connections between different circuits and brain areas may be a significant factor in intelligence. Axons that don't go to the right places during brain development would lead to processing inefficiencies.

Other genes that may be involved in differences among individuals in intelligence affect signaling pathways involved in neuron proliferation and migration (during prenatal brain development; see section in Chapter 4 on development of the nervous system) and synaptic communication throughout development.

Other genes that may be involved in differences in intelligence among people are genes that organize pre-synaptic neuron activities especially synaptic vesicles and their release of transmitter.

Others regulate cAMP and CREB involved in gene transcription that for neurons plays a role in synaptic plasticity, learning and memory.

Still others play a role in voltage-gated calcium channel function. Recall that calcium channels open when an action potential reaches an axon ending stimulating movement and binding of synaptic vesicles to the pre-synaptic axonal membrane followed by transmitter release.

Interestingly, most of the energy consumed by the brain (20% of the body's total) is for generation of post-synaptic potentials (PSPs). "Notably, the emergence of higher cognitive functions in humans during evolution is also associated with the increased expression of energy metabolism genes" and "cognitive ability associates with genetic variation in several genes that code for regulators of mitochondrial function" essential to energy metabolism.

"In addition, genes involved in lipid metabolism (BTN2A1 and BTN1A1) and glucose and amino acid metabolism (GPT) . . . [as well as] "microtubule-associated proteins [which] . . . affect recycling of synaptic receptors and neurotransmitter release . . . linked to intelligence by several studies . . . are among the candidate genes of intelligence" (Goriounova and Mansvelder, 2019). The genes affecting microtubule-associated proteins are known to be altered in Alzheimer's, Parkinson's, and Huntington's Disease.

The highest expression of the genes associated with intelligence occur "within pyramidal neurons in hippocampal area CA1 and

cortical somatosensory regions . . . [and significant expression] in medium spiny neurons. . . . Pyramidal neurons are the most abundant neuronal types in neocortex and hippocampus, structures associated with higher executive functions, decision-making, problem-solving and memory. Striatal medium spiny neurons constitute 95% of all neuronal types within the striatum, a structure responsible for motivation, reward, habit learning and behavioral output" (Goriounova and Mansvelder, 2019).

A Central Role for Pyramidal Neurons and Implications of Cross-Species Comparisons

According to Goriounova and Mansvelder (2019), "Genetic studies indicate that expression of genes associated with intelligence accumulates in cortical pyramidal neurons (Savage et al., 2018; Coleman et al., 2019). Comparisons of key cellular properties of pyramidal neurons across species may offer insights into functional significance of such differences for human cognition . . . compared to rodents and macaques, human layer 2/3 pyramidal cells have threefold larger and more complex dendrites (Mohan et al., 2015). Moreover, these large dendrites also receive two times more synapses than rodent pyramidal neurons (DeFelipe et al., 2002). Apart from structural differences, human pyramidal neurons display a number of unique functional properties. human excitatory synapses recover 3–4 times faster from depression than synapses in rodent cortex, have more speedy action potentials and transfer information at up to nine times higher rate than mouse synapse (Testa-Silva et al., 2014)." In humans, larger pyramidal neurons, with longer dendrites, more complex dendritic branching, more synaptic connections, and faster onset of action potentials, combine to make possible the processing of greater amounts of information, with greater efficiency and integration among brain areas, than in other animals, and these large neurons may play a central role in the vast differences between human and non-human animal intelligence (see Figure 14.8.5).

Brain Correlates of Creativity

Jung and Haier (2013) report a number of brain correlates of intelligence and creativity. However, they argue against the idea of one brain area for one cognitive function. Instead, as discussed in the prior module, they argue that brain networks involving multiple brain areas are involved in cognition, especially in complex psychological processes such as intelligence and creativity. Nevertheless, they recognize that brain injury and lesion studies reveal brain structures that are necessary, though not sufficient, for certain psychological functions. They give three examples: 1) Phineas Gage, who survived an iron rod passing through his **frontal lobe** resulting in personality and emotional changes as well as impaired judgement and loss of many social inhibitions; 2) "Tan," whose brain damage led to identification of Broca's area for language expression; and 3) H.M., whose bilateral surgical removal of **temporal lobe** structures including **hippocampus** revealed the role of hippocampus and related structures in formation of new long-term explicit memories and their retrieval.

Within this context, Jung and Haier (2013) note some interesting observations from post-mortem examination of the brain of the famous theoretical physicist, Albert Einstein (whose work led to the equation, $E=mc^2$), and what it might suggest about brain mechanisms in creativity. Einstein's brain was unremarkable in many ways. Its size and weight were within the normal range for a man of his age, and frontal and temporal lobe morphology and corpus callosum area were no different from control brains. However, there was one pronounced difference. According to Jung and Haier, Einstein's brain was missing the parietal operculum, the typical location of the secondary somatosensory cortex, resulting in a larger inferior parietal lobule. In Einstein's brain, the **inferior parietal lobule** was approximately 15% wider than in the brains of normal controls. According to Jung and Haier, this region of brain is associated with "visuospatial cognition, mathematical reasoning, and imagery of movement . . . and its expansion was noted in other cases of prominent physicists and mathematicians." They add that further examination of this area of Einstein's brain revealed that rather than more neurons, this region of his brain had a much larger number of **glial cells**, which provide nutrition to neurons, perhaps indicating an unusually large amount of activity among neurons in this region of his brain.

Significantly, as described in the prior module, **parietal cortex** has strong linkages with **prefrontal cortex** forming a **frontoparietal network**: the **inferior parietal lobule** is primarily **connected with dorsolateral prefrontal cortex** (Bruner, 2010), associated, in part, with abilities for abstract thought, while **upper parietal regions**, according to Bruner, as discussed in module 14.2, are associated in the literature with functions such as abstract representation, internal mental images, “imagined world[s],. . . and thought experiment” (i.e., imagination). Jung and Haier detail another study of Einstein's **right prefrontal association cortex**, where researchers found **greater packing density of neurons** (same number of neurons in a smaller space), which was interpreted as **shorter conduction times between cortical neurons in Einstein's brain** compared to control brains. Jung and Haier conclude that **Einstein's brain differed from controls in the frontoparietal network**. These authors have proposed that the **frontoparietal network is crucial to human intelligence**; furthermore they hypothesized that differences among people in the efficiency of neural communication between the frontal and parietal regions of cortex

accounts for differences in intelligence in humans (Jung & Haier, 2007). In part, this idea is based on their finding that **high IQ people** show **less activity** in these brain areas during a complex cognitive task, while lower IQ people show more brain activity, suggesting that high IQ is related to **efficiency** in neural information processing operations. Moreover, higher IQ and ability for abstraction are both inversely correlated with cerebral glucose metabolic rate (Haier et al., 1988, 1992, 2003, 2004), suggesting an efficiency model of individual differences in *g* in which superior **ability for abstraction increases processing efficiency**. In their **Parietal-Frontal Integration Theory (P-FIT)** of the neural basis of intelligence, after sensory processing, information "is then fed forward to the **angular, supramarginal, and inferior parietal cortices**, wherein structural symbolism and/or abstraction are generated and manipulated. The **parietal cortex** then **interacts with frontal regions** that serve to **hypothesis test various solutions** to a given problem." They add that "the **anterior cingulate** is involved in response selection as well as inhibition of competing responses. This process is critically dependent on the fidelity of underlying **white matter** needed to facilitate rapid and error-free transmission of data **between frontal and parietal lobes**" (Jung & Haier, 2013, p. 239). They also note that research in genetics shows that "intelligence and brain structure (i.e., gray and white matter) share common genes" (p. 240).

Regarding creativity specifically, these authors refer to a theory by Flaherty (2005) which proposes a **frontotemporal system** driven by **dopaminergic limbic activity** which provides the drive for creative expression whether art, music, writing, science, etc. and as measured by tests of divergent thinking. Jung and Haier (2013) explain that the **temporal lobe normally inhibits the frontal lobe** so that lesion or mild dysfunction of the temporal lobe releases activity from the frontal lobe by disinhibition causing increased interactions of frontal lobe with other brain regions, sometimes leading to increased creative outputs from neurological patients with left side damage. They argue that this and other data from "three structural studies point to a decidedly left lateralized, frontosubcortical, and disinhibitory network of brain regions underlying creative cognition and achievement" (p. 244). They add that this model, which still requires much more empirical investigation, "appears to include the frontal and temporal lobes, with cortical “tone” being modulated via interactions between the frontal lobes, basal ganglia and thalamus (part of the dopamine system) through white-matter pathways" (p. 244). Although this model is speculative for such a complex form of cognition as creativity, it can guide continuing research into how humans develop creative intellectual and artistic products.

Inferior parietal lobule

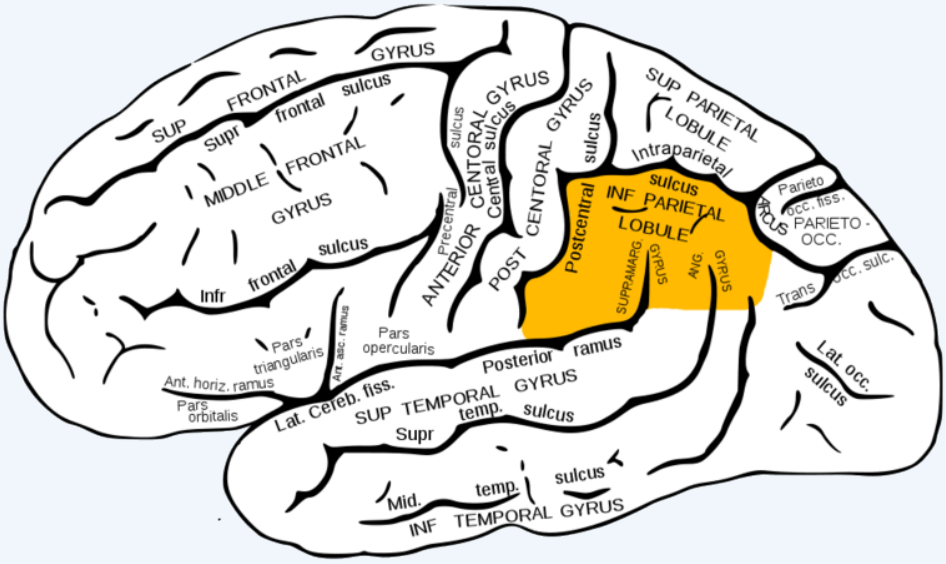

Figure 4.1.5.6: Lateral surface of left cerebral hemisphere. Inferior parietal lobule is shown in orange. Intelligence Testing and Conceptions of Human Intelligence

The development of tests to measure intelligence has had a major impact on the development of ideas about the nature and structure of human intelligence, and its biological basis in the brain. Most theories of human intelligence are based on data derived from intelligence tests, data which is analyzed using factor analysis, a mathematical method for analyzing patterns of correlations among different measures of mental abilities. In section 14.2, we have already discussed how this method, invented and used by Spearman (1904), revealed the "g" factor in human intelligence.

To understand current thinking and research about the biological basis of human intelligence, it is essential to gain at least a general familiarity with the major theoretical models of human intelligence psychologists have developed. For this purpose, this chapter has a supplementary section entitled, "Traditional Models of Human Intelligence." It is highly recommended that students read that supplementary section. The theories we examine in that section are based to a large extent on intelligence testing and factor analysis, while others are more intuitive. That section also introduces key historical figures, major theories of intelligence, and common assessment strategies used to measure human intelligence.

In section 14.2, we discussed a number of enduring, across-generation, universal regularities of the environment which have been incorporated by evolution into brain organization and intelligence. As described in that section, these enduring facts about how the world works include innate, genetically internalized information about objects in three-dimensional space, the passage of time, daily cycles of light and dark, causality relations (forming basis for causal logic and inference), similarity relations (leading to category formation and categorical logic and inference), and predictive relations, based on covariation of events, allowing human and animal brains to mentally project the organism into future time. All of these invariant properties of the world must be included in the brain's neural models or cognitive maps of the world if the brain is to effectively guide adaptive behavior.

When we examine the traditional models of intelligence in the above referenced supplementary section, you will recognize that each focuses on only one, or a few of the facets of intelligence discussed in the evolutionary approach taken in section 14.2. In a sense, each theory discussed in that section is akin to the fable of the blind men trying to describe an elephant. Each blind man only knows that part of the elephant which he happens to feel and so each man has a different and incomplete understanding of the whole. Likewise, each theory of intelligence focuses on only part of the complex of processes that we collectively refer to as "intelligence." Nevertheless, each theory makes a contribution, and each, in one or more ways, is related to the evolutionary discussion in section 14.2.

For example, as you will see, emotional intelligence, including Gardner's intra- and inter-personal intelligence, is related to

neural representations of the contingencies of the social environment--brain mechanisms for which are the focus of the new field of **social cognitive neuroscience.** Gardner's multiple intelligences include spatial intelligence related to representation of objects in three-dimensional space, abilities which require portions of **parietal cortex** and **hippocampus**. At Level III in Carroll's theory of intelligence is "g," general intelligence, related to representations of causal, similarity, and predictive relations, likely involving the **frontoparietal network** (Jung & Haier, 2007). Of these theories, the first, Carroll's three-stratum theory of human intelligence is by far the most widely accepted and most productive in terms of explanatory power and empirical evidence. With this background, you will be better prepared to understand the traditional models of intelligence and, perhaps more importantly for this course, you will gain a better understanding of the biological bases of intelligence and thinking, the primary focus of this chapter.

In Charles Dickens' *A Christmas Carol*, the protagonist, Ebenezer Scrooge, is a penny-pinching businessman who changes his ways after being visited by ghosts of Christmas Past, Present, and Yet to Come. However, in our real life, it is possible to relive the past and imagine the future without the help of a ghostly guide. Even as you sit and read this chapter, you are able to pause and remember last Thanksgiving or your first kiss. In other words, you perform mental time travel. You can even imagine future scenarios—graduation day or a party that you are looking forward to attending in the near future. Indeed, the remarkable ability to learn and remember is a core feature of our human experience. In this chapter, we will explore what is known about how the nervous system accomplishes this extraordinary task. We will learn about the different types of memory that are subserved by different brain memory systems and about what goes wrong in the brain when memory fails. As part of this process, we will also learn about learning. Learning refers to the acquisition of new information or skills while memory is the process by which that information is stored and later retrieved. These are separate processes, each with their own neural substrates that we will examine in the following sections.

4.2.2: Memory is Classified Based on Time Course and Type of Information Stored

Learning Objectives

By the end of this section, you should be able to

- 18.1.1 Differentiate between short-term and long-term memory.
- 18.1.2 Differentiate between the different types of memory and learning and the brain systems subserved by each.
- 18.1.3 Describe the major memory disorders and their underlying pathology and treatments.
- 18.1.4 Define memory consolidation and reconsolidation.

We know from over a century of research on the brain that there are certain brain functions that can be localized to specific brain regions. For example, the primary visual cortex in the occipital lobe is necessary for elementary visual perception and Broca's area, a region of the left frontal lobe, is critical for language production. But, is there a specific circuit or neural system responsible for learning and memory? After decades of research, we now know that there are several forms of learning and memory, each supported by distinct brain regions. By studying organisms ranging from sea slugs to humans with injury-induced memory impairments, we have learned a great deal about the different facets of memory and the separable brain systems to which they contribute. In this section, we will learn about the major classifications of memory, which are based on two key dimensions: the amount of time over which the memory is stored and the type of information the memory contains.

The time course of memories

You might think of a memory as being immutable knowledge that you will carry with you for your entire lifetime—stories you will tell your grandchildren time and time again. These types of memories are long-term memories. However, not all memories are stored indefinitely. Memories can last for durations as short as a few seconds and as long as a lifetime. As shown in Figure 18.2, the three broad categories of memory time courses are sensory memories, which last a few seconds, short term memories, which last a few minutes, intermediate term memories that last hours to days, and long-term memories, which can endure for decades.

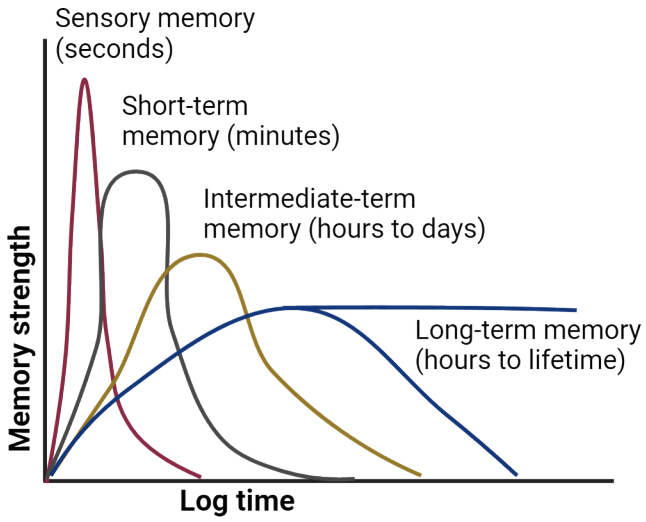

Figure 18.2 Time course of memory

Sensory memories

The shortest duration memories are sensory memories: information that is briefly held by the sensory systems. These sensory memories are divided into subcategories depending on whether the information is held in the somatosensory (haptic), auditory (echoic), or visual (iconic) sensory organs and circuitry. One of the most famous researchers who studied sensory memory and coined the term "iconic memory" was the cognitive psychologist, George Sperling. In the 1960s, Sperling carried out a set of experiments showing that participants could retain a visual memory for a brief period of time before the memory faded (Sperling, 1963). Sperling showed participants a screen with rows of letters that were flashed on very briefly (less than a second). He then had the participants immediately report what letters they could remember. You can experience your own sensory memory like Sperling's participants by looking at a photograph and then closing your eyes. Can you still "see" the photo for a few seconds after you close your eyes? You can carry out similar experiments with touch and sound. The memory of the sensory experience lingers briefly although the stimulus is no longer present. In terms of brain regions, sensory memories like these typically rely on transient activity within the relevant sensory pathways up to the primary sensory cortex. For example, an iconic sensory memory would primarily rely on activity in the visual pathway to the primary visual cortex. If that activity is not relayed further in the brain, the sensory memory fades within seconds. If it is relayed, it may become a short-term memory.

Short term memories

Short-term memories last longer than sensory memories, allowing us to hold information for several seconds. One type of short-term memory, called working memory, refers to information that is temporarily stored, used, and subsequently discarded. Much like sensory memory, the type of information that is temporarily stored in working memory determines what brain system is required. For example, speech-based information, such as repeating a multi-digit code used for 2-factor authentication, is supported by language centers in the brain, such as Broca's area. Conversely, object and spatial information, such as remembering where you parked your car, is supported by interactions among a network of brain regions in the frontal, parietal and occipital cortex. The key difference between working memory and the next potential step in memory storage (long-term memory) is that information stored in working memory is discarded when it is no longer needed. For example, it would not be useful to remember where you parked your car last Tuesday. You only need to remember where you parked this morning. Long-term memory, on the other hand, refers to information that is transferred from short-term memory and stored, sometimes for a lifetime. This transfer process is called consolidation.

Consolidation and retrieval: Memory consolidation

For over a century, memory researchers have been guided by a hypothesis that new memories undergo a process called consolidation. Consolidation is the process by which some recent experiences in working memories are turned into long-term memories. Figure 18.3 shows the hypothesized flow of memories from sensory memory, through working memory and then into long-term memory via consolidation.

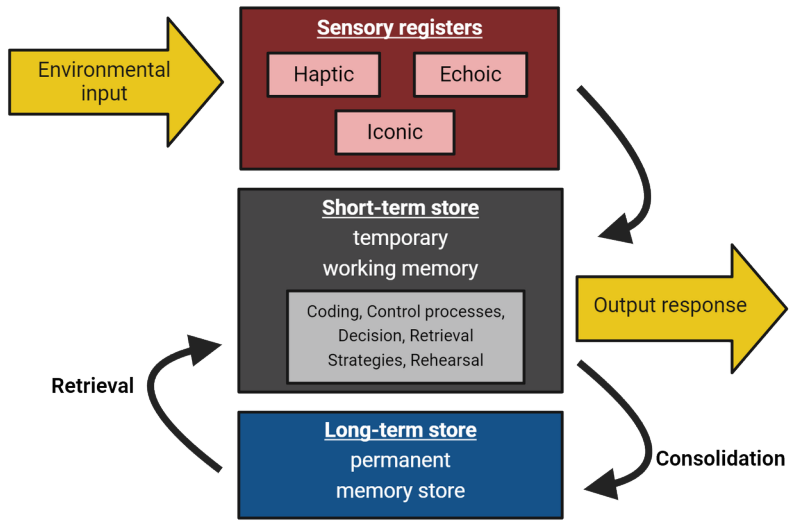

Figure 18.3 Memory storage process

Consolidation processes take time, and during that time, memories are initially vulnerable to disruption before becoming stable.Why would our brains evolve to require time to consolidate memories? One idea is that time is needed in order to preferentially strengthen memories that carry the highest emotional significance. Early work investigating the process of consolidation showed the importance of emotion modifying consolidation using pharmacological treatments such as epinephrine or corticosterone (see Chapter 12 Stress). In these studies, researchers gave these stimulants to participants right after training in a memory task to mimic the emotional arousal that typically leads to enhanced memory. These stimulants were consistently shown to enhance memory in a variety of tasks when they were given right after the task was completed, but not if they were given before the task was learned or just before the memory was tested. These findings suggest that emotional stimuli enhance memory consolidation processes happening right after a memory is acquired.

While it was clear from early work that memories remained flexible during consolidation processes, the question remained whether or not, once a memory was consolidated, if it could be modified or it would remain unchanged for life. Later studies helped answer this question, showing that even old memories could become vulnerable to disruption during recall. Recall is the process of retrieving memories from long-term storage. It turns out that recall is not a passive process, like playing back an old movie. Instead, when a memory is retrieved, it becomes temporarily subject to being altered. An example of the evidence for vulnerability of memory during retrieval comes from studies using a drug that inhibits protein synthesis (blocking the translation of mRNA into protein) in rats. For example, Nader et al., 2000 trained rats on a tone fear task (tone, followed by footshock). Twenty-four hours later, they played the tone again and immediately administered a protein synthesis inhibitor into the amygdala, which is a site critical for fear learning. The idea was that if they reactivated the fear memory by playing the tone, they could make the memory vulnerable to disruption. As expected, the previously-consolidated memory was disrupted with administration of anisomycin, a protein synthesis inhibitor, only if the memory was reactivated prior to the memory test and not if the drug was administered without first playing the reminder tone. These results suggest that whenever a memory is reactivated during recall, it is vulnerable to being altered and must be stabilized once again. We call this restabilization process reconsolidation.

Long term memory

Once a short-term memory is consolidated, it becomes a long-term memory that could potentially last years. Researchers in the memory field have learned an extraordinary amount about memory from a man who lost the ability to form new long-term memories, Henry Molaison, who was known to the scientific community as patient H.M. until his death in 2008. Some of the most impactful findings in science have been accidental discoveries. Mr. Molaison presented one of these accidental discoveries, helping us understand the distributed nature of long-term memory in the brain through the unique memory impairment he acquired as an adult. Prior to acquiring his unique impairment, Mr. Molaison had suffered from severe epilepsy since he was a child. Despite taking high doses of anticonvulsant medication, the seizures prevented him from working or otherwise having a normal life. Consequently, with the support of his family, at the age of 27, he underwent a radical surgery that removed the anterior two-thirds of his temporal lobes: a bilateral temporal lobectomy (Figure 18.4). This experimental surgery, performed by William Scoville in 1953, was successful in that it reduced the frequency of Molaison's seizures. However, the reduction of seizures came at a tragic cost. It seemed that he could no longer form new memories. Ironically, the patient from whom we learned so much about memory suffered from a severe memory deficit called anterograde amnesia, the inability to form new memories.

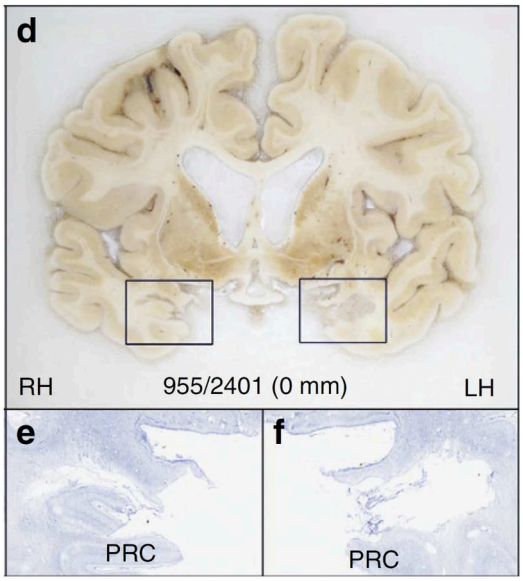

Figure 18.4 H.M. Images of H.M.'s brain show large portions of the hippocampus is missing. Counterstaining of the sections in boxes on the top are shown on the bottom. Image credit: Annese, J., Schenker-Ahmed, N., Bartsch, H. et al. Postmortem examination of patient H.M.'s brain based on histological sectioning and digital 3D reconstruction. Nat Commun 5, 3122 (2014). https://doi.org/10.1038/ncomms4122. CC-NC-ND 3.0

The first person to study Molaison was Brenda Milner, a graduate student at McGill University who was in the process of completing her doctoral work under the mentorship of Donald Hebb, who will appear again later in this chapter in 18.4 Synaptic Mechanisms of Long-Term Memory. When Milner heard about Molaison's unexpected memory loss following the surgery, she traveled to Hartford to conduct testing to understand the nature of the memory deficit. Milner and her colleagues, most notably, her former student, Susan Corkin, continued to study Molaison's memory deficits for the next five decades and even examined his brain in detail after his death.

The remarkable discovery that Molaison inspired was not just that temporal lobe removal could cause memory loss, but also the specificity of the deficit. Molaison's working memory, personality, intelligence, and perceptual abilities appeared to be unaffected by the surgery. Molaison could even recall events from the distant past, suggesting that remote and recent memories might be stored in different brain regions. Even more fascinating was the fact that Molaison could acquire new skills, demonstrating intact procedural memory: "skill-based knowledge that develops gradually but with little ability to report what is being learned" (Squire 2009). To test Mr. Molaison's procedural memory, Dr. Corkin asked him to trace a diagram of a star while looking at his hand only as a reflection in a mirror. You can try this activity yourself here. What you will probably notice is that your ability to trace the star will improve with practice. The same was true for Molaison. He learned the skill within ten trials and showed excellent retention of the skill across the next three days of testing (Squire, 2009). Interestingly, Molaison had no recollection of learning the skill and was surprised to observe how well he could perform it given that he had no memory of learning it.

Following Milner's work with Molaison, there have been numerous follow-up studies corroborating the notion that medial temporal lobe damage, specifically including the hippocampal formation, results in a selective loss of the ability to form new declarative memories, memories that are easy to verbalize, with the preserved ability to learn new skills. These discoveries have led to the theory that there are multiple independent brain memory systems that operate in parallel to process and store information about lived experiences (White & McDonald 2002). Several of these systems are diagrammed in Figure 18.5.

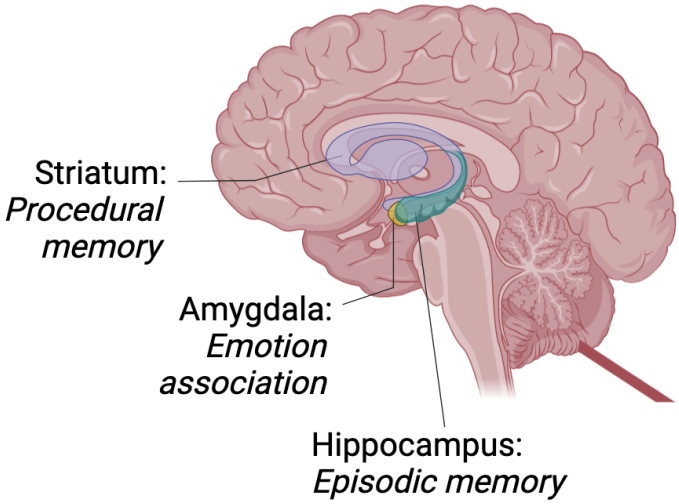

Figure 18.5 Major parallel pathways for long-term memory consolidation Memory is processed and stored into long-term memories by different brain systems depending on the type of memory.

Broadly, the hippocampus and related structures support episodic memory, the ability to recall specific experiences including the time and place of their occurrence. The striatum supports procedural memory, which results from the formation of an association between a stimulus and a response (see 18.2 Implicit Memories: Associative vs. Nonassociative Learning). The amygdala supports the formation of an association between a neutral stimulus and an emotional state (for example, fear).

Today, we have classified memory into several functional categories based on the kind of information stored. In support of the separable nature of these categories, each category relies on different brain regions. Figure 18.6 shows these categories and how they relate to each other.

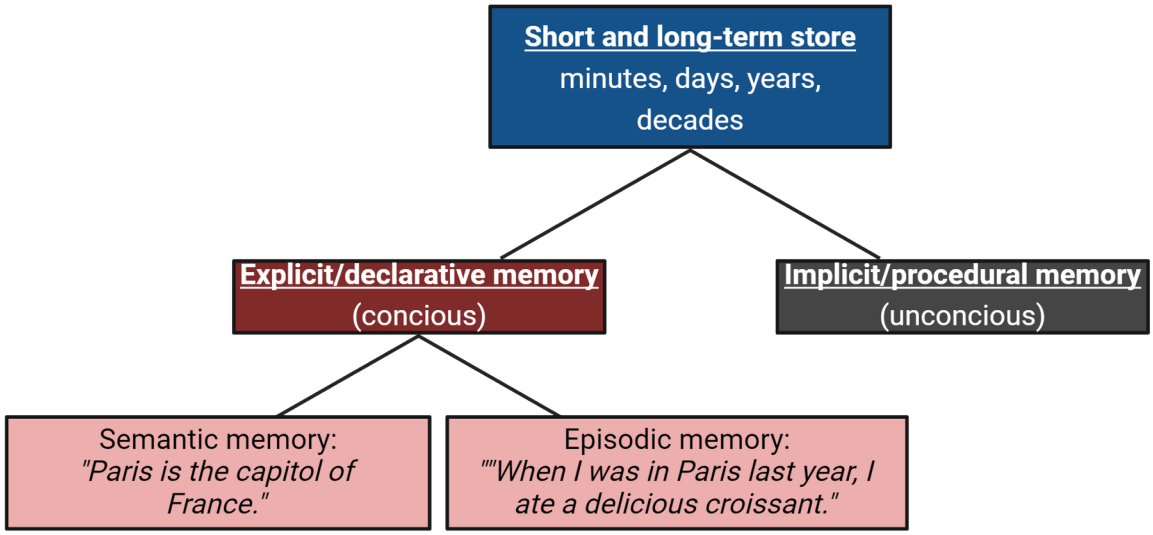

Figure 18.6 Types of memory

Long-term memory can be divided into two broad categories: explicit memory and implicit memory. Explicit memories are memories of which you are consciously aware.This category includes both semantic memories, which are facts that you know about the world, like “Paris is the capital of France”, and episodic memories, which are memories for specific episodes that occurred in a particular place and time, like “When I was in Paris last year, I ate a delicious croissant”. We sometimes also call explicit memories declarative memories, deriving from the fact that humans can describe them in a narrative fashion, as demonstrated above with Paris-related memories/facts. Non-human animals can also have these kinds of memories but obviously cannot describe it to us, making the term explicit memory a more cross-species applicable one.

Implicit memories are memories of which we are *not* consciously aware. There are several categories of implicit memories, all dependent upon different brain systems. Priming is a paradigm that is used to detect the existence of an implicit memory in which exposure to a stimulus affects a later response to that stimulus. For example, participants could be asked to view letters on a screen and indicate whether the letters shown are a word or not a word. If the word “paper” is preceded by the word “pencil,” it would be recognized faster than if it were preceded by the word “dog.”This increase in recognition speed happens because “paper” and “pencil” are related to each other for most people and the implicit memory of the word “pencil” makes us faster to recognize the presentation of the word “paper.”

Another category of implicit memory is called procedural memory. As you read in the section above, H.M. had normal procedural memory. These memories are memories for *how* to do something, like play a scale on the piano, ride a bike, or type on a keyboard. These skills improve with practice and may initially require conscious awareness, but after practice can be executed automatically. You may not have a memory of the first time you rode a bicycle without training wheels, but the memory of how to ride a bicycle persists. This example is an illustration of the distinction between episodic memory and procedural memory. Procedural memory is sometimes known as “muscle memory”, referring to the idea that the action can be carried out without much intentional thought, thus becoming a habit. Habits are acquired gradually over time with practice. They are difficult and cumbersome at first and become highly refined with practice. These skills also become automatic, freeing up valuable mental resources for other tasks. One critical neural system that supports procedural memory is the basal ganglia, which includes the caudate nucleus, putamen, globus pallidus, subthalamic nucleus, nucleus accumbens, and substantia nigra (see Chapter 10 Motor Control).

When memories fail

Much of what we know about memory comes from unfortunate and sometimes tragic cases of memory loss. One such case, the case of Henry Molaison, is detailed in the section above. In addition to amnesia, memory impairments are the key feature of some neurological disorders such as Alzheimer’s disease and Korsakoff’s syndrome. Before we discuss neurological disorders, however, it is important to understand that memory failure is something everyone experiences. Although you might think of your memories as being a veridical record of past events, similar to a video, we know that memory mistakes are very common. Memory researcher, Elizabeth Loftus, has been a leader in studying what is known as the misinformation effect. Dr. Loftus’ work showed that when presented with inaccurate information after witnessing an event such as a car crash or terrorist bombing, almost half of the participants will report with confidence that the suggested information was in the original memory even though it was not. Participants, for example, “remember” broken glass that was never shown in a car crash video after being asked leading questions. Researchers have a term for extremely vivid, long-lasting memories that often accompany traumatic events like those depicted in Dr. Loftus’ work: flashbulb memories. There is an abundance of evidence that suggests that, despite the vividness of the memory and the confidence that the participant has in the accuracy of the flashbulb memory, these memories are often distorted and sometimes completely wrong. For example, Talarico and Rubin (2003) asked participants to recall the events of the terrorist attacks of September 11, 2001 one day, one week, six weeks and 32 weeks later. They were also asked to recall events that occurred in their everyday lives. Consistency of memories of the attacks and of events in their everyday lives declined over time. However, while belief in the accuracy of everyday events declined over time, memories of the terrorist attack did not. These results suggest that flashbulb memories are not especially accurate and the persistent belief in their accuracy is unwarranted. These distorted memories often have little consequence. However, in some cases, such as eyewitness testimony, the consequences can be far more dire.

Amnesia

Though successful as a plot device, the dramatic memory loss that is often portrayed in movies or television shows in which a person forgets their whole identity has little basis in reality. Real cases of amnesia are usually not so drastic, though they can still be quite disruptive to one’s quality of life. Amnesia can be divided into categories based on whether new or old memories are more affected. In retrograde amnesia, memories that were formed before the event that led to the amnesia are lost. Conversely, anterograde amnesia, as described in the section above, is characterized by the inability to form new memories. Individuals can experience retrograde amnesia, anterograde amnesia, or both at the same time. The latter is true especially in the case of a severe head injury, a condition known as post-traumatic amnesia. One type of amnesia that is not associated with damage to the brain that in fact everyone experiences is infantile amnesia, the inability to recall events from early childhood. If I asked you about your earliest memory, you might be able to recall a few fuzzy memories from preschool, but probably not many memories at all from earlier in your toddlerhood. Memories from the first two to three years of life are absent and those formed between the ages of three and seven are low in number and lack detail. No one is sure if infantile amnesia has some kind of adaptive advantage, or if it is just a side effect of all of the changes that are happening so quickly in the young brain. The prevailing hypothesis is that infantile amnesia results from the constant addition of neurons to the hippocampus, a phenomenon called

neurogenesis, that happens at particularly high rates in this developmental time period (Josselyn & Frankland 2012) (see Chapter 5 Neurodevelopment).

Memory disorders

Memory deficits are also a core symptom of numerous neurological disorders such as Alzheimer's disease, seizure disorders, and Korsakoff's syndrome. Memory degradation is common as individuals age, but contrary to popular belief, memory loss is not an inevitable consequence of aging.

Alzheimer's disease

Alzheimer's disease, the most common type of dementia, is characterized by a gradual loss of cognitive abilities such as memory, planning, and decision-making. For Alzheimer's disease in particular, the core symptom is a dramatic deterioration of episodic memory followed by a loss of executive functions such as planning, decision-making, and reasoning. The survival time from diagnosis ranges from 7–10 years (Todd et al., 2013). Most individuals who are eventually diagnosed with Alzheimer's disease initially show mild symptoms such as impaired memory and spatial navigation, a condition known as mild cognitive impairment. The impairments get progressively worse over time. At later stages of the illness, the individual becomes unable to carry on a conversation or respond to their environment and requires around-the-clock care. Though not an inevitable consequence of aging, the risk of developing Alzheimer's disease increases with age, reaching rates of almost 40% by age 85 (Rajan et al., 2021).

There are three abnormalities that characterize the core pathology underlying Alzheimer's disease, all shown in Figure 18.7.

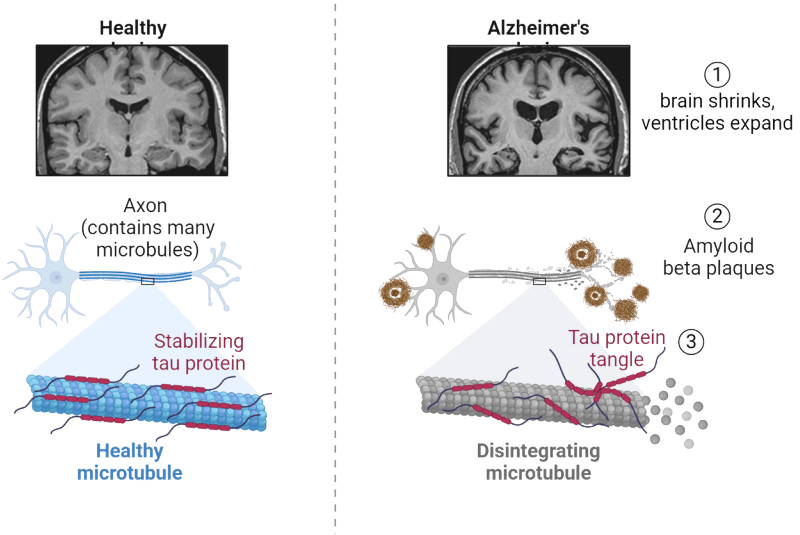

Figure 18.7 Pathology of Alzheimer's disease

First of all, the brain shrinks in size—ventricles become larger, sulci widen and gyri narrow. This brain atrophy arises due to the progressive widespread death of neurons that is a common feature of all neurodegenerative diseases. Another hallmark pathology of the disease is the accumulation of amyloid plaques, located in the extracellular environment, that appear in high concentrations in the inferior and medial parietal lobe, the medial frontal lobe, the medial temporal lobe, and the posterior cingulate cortex. The plaques are made up of a protein called beta-amyloid, the normal function of which is not well understood. At high concentrations, these proteins can accumulate and bind together and form amyloid fibrils, fibers that bind together and are resistant to degradation. Whether the plaques are a cause of neuronal cell loss or a secondary consequence of another pathological process is still controversial (Herrup 2022). It used to be only possible to confirm the AD diagnosis by measuring amyloid plaque formation post-mortem. However, amyloid protein can now be detected in CSF and using PET imaging. A third biomarker associated with Alzheimer's disease is the accumulation of neurofibrillary tangles, which are abnormalities in the cytoskeleton of neurons. Neurofibrillary tangles are formed by the accumulation of proteins called tubulin associated unit (tau) proteins that build up inside the neurons. Together with amyloid plaques, neurofibrillary tangles have been shown to be negatively correlated with cognitive ability (Braskie et al., 2010).

There are two main risk factors for the development of Alzheimer's disease: age and a specific genetic mutation. According to the

National Institute on Aging, the risk of being diagnosed with Alzheimer's disease doubles about every 5 years after age 65 and about one third of people over the age of 85 have Alzheimer's disease (National Institute of Aging, 2021). The genetic risk factor is found primarily in a gene that codes for the protein apolipoprotein E (ApoE). This gene has three possible forms that differ slightly from each other in the amino acid sequence they encode. The ApoE4 allele is present in 40-50% of individuals with an Alzheimer's disease diagnosis, making those who carry the allele four times more likely than the general population to develop Alzheimer's disease (National Institute of Aging, 2021). Although it is not yet clear how this particular polymorphism in the ApoE gene leads to the disease, this allele is also a risk factor for other neurological diseases, suggesting that ApoE4 has a general role in neurodegeneration. Beyond ApoE4, there are other, more rare, genetic mutations that are associated with early onset AD. These cases are called familial AD and individuals with familial AD can start to show symptoms of decline well before age 60. These are a minority of AD cases, however. Many Alzheimer's cases are late-onset (after age 65) and sporadic, meaning that they cannot be linked to a particular cause.

In the summer of 2021, after 18 years of no new treatments for AD, the FDA granted accelerated approval of *Aducanumab* as a treatment for Alzheimer's disease. The drug is an immune based treatment called a monoclonal antibody that binds to the amyloid plaques and stimulates the immune system to help clear the plaques, lowering the amyloid plaque buildup (see 17.1 Cells and Messengers of the Immune System). The drug is administered intravenously by infusion once a month. The results of the clinical trials showed that the drug clearly lowered the concentration of amyloid protein in the brain, but there were mixed results on the improved memory loss, with one study showing improvement and another study showing no improvement (Yeo-Teh and Tang, 2023). The treatment is only recommended for individuals who are in the early stages of the disease, when amyloid plaques tend to form. It is important to note that *Aducanumab* is not a cure. More recently, two new drugs have been approved for use in Alzheimer's disease patients: Lecanemab and Donanemab. These drugs share similar mechanism of action and risks with *Aducanumab*, but have been more extensively studied. Unfortunately, while some patients show improvement on neurocognitive tests in the lab with these treatments, the real-world clinical benefits were minimal (Granzotti & Sensi, 2023).

Korsakoff syndrome

In his book, "The Man who Mistook his Wife for a Hat", the neurologist Dr. Oliver Sacks recounts the case of Jimmy G., a man he calls "the lost mariner". Jimmy had severe anterograde and retrograde amnesia. Sacks describes Jimmy as a friendly and cooperative 49-year-old man who had preserved memories of his life up until the age of nineteen. What was unusual about Jimmy's case is that he believed that he was nineteen years old and was shocked and disturbed when his own reflection in a mirror revealed the face of a forty-nine-year-old man.

After taking Jimmy's history, Sacks hypothesized that Jimmy suffered from Korsakoff's syndrome, a memory disorder that is caused by chronic vitamin B1 (thiamine) deficiency (Popa et al., 2021). Thiamine is an essential component of neuronal metabolism, helping neurons make energy from sugar. Without thiamine, neurons cannot generate enough energy to function properly. In Jimmy's case, the thiamine deficiency was due to chronic alcohol consumption, which is one of the common causes of Korsakoff's syndrome. It can also be caused by some cancers, AIDS, chronic infections or even nutritional deficits, such as during dramatic weight loss after bariatric surgery. In most cases, Korsakoff's syndrome is preceded by an acute illness called Wernicke's encephalopathy, characterized by movement problems and confusion. Wernicke's encephalopathy is the brain's immediate reaction to a severe lack of thiamine, while Korsakoff's syndrome is the result of long-term neuronal death in several brain regions associated with memory.

The amnesia in Korsakoff's syndrome is most strongly linked to destruction of the mammillary bodies. However, imaging studies have shown that there is widespread damage to the brain, including atrophy of the frontal lobes, hippocampus, amygdala, thalamus, and cerebellum. Not surprisingly, individuals with Korsakoff's syndrome exhibit executive dysfunction, blunt affect, motor disturbances, and confabulation, a condition that is often called "honest lying" in which the individual unknowingly forms a false memory that she/he believes to be true, presumably filling in missing information from incomplete memories.

Seizures and memory impairments

Epilepsy is a general term used to describe a condition in which an individual repeatedly has epileptic seizures, periods in which neuronal populations become hyperexcitable and abnormally fire in synchrony (Scharfman, 2007). One of the most common forms of epilepsy in humans is temporal lobe epilepsy (TLE), meaning structures in their temporal lobes are the source of the aberrant neuronal firing. It was this form of epilepsy that led H.M. to have his bilateral temporal lobes removed. For individuals who suffer from temporal lobe epilepsy, cognitive impairments, including memory problems, are a common complication that can interfere with daily life to the same degree as the seizures themselves. These impairments can be attributed to a number of factors, including the pathology underlying the seizures, the seizures themselves, the drug therapy, or interictal epileptiform

discharges (IEDs), which are brief spikes of activity thought to reflect a transient disruption of local neural circuitry (Lenck-Santini & Scott 2015). Unlike most seizures, IEDs are not accompanied by overt symptoms. Only with EEG recordings have researchers been able to study the impact of IEDs on cognition (see Methods: EEG/ERP and Methods: Sleep Studies and EEG Technology). An example of what IEDs look like in an EEG recording is shown in Figure 18.8.

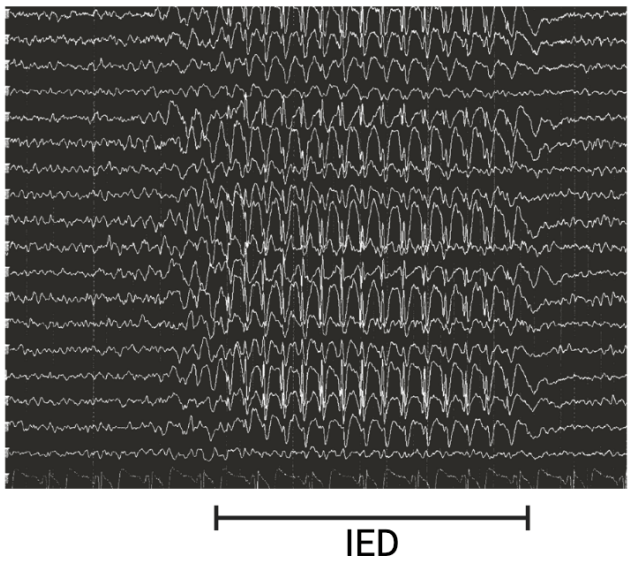

Figure 18.8 Seizures Interictal epileptiform discharges (IED) show up via EEG as a generalized 3 Hz signal. Image credits: EEG traces by Bromfield EB, Cavazos JE, Sirven JI, editors. - www.ncbi.nlm.nih.gov/books/N...ort=objectonly An Introduction to Epilepsy [Internet]. American Epilepsy Society; 2006. CC BY-SA 4.0, https://commons.wikimedia.org/w/inde...curid=57797002

Just because these seizures do not turn into obvious motor convulsions does not mean that they have no effect on behavior. One study (Kleen et al., 2013) investigated the impact of IEDs on short-term memory in a group of patients implanted with depth electrodes in their hippocampus in order to preoperatively localize the seizures. They found that IEDs that occurred at the time of memory maintenance or retrieval significantly decreased task choice accuracy, suggesting that IEDs can contribute to cognitive impairment in epilepsy. It therefore seems likely that undetected IEDs are contributing to memory impairments in patients' daily lives.

Another possible explanation for cognitive impairment in epilepsy is that an abnormality that causes the seizures also directly disrupts cognition. Evidence for this notion comes from studies done on a severe form of epilepsy called Dravet syndrome that is associated with cognitive impairments. In the majority of cases, there is a mutation in the SCN1a gene that codes for a voltage-gated sodium channel (Nav1.1) (see Chapter 2 Neurophysiology). However, there is no relationship between the severity of the seizures and the severity of the cognitive impairment, as would be expected if the cognitive impairment resulted from the seizures themselves (Scheffer & Nabbout 2019). This finding suggests that the cognitive impairment is a direct consequence of the mutation rather than being a secondary effect of the seizures.

Drug therapy can also be the culprit of cognitive impairments for people who are living with epilepsy. Although cognition can improve with antiepileptic drug treatment by controlling seizures, some antiepileptic drugs, such as lacosamide, can have cognitive side effects (Li et al., 2020).

Neuroscience across species: Normal age-related memory changes

Not long ago, it was a commonly held belief that dementia was an inevitable consequence of old age. Thankfully, we now know that this is not the case. Although cognition changes across the lifespan, it is possible to retain a high level of cognitive function into old age. Still, memory decline with aging is common and can be linked to age-related changes in brain structures that support memory processes.

A common means of studying changes in cognition with aging is to use animal models. The lifespan of a rat is about two years, so an 18 month old rat would be considered to be aged. Mice have a similar lifespan and are also common animal models used to study aging. One way that memory can be assessed in experimental animals like rats and mice is through spatial navigation tasks. Two common tasks are the Morris water maze and the Barnes maze.

The Morris water maze task is shown in Figure 18.9. In this task, an animal (usually a rat or mouse) is placed into a pool of murky water where they swim around until they find a hidden escape platform. Over many trials, the animal learns where the platform is, and as a result, swims more directly to it. A more direct path to the platform indicates learning and spatial memory. In many versions of this task, experimenters perform a probe trial, where they remove the platform and not only look at the path to the platform location but also at how much time the animal spends swimming right around the platform location. More time spent near the former platform location is often interpreted as a better spatial memory, like a person walking back and forth the same area where they feel sure they parked their car.

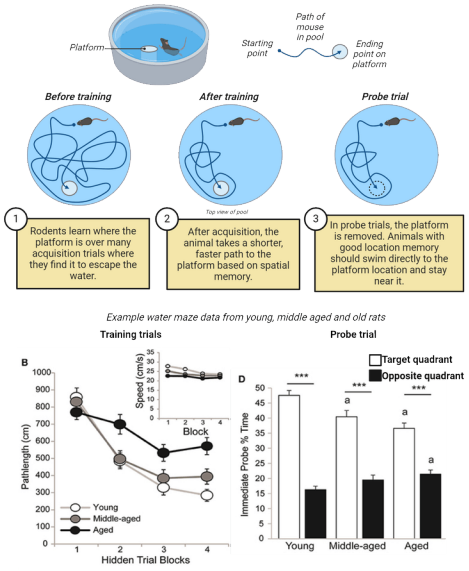

Figure 18.9 Morris water maze Data graphs from: McGuiness JA, Scheinert RB, Asokan A, Stadler V-C, Lee CS, Rani A, Kumar A, Foster TC and Ormerod BK (2017) Indomethacin Increases Neurogenesis across Age Groups and Improves Delayed Probe Trial Difference Scores in Middle-Aged Rats. Front. Aging Neurosci. 9:280. doi: 10.3389/fnagi.2017.00280. CC BY 4.0.

The bottom of Figure 18.9 shows some example data from old, middle-aged and young rats tested in the water maze. Notice how during acquisition, all the rats show shorter pathlengths to find the platform, but young and middle-aged mice show the greatest decrease in pathlengths, indicating that they are swimming more directly to the platform with repeated trials. We interpret this difference to mean that the younger rats are learning the platform location more quickly (with fewer trials). In the probe trial, experimenters quantified what percent of the time rats spent in the area around where the platform was during acquisition (i.e. the target quadrant of the pool). All the rats spend more time in the target quadrant than in the quadrant opposite it. The young rats, however, show the highest percent time swimming in the target quadrant, while middle-aged and old rats spend less time in the target quadrant. We interpret this decrease in time near the platform to indicate a poorer memory for where the platform was.

A similar task is the Barnes maze. Figure 18.10 shows this task, which is like a dry-land version of the water maze. In this task, the animal (again, usually a rat or mouse) is placed on an elevated platform that has holes around the periphery, but with only one hole leading to an escape hatch (rats do not like being out in the open). Over many trials, the animal learns where the escape hole is and, if they can remember it, takes a more direct path there, performing fewer errors (looking down in holes that do not have the escape) as they go. As with the water maze, experimenters often perform a probe trial, where the escape is removed and just a hole open to the floor remains. In addition to a shorter path to the former escape and fewer errors looking in non-escape holes, the time spent hovering around and looking in the former escape hole can also be used as an indicator of good memory.

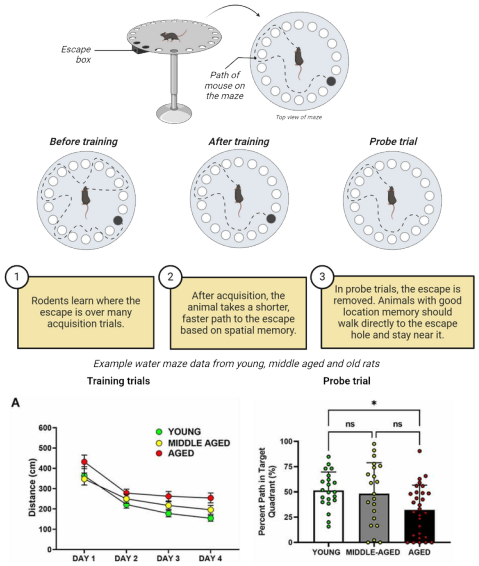

Figure 18.10 Barnes maze Data from: Souza KA, Powell A, Allen GC and Earnest DJ (2022) Development of an age-dependent cognitive index: relationship between impaired learning and disturbances in circadian timekeeping. Front. Aging Neurosci. 14:991833. doi: 10.3389/fnagi.2022.991833. CC BY 4.0

The bottom of Figure 18.10 shows some example data from old, middle-aged and young mice tested in the Barnes maze. Similar to the water maze, all the mice showed decreases in pathlength to the escape over multiple trials, with aged mice showing the least gains in pathlength efficiency and young mice showing the most. We interpret this difference to mean that the younger mice are learning the escape location more quickly (with fewer trials) than the aged mice. In the probe trial, experimenters quantified what percent of the time mice spent in the area around where the escape was during acquisition (i.e. the target quadrant of the maze). The young and middle-aged mice showed higher percent time swimming in the target quadrant than the old mice. We interpret this decrease in time near the platform to indicate a poorer memory for where the platform was in aged mice.

Work by Dr. Carol Barnes and many others in the field of aging neuroscience have helped us understand features of brain aging (see feature box on People Behind the Science: Student discovery becomes a key technique in aging neuroscience (Carol Barnes)). We looked at two studies in Figure 18.9 and Figure 18.10. These were just examples. Numerous studies confirm that aged rats and mice show impairments on both the Morris water maze and Barnes maze tasks, meaning that on probe trials they take longer paths to the escapes (or make more errors) and/or spend less time around the escapes than younger animals (Barnes, 1979; Frick, 1995; Gage et al., 1984; Gallagher & Burwell, 1989; Nyffeler et al., 2010). While these behavioral studies help show that age-related decline in memory is conserved across species, work using rats and mice has been particularly essential to advancing our understanding of what underlying changes occur in the brain that cause spatial navigation problems in older animals. It was thought in the 1970's that neurons shrivel up and die as we age. However, thanks to investigations in rats, mice, dogs, monkeys and humans, we now know that hippocampal cells do not decline in number as an animal ages. Moreover, biophysical properties of hippocampal cells are preserved in aged rats. So why do animals and humans do worse on spatial memory tasks as they age? The answer is that there are changes in the number of functional synapses and a decrease in synaptic plasticity, the ability for synapses to change their strength based on activity. Synaptic plasticity will be discussed in 18.4 Synaptic Mechanisms of Long-Term Memory.

People Behind the Science: Student discovery becomes a key technique in aging neuroscience (Carol Barnes)

The Barnes maze got its name because it was developed by Dr. Carol Barnes, a Professor in the Department of Psychology at Arizona State University and Evelyn F. McKnight Chair for Learning and Memory in Aging. In addition to the maze that bears her name, Dr. Barnes is best known for her work on normal cognitive decline that occurs with aging and the associated changes that occur in the brain. She studies how the brain changes during the aging process by comparing behavioral and neurophysiological measures between aging and young animals. But when Dr. Barnes designed Barnes maze, she was a graduate student. At the time, she called the task the "circular platform task". This task has several advantages over the Morris water maze task. For example, it is thought to be less stressful for the rats. Another advantage is that the Barnes maze task

can be performed more easily by animals that have balance, motor, and coordination challenges. Other researchers started calling it the Barnes maze, and that is the name that has stuck. The Barnes maze has now been adapted and used in over 900 peer-reviewed studies to study brain systems that support memory, and it was developed by a graduate student!

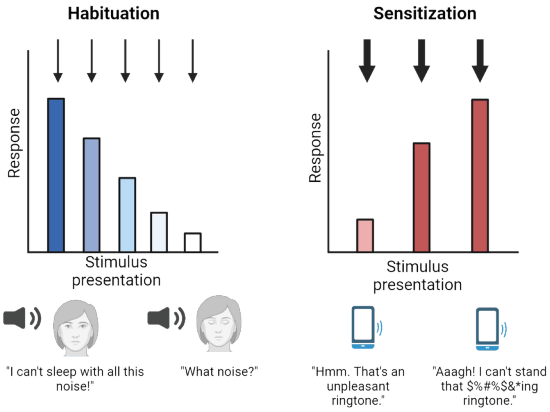
4.2.3: Implicit Memories- Associative vs. Nonassociative Learning

Learning Objectives

By the end of this section, you should be able to



- 18.2.1 Describe two kinds of nonassociative learning.
- 18.2.2 Explain a typical classical conditioning experiment.
- 18.2.3 Describe the conditioned fear paradigm.
- 18.2.4 Explain a typical operant conditioning experiment.

As we learned in 18.1 Memory is Classified Based on Time Course and Type of Information Stored, long-term memories can be categorized as implicit or explicit. In this section, we will dive more deeply into how implicit memories are formed. In the next section, we will cover explicit memory formation.

Implicit memory can be divided into associative and nonassociative categories. These categories are distinguished by the number of stimuli involved in learning. Nonassociative learning (and therefore non-associative memory) involves learning information about one stimulus. Conversely, associative learning (generating associative memories) refers to a type of learning in which the relationship between two stimuli is learned.

Nonassociative learning

Nonassociative learning involves the presentation of a single stimulus either once or multiple times. There are two main types of nonassociative learning: habituation and sensitization (Figure 18.11). Habituation refers to a diminished response to a stimulus that has been presented multiple times. An example would be someone who moves to a busy city from a small town. At first, the traffic noise may keep the person awake at night. However, after a few days, the person no longer notices the noise and can fall asleep easily. Sensitization refers to an exaggerated response to a stimulus after it is presented multiple times. In order for sensitization to occur, the stimulus must be intense and/or unpleasant. An example of sensitization would be the repeated loud ringing of a phone getting more and more annoying as time passes.

	Habituation	Sensitization
Stimulus quality	Mild	Noxious
Stimulus frequency	Repeated	≥1x
Response	Decreases	Increases

Figure 18.11 Habituation and sensitization

Neuroscience across species: Mechanisms of sensitization in a sea slug

Non-associative learning is a relatively simple form of learning and much of what we know about the central circuits supporting it first came from study of an organism called Aplysia (Figure 18.12). Aplysia, also known as sea slugs, have only ~10,000 neurons in their nervous system. This relatively simple nervous system enabled researchers like Nobel prize winner Dr. Eric Kandel to study nonassociative learning and determine the specific circuit mechanisms that mediate it.

Figure 18.12 Aplysia Californica *Aplysia Californica* releasing ink. Study of aplysia has helped us understand the neural mechanisms of non-associative learning. Image credit: Genny Anderson - http://marinebio.net/marinescience/0...logy/tptre.htm, CC BY-SA 4.0, https://commons.wikimedia.org/w/inde...p?curid=264835

To study non-associative learning, Kandel took advantage of a defensive reflex that Aplysia show called the gill and siphon withdrawal reflex. The gill of Aplysia is a delicate tissue through which they exchange oxygen and is located on the ventral side of the animal. The siphon is a small tube, extending from the ventral side of the animal out the caudal side, and is used to flow water through the animal as it moves. When the siphon is touched, this causes the gill to retract, a reflex meant to protect the delicate gill from whatever unknown threat may be approaching from behind. This reflex can undergo both forms of plasticity: habituation and sensitization. In the case of habituation, repeatedly touching the siphon eventually results in a weaker response. To observe sensitization, researchers paired a touch of the siphon with a shock to the tail. After repeated pairings (or even after just one pairing with a particularly large shock), a touch to the siphon elicits an exaggerated gill withdrawal response. Kandel and colleagues studied these changes in reflexes to show that they relied on central changes in synaptic strength and not, for example, changes in muscle fatigue or sensory receptor sensitivity.

Figure 18.13 shows some of the underlying mechanism for how sensitization happens and provides an example of how Aplysia helped us define a simple learning circuit. Underlying this exaggerated response is a larger amplitude EPSP in the gill withdrawal motor neuron compared to the EPSP seen before sensitization. This larger EPSP results from increased neurotransmitter release from the presynaptic neuron, which in the case of the gill withdrawal reflex is the siphon sensory neuron.

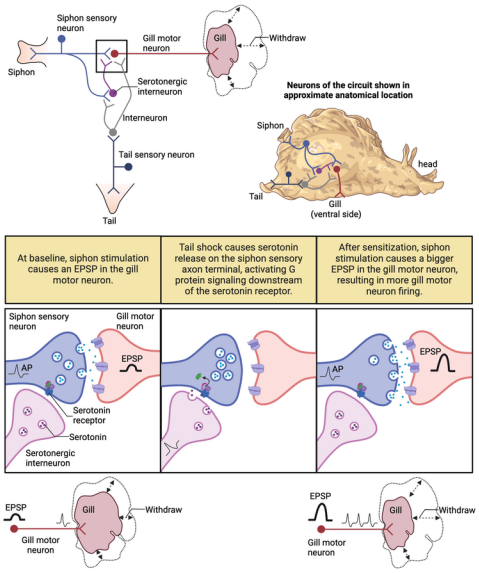


Figure 18.13 Aplysia sensitization

Let's walk through how this change occurs. The siphon has sensory neurons which connect directly to the gill motor neurons. At baseline, a touch of the siphon releases neurotransmitter on the gill motor neuron, exciting the gill motor neuron (an EPSP) and causing it to fire. The gill muscle contracts, and the gill withdraws. The synapse between the siphon sensory neuron and the gill motor neuron is not isolated, however. It receives other inputs, the most important for us here is from a serotonergic interneuron. That serotonergic interneuron releases serotonin on to receptors on the presynaptic siphon sensory terminal. The serotonergic neuron gets its input indirectly from tail sensory neurons. When the tail is shocked, that serotonergic neuron releases serotonin on the siphon sensory presynaptic terminal. The downstream G protein signaling cascades following serotonin receptor activation change the siphon sensory presynaptic terminal such that it will now release more neurotransmitter in response to single siphon axon action potential. The next touch of the siphon now releases more neurotransmitter, causing a larger EPSP in the motor neuron, more motor neuron action potentials and greater gill muscle contraction. The end result is the same siphon touch results in more gill withdrawal after sensitization by tail shock than it did before. You can read more about Eric Kandel's discoveries at The Lasker Foundation.

Associative learning

Unlike habituation and sensitization, where response to a single stimulus changes as a result of experience, in associative learning, a relationship between two stimuli is learned by presenting the stimuli close together in time. There are 2 main types of associative learning: classical conditioning and operant conditioning.

Classical conditioning

Dr. Ivan Pavlov is a central figure in the history of associative learning. Pavlov was a Russian physiologist who won the Nobel prize in Physiology or Medicine in 1904 for his discoveries about the physiology of digestion. However, he is best known for discovering classical conditioning, a field that even bears his name as it is sometimes called "Pavlovian conditioning". His discovery was purely accidental while he was studying the gastric system of dogs. He was interested in the amount of saliva dogs produced when presented with food vs. non-food items and discovered, not surprisingly, that dogs salivated when food was placed in front of them. However, he also made a curious observation: the dogs began salivating before the food was presented in response, for example, to hearing the footsteps of the research assistants coming down the hall to bring the food. These auditory stimuli now elicited salivation after being reliably paired with food presentation. He then tested other signals, including a ringing of a bell, to signal that the food was on its way and observed that no matter what the signal, the dogs would salivate in anticipation of the food, suggesting that they had learned the association between the food and the signal.

Figure 18.14 describes the process that Pavlov was uncovering in his work and that we now call classical conditioning. The food is referred to as the unconditioned stimulus, and salivation as the unconditioned response. These are physiological responses that are not learned but are innate. Conditioned stimuli, like Pavlov's bell, are stimuli that signal and thus come to be associated with the unconditioned stimulus. Conditioned responses are the responses that are triggered by the conditioned stimulus after

learning. In the case of the dogs, the conditioned response was salivation but only when it occurred after the conditioned stimulus. Thus, the conditioned response and unconditioned response are often the same physiological responses (salivation in this case) and are distinguished only by the timing of their occurrence, with conditioned responses happening after the conditioned stimulus but before the unconditioned stimulus is present.

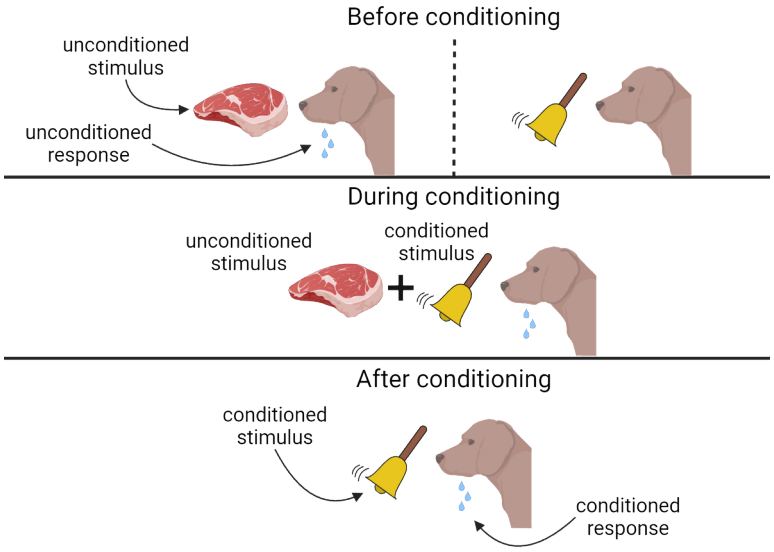

Figure 18.14 Classical conditioning

While Pavlov's work was transformative for the study of learning, the brain mechanisms remained a mystery at the time. In particular, the effort to localize memory to a specific part of the brain, much like speech can be localized to Broca's area, has occupied researchers for decades and continues to be a focus of research today. This memory trace in the brain is sometimes referred to as an engram. Dr. Karl Lashley, for example, launched numerous studies in the early 1900s where he made extensive cortical lesions in rats, looking for which area held the engram. After repeatedly observing no behavioral deficit, Lashley concluded in frustration that the memory engram could not be found. In Lashley's words: "I sometimes feel, in reviewing the evidence on the localization of the memory trace, that the necessary conclusion is that learning is just not possible".

About one hundred years after Pavlov won the Nobel prize, however, Pavlov's scientific "great-grandson", Dr. Richard Thompson, discovered a specific brain region underlying a specific form of Pavlovian conditioning. Instead of salivating dogs, Thompson used blinking rabbits. He developed a paradigm, rabbit eyeblink conditioning, in which an airpuff to the eye (the unconditioned stimulus) triggers a reflexive eyeblink, the unconditioned response. If the airpuff is preceded by a tone, the conditioned stimulus, the rabbit eventually starts blinking to the tone, thus emitting a conditioned response. Instead of looking in the cortex like Lashley did, Thompson set out to discover the memory engram in subcortical structures. Thompson and his doctoral student, David McCormick, published a paper demonstrating that they had indeed localized the memory engram. Lesions of the ipsilateral dentate-interpositus nuclei of the cerebellum completely eliminated the learned eyeblink response (McCormick & Thompson 1984). Importantly, the lesioned rabbits were still able to produce an eyeblink in response to the puff of air, indicating that the motor capacity persisted, but that ability to learn the association did not. Consequently, this particular type of associative learning is supported by the cerebellum. However, other types of associative learning, such as conditioned fear, rely on a different network of brain regions.

Neuroscience in the lab: Fear learning as a special case of classical conditioning

Many forms of fear learning are forms of classical conditioning. Fear memory is an umbrella term for a number of paradigms in which there is association formed between a threatening stimulus and a neutral stimulus. Research with human subjects can rely on self-report to examine fear. However, how do we study fear using animal subjects? Although it is not possible to directly measure fear in experimental animals, we can rely on species-typical defense behaviors to give us a clue about what brain circuitry gives rise to the perception of threats and avoidance of danger. The visual systems of predators that hunt rodents are exquisitely sensitive to movement. Thus, one species-typical behavior of mice is to freeze to avoid predation. Researchers capitalize on the tendency of rodents to freeze when they feel threatened as a way to indirectly measure the animals' emotional state.

Figure 18.15 shows two typical fear conditioning paradigms, both of which involve delivering a foot shock as the unconditioned stimulus in association with differing neutral stimuli. In both cases, freezing behavior is used to measure fear elicited by the formerly neutral stimuli. In cued fear conditioning, the shock is paired with a tone, which then becomes the conditioned stimulus. Similar to eyeblink conditioning described above, the previously-neutral tone comes to elicit the conditioned response, freezing. In contextual fear conditioning, the shock is delivered without a tone. As a result, the environment where the shock was delivered serves as the conditioned stimulus. The next time a rodent is placed in the shock context, it will freeze, reflecting that it learned and remembered the association of the context with unpleasant footshock. There is general consensus that all types of fear conditioning depend on the amygdala, while contextual fear conditioning also relies on the hippocampus (Izquierdo et al., 2016).

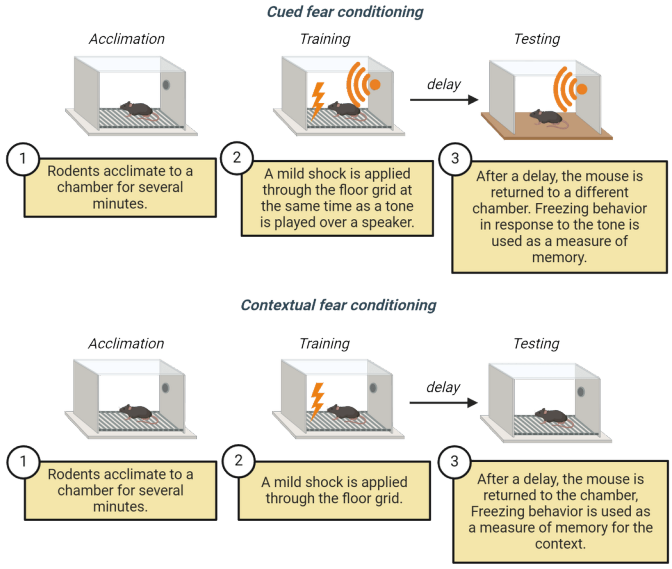

Figure 18.15 Fear conditioning

People Behind the Science: Steve Ramirez (inducing false memories)

Dr. Steve Ramirez, an assistant professor of Neuroscience at Boston University, is best known for his discovery alongside his colleague Dr. Xu Liu that memories can be engineered (i.e. artificially created). To do this, they first had to capture a memory in the brain by tagging neurons in the dentate gyrus subregion of the hippocampus that were active during memory formation. Using a combination of genetic and optogenetic tools, they tagged neurons that were active during fear conditioning with Channelrhodpsin-2 (see Methods: Optogenetics), which allowed them to activate this same set of neurons in a different environment. Contextual fear conditioning is quite specific. If a mouse undergoes contextual fear conditioning in one environment, it will only freeze in the shock context and not in a “safe” context where it has never been shocked. Liu and Ramirez found that when they reactivated the group of neurons in the “safe” context, the mice froze as if they were in the fear context (Liu et al., 2012). Thus, each memory activates a specific set of hippocampal neurons and can be recalled when that set of neurons is reactivated. They concluded that this set of neurons that are activated by a memory are the neural substrate for a memory engram. Dr. Ramirez has the goal of applying these findings to therapeutic interventions for disorders such as depression and post-traumatic stress disorder.

Operant conditioning

Unlike classical conditioning, which requires the association between the conditioned and unconditioned stimuli, operant conditioning requires the association of a voluntary behavior with a consequence. The most well-known experimental example of operant conditioning is training a rat to press a lever to get a food pellet. However, you might be more familiar with the same type of operant behavior when you train your pet dog to do tricks using positive reinforcement. Every time your dog does something that is desirable, you give him a treat (a reinforcement), making it more likely that the behavior will occur again. Punishments, conversely, are actions that decrease the likelihood that the behavior will occur again. Punishments are often confused with negative reinforcement, which is the *removal* of an undesirable stimulus and has the consequence of making a behavior *more likely* to occur. A common example of negative reinforcement is the use of alcohol to alleviate nervousness in a social situation. The alcohol mitigates the nervous feelings, thus making it more likely that the person will drink alcohol the next time they

encounter a social situation. There can also be positive punishment in which something is added to the environment to decrease the behavior. For example, giving students extra homework when they fail to complete the assigned work. Figure 18.16 diagrams the different forms of operant conditioning and their effect on behavior.

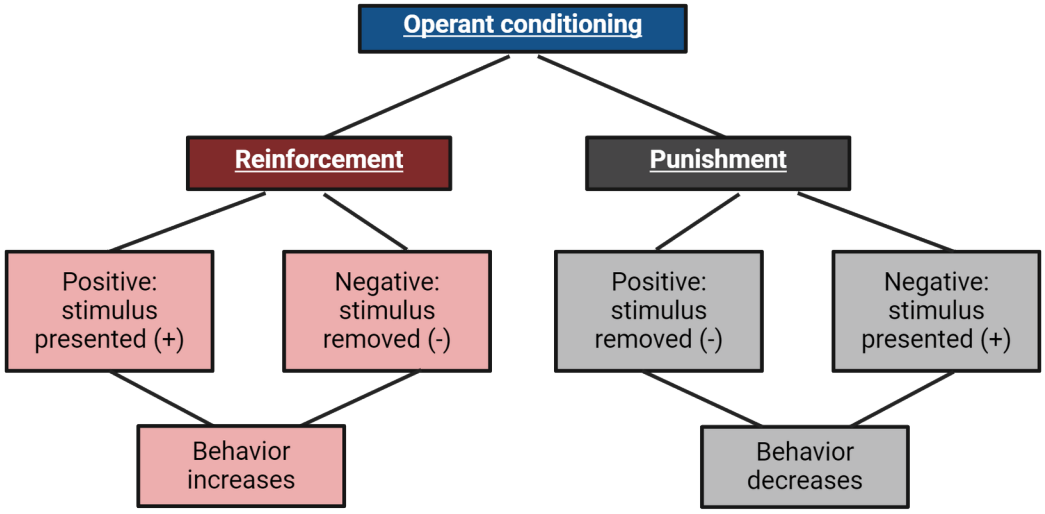

Figure 18.16 Operant conditioning

A number of brain regions contribute to operant conditioning. One important brain region is the basal ganglia, especially the caudate and putamen, collectively known as the striatum (see Chapter 10 Motor Control). The striatum receives input from many cortical regions, most importantly to the motor cortex, and sends projections via the globus pallidus and substantia nigra to the thalamus, and ultimately back to those same cortical regions. This cortical-striatal system is thought to be critical for making associations between stimulus and response. In addition, the medial prefrontal cortex, amygdala, and the mesolimbic dopamine system (i.e. “reward pathway”) all contribute to producing goal-directed behaviors and stimulus-response behaviors (Rudy, 2008).

4.2.4: Explicit Memories- Episodic and Semantic Memories

Learning Objectives

By the end of this section, you should be able to

- 18.3.1 Describe the anatomy of the hippocampus.
- 18.3.2 Explain the role of the hippocampus in episodic memory.
- 18.3.3 Describe place cells, grid cells, and other spatially coding cells in the hippocampal formation.

In the previous section, we discussed implicit memory, which included the associative and non-associative memories that can often guide our behavior without us being consciously aware of them. Here, we will learn more about the other major category of memory: explicit memory. As the name implies, explicit memories are the kinds of memories we feel more aware of and are probably what most people are referring to when they talk casually about their "memory." There are two categories of explicit memory: episodic and semantic. They are distinguished by the nature of the information that the memory contains. Episodic memories, in short, are memories of the sequence of events in our lives, while semantic memories are more like knowledge, or memories for facts, independent of where in our life narrative we learned that fact. In this section, we will focus on episodic memories and the neural structures that support it. We will also learn about how episodic memory is inherently intertwined with encoding of spatial information about the environment.

Neuroscience across species: Episodic memory depends on the hippocampus

Dr. Endel Tulving (1987) defined episodic memory as an event that is remembered in a spatiotemporal cortex: What happened? Where did it happen? When did it happen? Episodic memory is distinct from having a knowledge of facts about the world, an operation known as semantic memory. You might be wondering how episodic memories can be studied in animals. One excellent example of episodic memory in the animal kingdom comes from the work studying food-caching birds. Certain species of birds hide their food in multiple specific locations over time and need to remember *what* food was stored, *where* it was stored, and when it was stored. Thus, studying food-caching behavior satisfies Tulving's definition of episodic memory. Clayton and Dickson (1998) designed an experiment to test episodic memory in western scrub jays. The researchers allowed the birds to cache either shelf-stable peanuts or perishable meal worms. Thus, the birds had to remember what they stored (worm or peanut), where it was stored, and when it was stored in order to retrieve the perishable worms before the nonperishable peanuts. Jays prefer mealworms over peanuts, but the jays would only retrieve worms if they were allowed to retrieve them shortly after caching. For long storage-to-retrieval intervals, the jays retrieved the less preferred, but nonperishable peanuts.

Several lines of evidence suggest that the hippocampus has an especially important role in these kinds of episodic memory. For example, Chettih et al., 2023, recorded from hippocampal neurons of chickadees, another food-caching bird species, during food caching events. They found that each caching event was accompanied by a burst of firing in a unique group of hippocampal neurons that were re-activated during food retrieval. They called these activity patterns "barcodes", similar to barcodes that you find on grocery items. As you read in the first section of this chapter, removal of the hippocampus in humans causes the inability to form memories of specific events. For example, after undergoing a bilateral temporal lobectomy, Henry Molaison could still learn new skills, but had the inability to form new episodic memories.

Studies with rodent subjects corroborate the importance of the hippocampus for forming new episodic memories. For example, rats with hippocampal damage are unable to remember a particular sequence of odors in an odor recognition task, even though they have no problem remembering individual odors. As shown in Figure 18.17, for this task, rats are trained to dig in cups of sand for a buried food reward. The sand is scented with different odors across multiple trials. In training, rats are presented with these scented sand cups in a particular order. Then, on a sequence probe trial are presented with two options and rewarded for digging in the cup containing the odor that was presented earlier in the training sequence (odor A vs. odor C). As shown in Figure 18.17, the hippocampal-lesioned group showed poorer accuracy on this sequence probe compared to the control group, but showed similar levels of accuracy on the recognition probe test in which they had to identify which odor was not presented during training. This and similar findings suggest that the hippocampus is critical for the memory for sequences of events, a key component of episodic memory (Fortin, Agster, & Eichenbaum, 2002; Kesner et al., 2002; DeVito & Eichenbaum, 2011).

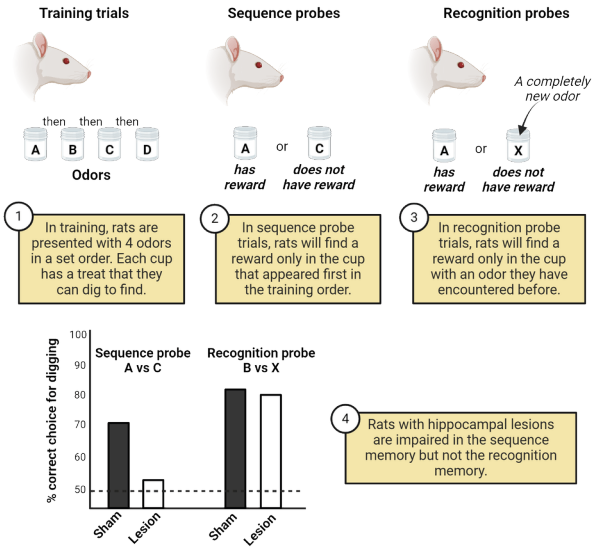

Figure 18.17 Odor sequence learning

The hippocampus is a three-layered structure, named for its resemblance to a seahorse, that resides in the temporal lobe of the human brain. The hippocampus and its associated structures are collectively referred to as the hippocampal formation and include the hippocampus proper, the dentate gyrus, the subiculum, presubiculum, parasubiculum, and entorhinal cortex. Although the expansion of the human neocortex in evolutionary history pushed the hippocampus down into the temporal lobe (see Chapter 5 Neurodevelopment), the hippocampus of rodents resides near the dorsal surface of the brain (Figure 18.18). Despite the different anatomical position, the neurons, pathways, and basic structure are similar across the phylogenetic scale.

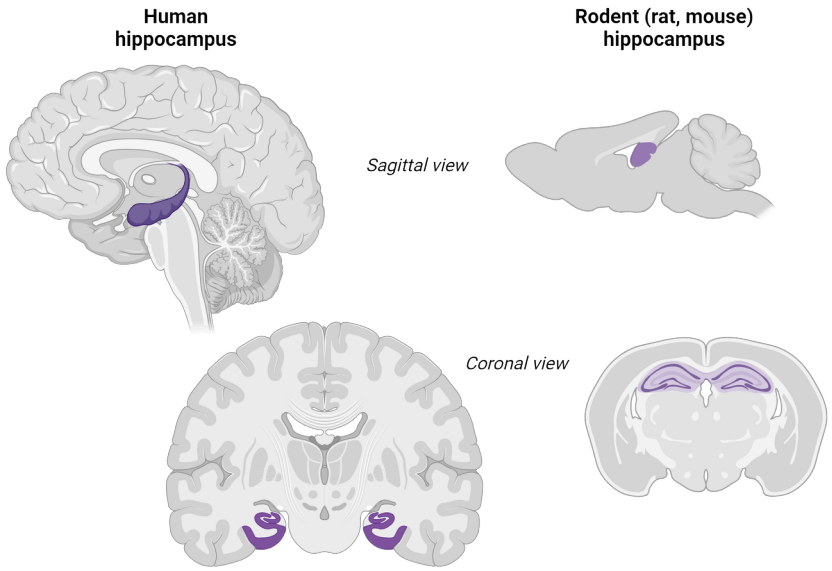

Figure 18.18 Hippocampus across species

The brain's GPS system: grid cells and place cells

What does the hippocampus do? This is a question that has been under debate for decades (for review, see Eichenbaum, Otto, and Cohen 1992). Broadly speaking, the hippocampus is necessary for two major cognitive functions: episodic memory, the ability to recall specific personal events in their spatial and temporal context, and the spatial representation of environments. As we covered above, the former notion grew out of the human clinical literature (see 18.1 Memory is Classified Based on Time Course and Type of Information Stored) that demonstrated that patients with damage that included, or in some cases was restricted to, the hippocampus exhibit profound anterograde amnesia (S. Zola-Morgan, L. R. Squire, and D. G. Amaral, 1986). We have also reviewed some of the evidence in rodents and birds that further support the role of the hippocampus in episodic memory.

The latter idea, that the hippocampus supports spatial memory, is particularly well-supported by a series of experiments in rodents showing the existence of hippocampal neurons that preferentially fire in response to an animal being in a particular spatial location. We call these cells place cells and they were first discovered in 1971, by two researchers, Drs. O'Keefe and Dostrovsky (see Feature box about The discovery of place cells). By recording from neurons while rats explored an area, O'Keefe and Dostrovsky discovered that pyramidal cells in the rat hippocampus were selectively active when the rat occupied specific regions of the environment. The top of Figure 18.19 shows an example representation of neuronal firing events by distinct hippocampal neurons (each represented as a different color) as a rat navigates a track. Note how each neuron shows a strong preference for firing around a single spatial location in the track. This discovery initiated a decades-long debate about the contribution of the hippocampus to spatial representations vs. episodic memory. The major takeaway for us here is that it is important not to think of the hippocampus as strictly a memory structure. Instead, the hippocampus is a structure that generates sequential patterns of activity that can represent past spatial locations, time, or even imagine future experiences (See Buzsaki & Tingley, 2018).

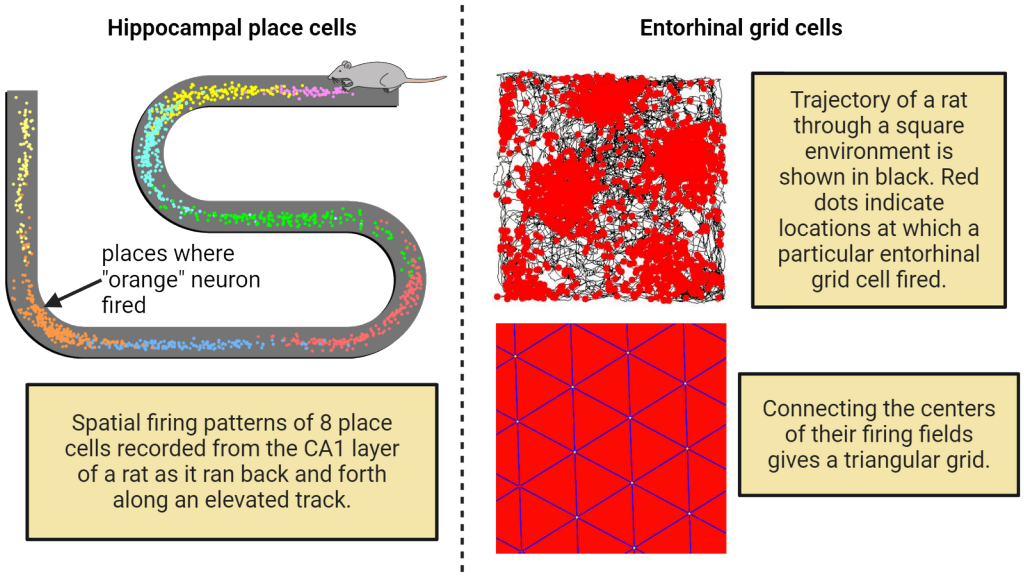

Figure 18.19 Place cells and grid cells Place cell (labels added an text modifed) by Stuartlayton at English Wikipedia, CC BY-SA 3.0, https://commons.wikimedia.org/w/inde...curid=43746578. Grid cell firing image and text by Khardcastle, CC BY-SA 4.0, commons.wikimedia.org/w/inde...curid=59507352. Grid pattern and text By Tomruen - en.Wikipedia.org/wiki/Image:U...ling_63-t2.png, CC BY-SA 3.0, commons.wikimedia.org/w/inde...?curid=1692087

After the discovery of place cells, the next question was where was this spatial code coming from? Was the spatial code generated in the hippocampus itself, or was the spatial code inherited from an input region? A logical first place to look was in the entorhinal cortex, the structure that provides the main cortical input to the hippocampus. Instead of a precise single place field, neurons in the entorhinal cortex fire in an extremely regular pattern. The multiple firing fields of these grid cells tiled the environment in a triangular array, which bears a striking resemblance to coordinates on a map (Hafting, Fyn, Moser, & Moser 2005). The bottom of Figure 18.19 shows examples of neuronal firing events (red dots) of entorhinal cortex cells layered over the physical location of the rat in an arena. Note how the neuron fired at a collection of locations and those locations together make a grid shape. It was later found that the direction and speed of the animal is used to generate the grid cell firing pattern. Specifically, the entorhinal cortex not only contains grid cells, but also contains head direction cells, which are selectively active when the animal faces a certain direction (Taube et al., 1990), speed cells, which are selectively active at different speeds (Kropff et al., 2015), and border cells, which are selectively active when the animal approaches the borders of the environment (Solstad et al., 2008).

In addition to the work with rodents, there have been compelling studies linking navigational performance to the hippocampus in human participants. For example, Dr. Elenore Macguire and her colleagues (2000) conducted a structural MRI on London taxi drivers. They hypothesized that if the hippocampus plays an important role in spatial navigation, individuals like taxi drivers, who in the days before cell phones with maps required superior navigational abilities to perform their job, would have anatomical differences in their hippocampi compared to age-matched controls. As predicted, taxi drivers showed significantly larger gray matter volume in the posterior hippocampus compared to controls. The posterior hippocampus is analogous to the same hippocampal subregion where place cells are found in the rodent. In addition, posterior hippocampal volume showed a significant positive correlation with time spent as a taxi driver. A few years later, place cells were discovered in the human hippocampus. A group of researchers used a unique subject pool: individuals with epilepsy who had been implanted with depth electrodes in the hippocampus in order to localize the seizure focus for possible surgical treatment. Subjects explored and navigated around a

virtual town as they played a taxi driver video game while the researchers recorded from their hippocampus. Consistent with the findings in rodents, each hippocampal neuron was selectively active at a specific location in the virtual environment (Ekstrom et al., 2003).

Neuroscience in the Lab

The discovery of place cells

Early studies of the hippocampus revealed a striking relationship between hippocampal cell firing and an animal's location in space almost completely by accident. In the late 1960's, John O'Keefe, a researcher at University College London, was trying to record from somatosensory cells in the thalamus in awake, freely behaving rats. By accident, he placed his recording electrode in the hippocampus and wound up recording from a cell that showed odd firing patterns, ones that he thought were related to some complex form of behavior tied to how the rat was moving. At the time, the hippocampus was known purely as a memory system. In his acceptance speech for the Nobel Prize in Physiology and Medicine many years later, O'Keefe recalls that "I immediately decided to abandon the somatosensory system and move to the study of the hippocampus in an attempt to see what memories looked like at the single cell level."

O'Keefe and a graduate student started recording purposefully from pyramidal cells in the rat CA1 area of the hippocampus as the rat ran around an enclosure foraging for food. Together, O'Keefe and the student, Johnathan Dostrovsky, recorded from hippocampal neurons as they took notes about the rats' activities, still not quite sure what the relationships were. A subset of cells, they noticed, were relatively inactive most of the time but "sprung into activity at irregular intervals". Only later did they realize that the sudden increases in firing rate corresponded not to any particular behavior, but instead, to the location of the rat (O'Keefe, 2014). This type of neuron came to be known as a "place cell" and the region of space where the place cell was active came to be known as its "place field". See Figure 18.19. Here is a video showing place cell firing. Subsequent studies showed that each hippocampal neuron has a different place field within a particular environment, similar to the receptive fields of neurons in the visual cortex (see Chapter 6 Vision). In fact, if enough hippocampal cells are recorded simultaneously, researchers can predict with high precision where the rat is located within the environment just by observing which neurons are active at that particular moment in time.

Linking spatial cognition to episodic memory

How do we reconcile the experimental findings in rats and humans that suggest that the hippocampus and related structures are part of a neural "GPS system" with the clinical findings in humans that implicate the hippocampus as a critical structure in episodic memory? One idea is that the hippocampus specializes in generating sequences and that this sequence generation is a common feature shared by both spatial navigation and memory. Brain rhythms are hypothesized to support information processing and synchronization in brain networks. Indeed, hippocampal pyramidal neurons fire in precise sequences in the environment and that sequence is preserved and compressed in time within a cycle of the most prominent brain rhythm, the hippocampal theta rhythm, a 6-10 Hz wave that appears during exploratory behaviors and REM sleep across species (Buzsaki, 2002). Support for the more generalized function of the hippocampus came in 2011 when a group of researchers discovered what they called "time cells" in the hippocampus. These cells fired at a specific time while a rat was running on a treadmill between trials of a T-maze alternation task, in which rats have to alternate visits to the left and right goal arms of the "T" in order to receive food reward. It is important to note that many of the neurons that were called time cells also had a place field on the maze, so time cells could also be place cells (MacDonald et al., Kraus et al., 2013).

4.2.5: Synaptic Mechanisms of Long-Term Memory

Learning Objectives

By the end of this section, you should be able to

- 18.4.1 Describe the similarities and differences between LTP and LTD.
- 18.4.2 Explain how LTP is demonstrated in a lab.

We have now learned about several brain regions that are important for memory encoding. But, what neural mechanisms within those regions are necessary for long-term memory? Decades of research, most of which used animal models, has supported the hypothesis that the long-term storage of information relies on changes in the strength of synaptic connections, in other words, changes in the ability of the presynaptic neuron to elicit a response (EPSP) in the postsynaptic neuron. Long-term changes in synaptic strength last hours, days, or weeks, which makes it tempting to link these changes in synaptic strength with memory. Currently, such long-lasting synaptic strength changes are the best supported mechanism for learning and memory, though the link between synaptic plasticity and memory is still under debate. In this section, we will learn about the molecular mechanisms by which synaptic connections can be changed to support memory formation.

Long-term potentiation and depression

There are two types of long-term synaptic plasticity: long-term potentiation (LTP) and long-term depression (LTD). LTP refers to a long-term increase in synaptic strength, where LTD refers to a long-term decrease in synaptic strength. Both types of plasticity are equally important for dynamically adjusting synaptic strength based on synaptic activity.

Our current understanding of the molecular mechanism of memory has its foundation in ideas first proposed over 70 years ago. In 1949, Dr. Donald Hebb suggested that memory might rely on simultaneous activity of the presynaptic and postsynaptic neuron, in other words “neurons that fire together, wire together”.

It wasn’t until 1973 that an experiment was done to test Hebb’s postulate. The Norwegian scientists, Drs. Bliss and Lomo, conducted an experiment where they recorded from and stimulated the hippocampus. To understand the experiment that Bliss and Lomo performed, we must first learn more about the unique circuitry of the hippocampus. The hippocampus is organized in a vastly different way than other brain structures. While different regions of the neocortex are reciprocally connected, receiving and sending input to the same brain areas (Felleman & Van Essen, 1991), regions of the hippocampus are connected through a series of excitatory glutamatergic pathways known as the trisynaptic loop (Figure 18.20).

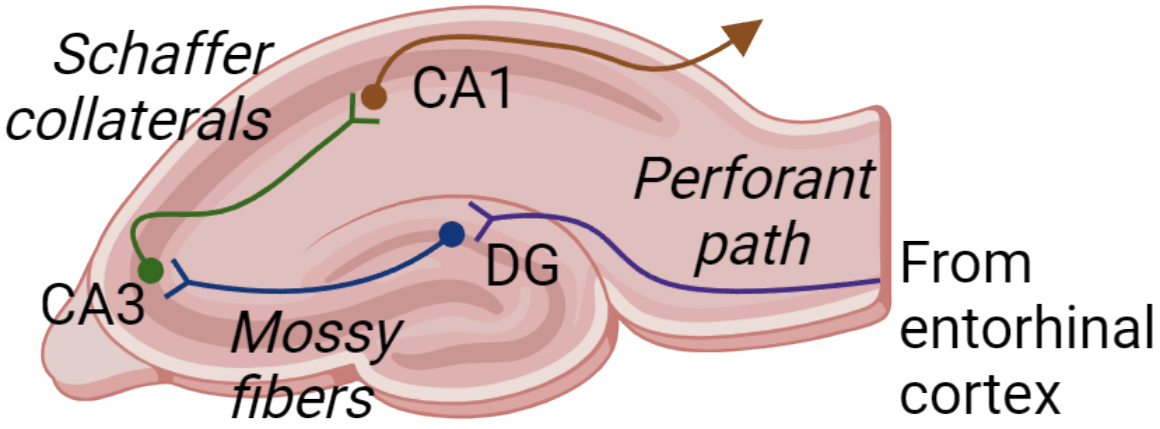

Figure 18.20 Hippocampal trisynaptic circuit

The first synapse is via the perforant path, which consists of axons from principal neurons whose cell bodies are located in the entorhinal cortex and terminate in the dentate gyrus. The second synapse is via the mossy fiber pathway, which consists of axons from principal cells in the dentate gyrus that send axon terminals to CA3. The third synapse is via the Schaffer collateral pathway, which consists of axons from principal cells in the CA3 that send axon terminals to CA1. There are other connections that course through the hippocampus, as well as an extensive network of inhibitory neurons that modulate the activity of the principal cells. As you will read below, this trisynaptic circuit in the hippocampus is where Bliss and Lomo first discovered the synaptic plasticity known as LTP (Anderson, 2007).

Bliss and Lomo's original experiments demonstrating LTP were performed by recording from the dentate gyrus in anesthetized rabbits (Figure 18.21). Specifically, they used an extracellular electrode to record the amplitude of the field/population EPSP (pEPSP), which reflects the summed activity of numerous simultaneously active neurons (see Methods: Electrophysiology). To get a baseline response, they first gave a test stimulation to the pathway of axons that provides input to the dentate gyrus, called the perforant path, and measured the amplitude of the pEPSP. They then delivered high frequency stimulation, called a tetanus, of the perforant path. Next, they delivered test pulses every few seconds and measured the pEPSP amplitude.As shown in Figure 18.21, the pEPSP amplitude increased by 300% after the tetanus and stayed elevated for at least 6 hours.

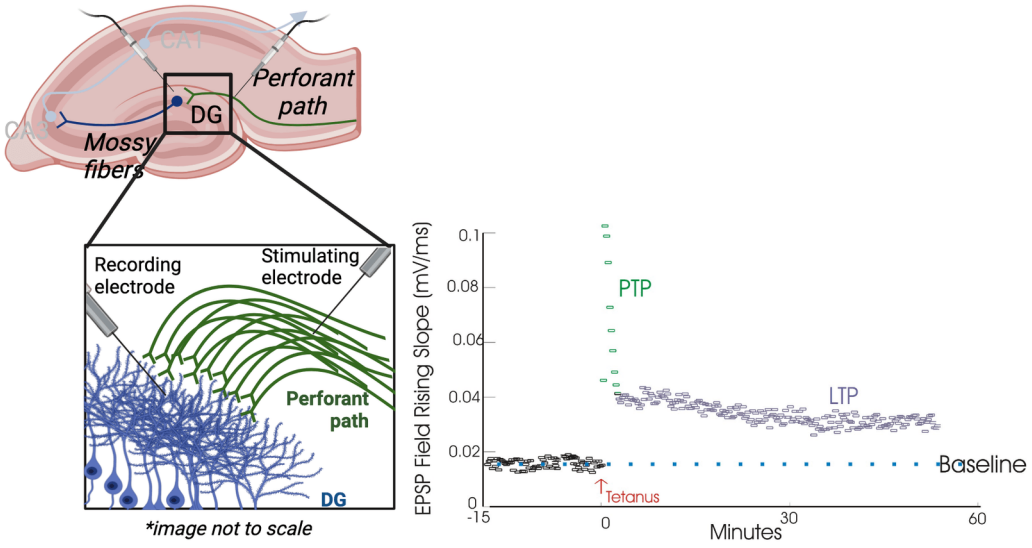

Figure 18.21 Bliss and Lomo experimental set-up This graph shows an example of long-term potentiation. The test stimulus leads to a small field EPSP at the start. After tetanus, field EPSP in response to the test stimulus is about 2x greater than before tetanus. Image credit: modification of work by Synaptidude at English Wikipedia. Following the findings of Bliss and Lomo, there were a number of follow up studies that contributed to the understanding of LTP. Bliss and Gardner-Medwin (1973) found that LTP lasts many weeks. Douglas and Goddard (1975) used theta-burst stimulation, a more physiologically-relevant stimulation, instead of a high-frequency tetanus to induce LTP. Other studies eventually showed that LTP is not something that only happens in one synapse at a time. While LTP can be homosynaptic (one pathway), it can also be associative (more than one pathway). In associative LTP, a weak synapse becomes stronger when it is stimulated simultaneously with a strong synapse. Stimulation of either synapse alone does not result in potentiation of the weak synapse; it's the combination of weak and strong firing together that makes LTP possible for the weaker synapse.

One could argue that decreases in synaptic strength are just as important as increases, thus the need for LTD. In LTD, synaptic strength decreases, rather than increases. There are two main reasons LTD is needed. First, being able to reduce synaptic strength prevents saturation and thus reaching a plasticity ceiling that would block further synaptic strengthening. Second, LTD is necessary to prevent network instability due to hyperexcitability, especially for structures like the hippocampus that are susceptible to seizures. Like LTP, LTD can either be homosynaptic or associative. The induction protocol for LTD is almost identical to the induction protocol for LTP, with one important difference: instead of high-frequency stimulation, LTD is induced by low-frequency stimulation. Low-frequency stimulation delivered to an already-potentiated synapse causes the synaptic strength to decrease to pre-potentiated levels, a term called depotentiation. By contrast, low frequency stimulation delivered to naive synapses leads to a decrease in synaptic strength below baseline. Both LTP and LTD are diagrammed, along with some of the molecular mediators that we will learn about, in Figure 18.22.

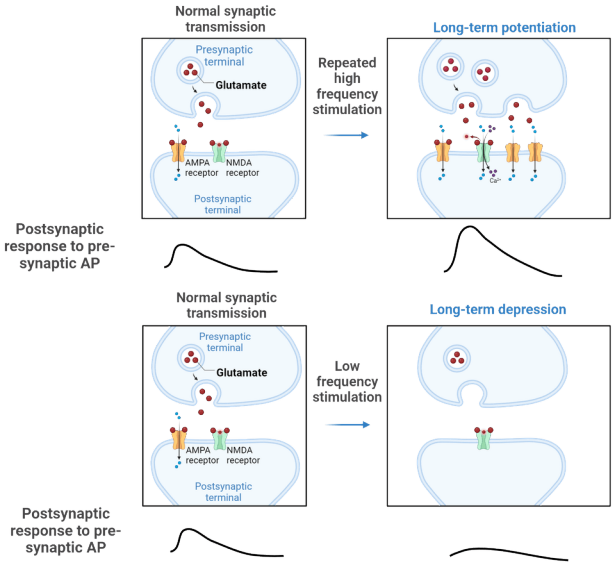

Figure 18.22 LTP vs LTD

Mechanisms of LTP and LTD

When Bliss and Lomo first described LTP in the 1970s, it was not clear how this could happen. What are the molecular changes that make a postsynaptic cell respond differently to the same presynaptic firing input? In 1983, a first clue was found when it was discovered that NMDA receptor antagonists blocked LTP induction, but did not affect LTP once it was induced (Collingsridge et al., 1983). Recall that NMDA receptors are nonspecific cation channels that, unlike AMPA receptors, are permeable to calcium (see Chapter 3 Basic Neurochemistry). In addition, calcium chelators that prevent a rise in internal calcium in the CA1 pyramidal cells blocked LTP. Together, these studies suggested that LTP results from postsynaptic changes and requires calcium.

In addition to changes at the synapse, further evidence suggests that protein synthesis is required for at least some types of LTP. Frey et al., 1993 discovered that protein synthesis inhibitors caused LTP to decay to baseline levels 3-4 hours after LTP induction. This finding suggests that there is a form of LTP, called early LTP, that depends on changes in the synapse and is independent of protein synthesis and a form of LTP, called late LTP, that is dependent on protein synthesis. In other words, early LTP is the strengthening of an existing synapse whereas late LTP is the creation of new synapses. We will next discuss the mechanisms of each of these sequentially.

Early LTP and LTD

To understand the molecular mechanism of early LTP, one must first appreciate the unique nature of the NMDA receptor, which we established above is critical to LTP. Recall from Chapter 3 Basic Neurochemistry that NMDA receptors, like AMPA receptors, are ionotropic glutamate receptors that are present on the postsynaptic membrane of many excitatory synapses and allow entry of positive ions when activated (Figure 18.23). You might therefore be wondering why NMDA receptors are necessary for LTP if glutamate binding to AMPA receptors causes a depolarization in the postsynaptic neuron. The answer is the NMDA receptor/channels have 2 key features that distinguish them from AMPA receptors.

A reminder from chapter 3

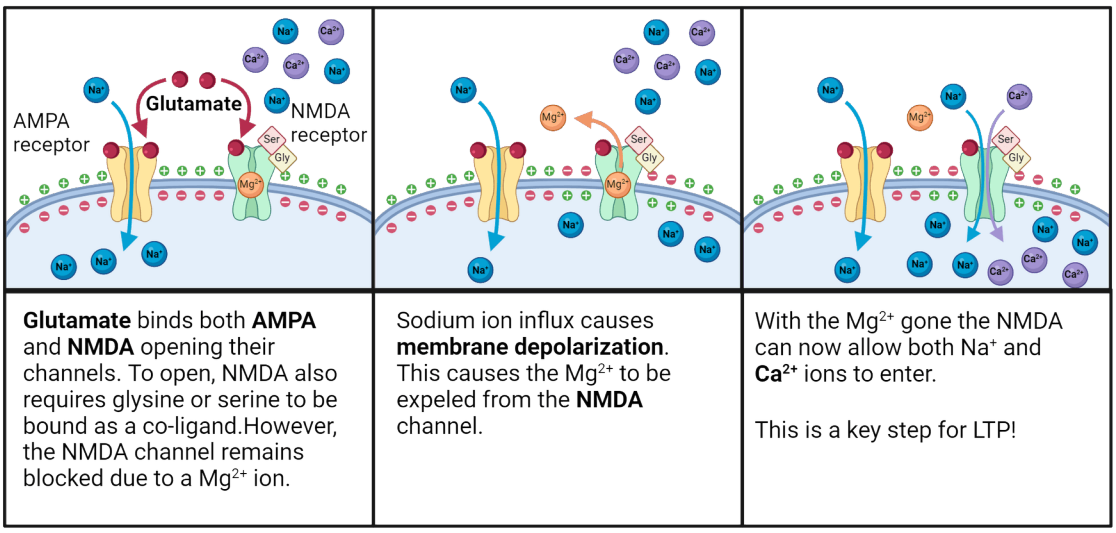

Figure 18.23 Reminder of AMPA/NMDA receptor functions

The first key feature is that NMDA receptors conduct not only sodium and potassium, but also calcium ions. Thus, activation of NMDA receptors leads to an increase in calcium concentration in the postsynaptic neuron. The early experiments mentioned above, showing that calcium was critical for LTP, therefore help further point us towards NMDA receptors as key in the LTP process. The increase in calcium concentration after NMDA channel opening leads to the activation of intracellular signaling pathways that are responsible for enhancing the response of the postsynaptic neuron to glutamate.

What are these changes that enhance response? It turns out that much of the enhancement comes from AMPA channels. We now know that when calcium enters through the NMDA channel, it binds to the enzyme calcium-calmodulin dependent protein kinase II (CAMKII), which either directly phosphorylates the existing AMPA receptors, causing them to be more permeable to sodium, or activates other enzymes which add new AMPA receptors to the postsynaptic membrane. Several lines of data support this model for early LTP induction. For example, LTP induction is prevented in CAMKII knockout mice, and direct addition of CAMKII to the postsynaptic membrane (thereby bypassing the need for AMPA and NMDA receptor activation) induces LTP.

From the above, it is clear that NMDA receptors are critical for the calcium entry that stimulates increased AMPA receptor conductivity (and therefore synaptic potentiation). But what makes this process sensitive only to high levels of input, like that from a tetanus in a classic LTP experiment? To understand this, we need to think about the second key feature of NMDA receptors that distinguishes them from AMPA receptors. While AMPA receptors open in response to glutamate alone, the NMDA channel is a molecular coincidence detector; there is a magnesium ion blocking the channel pore when the neuron is at its resting membrane potential, thus requiring not only glutamate for its activation, but also a membrane depolarization (Mayer et al., 1984; Nowak et al., 1984). Consequently, the postsynaptic membrane must be depolarized at the same time that glutamate is released from the presynaptic neuron. AMPA receptors work synergistically with NMDA receptors to activate this coincidence detector system. Specifically, glutamate activation of AMPA receptors provides the depolarization that is required for activation of the NMDA receptors. The AMPA channel activation has to be large enough to cause enough depolarization to kick out the magnesium block in the NMDA channels.

This process of AMPA-induced depolarization leading to NMDA channel unblocking is diagrammed in Figure 18.23. The steps for how that change contributes to LTP at the synaptic level are diagrammed in Figure 18.24. That threshold for NMDA unblocking is what makes the process sensitive to how strong the presynaptic firing is. More pre-synaptic firing in quick succession (like in a

tetanus stimulus) causes glutamate to build up in the synapse, opening many AMPA channels to create enough depolarization to "unclog" the NMDA channels and allow calcium to enter.

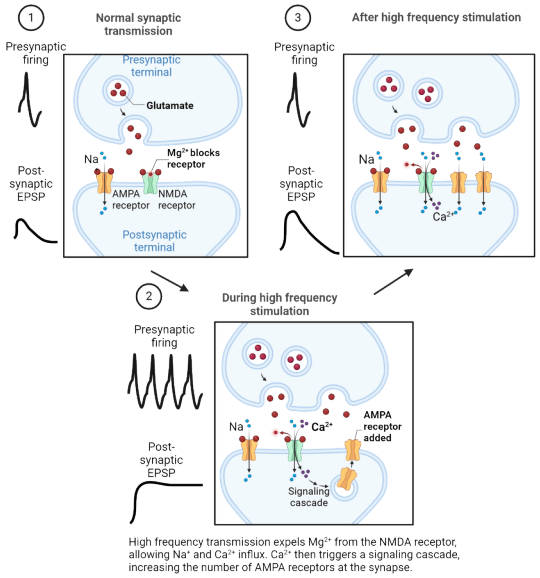

Figure 18.24 LTP

As you might guess, the mechanisms of LTD are opposite those of LTP (Figure 18.24). Postsynaptic AMPA receptors are downregulated, or removed from the synapse. AMPA receptors also show decreased conductance after LTD due to dephosphorylation by protein phosphatase. Although it might be tempting to think that LTD is a result of reduced postsynaptic calcium, both LTP and LTD have been shown to rely on increases in postsynaptic calcium. Whether LTP or LTD is induced depends on whether there is a large or small increase in calcium concentration, respectively.

Silent synapses reveal mechanisms of early LTP

One of the key discoveries that helped researchers figure out how LTP is induced actually came from finding synapses that don't work. In trying to better understand excitatory synapse LTP, researchers stumbled on synapses that are devoid of AMPA receptors, thus rendering them silent synapses—synapses that are unable to be potentiated. Can silent synapses be unsilenced? Two research groups conducted experiments to test this question. In both experiments, it was found that LTP induction caused an enhancement of the postsynaptic response to glutamate for AMPA, but not NMDA receptors, suggesting that unsilencing relied on a change in the postsynaptic response of AMPA receptors to glutamate (Kauer, Malenka & Nicholl, 1988; Liao, Hassler & Malinow, 1995). What properties of the postsynaptic neuron changed to allow this unsilencing? Two possibilities could have contributed to the increase in AMPA receptor conductance following LTP induction: either AMPA receptors were added to the postsynaptic membrane or existing AMPA receptors increased their conductance.

Late LTP

As mentioned above, LTP has two phases: an early phase which lasts 1-3 hours and a late phase that can last days or even weeks. Late LTP relies on the transcription factor, cAMP response element binding protein (CREB), which is responsible for synthesizing new proteins that are involved in the formation of new synapses. Experimental evidence supporting the idea that late LTP requires protein synthesis comes from studies showing that protein synthesis inhibitors (the same types of drugs that impair consolidation) disrupt late LTP (Frey et al., 1988). Furthermore, Engert and Bonhoffer (1999) used two-photon imaging to monitor hippocampal dendritic spines before and after LTP induction. They showed that after the LTP induction protocol, new dendritic spines emerged on the postsynaptic membrane. In summary, early LTP involves changes to existing synapses to increase their strength, whereas late LTP involves the growth of new synapses.

Do long-term changes in synaptic plasticity underlie learning and memory?

It is tempting to conclude that long-term changes in synaptic plasticity is the underlying cellular mechanism for memory. What is the experimental evidence that supports this idea? One of the first research groups to investigate the relationship between LTP and learning and memory was that of Dr. Edvard Moser. Dr. Moser's lab recorded synaptic potentials from the dentate gyrus in response to stimulation of the perforant path as rats explored a novel environment. The hypothesis was that as the rat learned the new environment, the synaptic potentials would increase in size, indicative of LTP. As predicted, the synaptic potentials increased in size, especially early in the session (Moser et al., 1993). Even stronger evidence came from research groups who demonstrated the manipulations that block NMDA receptors, for example with NMDA receptor antagonists, also disrupt learning and memory (Davis, Butcher, and Morris, 1992). Conversely, genetically altering rats to overexpress one of the subunits that comprise the NMDA receptor, NR2B, resulted in improved memory on a variety of memory tasks (Wang et al., 2009; Tang et al., 1999). Other studies support the idea that LTD is also critical for learning and memory. For example, Nicholls et al. (2008) found that by genetically altering mice so that they could not express LTD, they could disrupt behavioral flexibility in two different tasks. The authors suggested that weakening of synapses allows for behavioral flexibility by weakening old memories when new information is learned. Together, these studies strongly support the hypothesis that LTP and LTD are the neural substrates for learning and memory.

Memory has many different categories that are supported by distinct brain regions. These categorizations can be based on time (short vs. long-term memory) or content of the memory (explicit vs. implicit). Once memories are encoded, they need to be stabilized in a time-sensitive process known as consolidation, but even then, the memories are not solidified; memories are vulnerable to disruption every time they are recalled and require reconsolidation to become stable once again. Much of what we know about memory comes from the unfortunate but common cases when memory fails, including amnesia and neurological disorders such as Alzheimer's disease. Although memory abilities are more likely to decline with aging, it is now known that severe memory loss like that associated with dementia is not an inevitable consequence of aging.

18.2 Implicit Memories: Associative vs. Nonassociative Learning

Implicit memories are memories that are formed without our conscious awareness. Implicit memories can be categorized into associative memories, including classical and operant conditioning, and nonassociative memories, including habitation and sensitization. In classical conditioning, two previously unrelated stimuli (one neutral, one inherently meaningful) are associated with one another, such that the previously neutral stimulus evokes the same species-typical response that the inherently meaningful one does. In operant conditioning, a stimulus is associated with a response, making responses that follow reward more likely to happen in the future and responses that follow punishment less likely to happen in the future. This type of learning is supported primarily by the cortical-striatal system, aided by structures such as the medial prefrontal cortex, amygdala, and mesolimbic dopamine system.

18.3 Explicit Memories: Episodic and Semantic Memories

The hippocampus is an essential structure for encoding episodic memory and aiding in spatial navigation in rodents and humans. Firing patterns of neurons recorded from the hippocampus and related structures predict both of these functions, helping to explain how they are linked to one another. One striking feature of hippocampal neurons is their tendency to dramatically increase their firing rate when a rodent occupies a specific location in the environment. We call these neurons place cells. A class of neurons recorded from medial entorhinal cortex also show spatial encoding, but with one important difference: these cells, termed grid cells, increase their firing rate in multiple locations of the environment, with the firing fields arranged in a regular pattern. Other classes of neurons within this network are sensitive to environmental boundaries, head direction, and speed. Together, this brain network of place cells is thought to provide an accurate representation of location in space, allowing for accurate navigation to goals. These spatially-tuned cells are likely to participate in other mental representations such as episodic memories, thereby integrating spatial information with formation of new episodic memories.

18.4 Synaptic Mechanisms of Long-Term Memory

Up until the early 1970's there was only speculation that the neural mechanism of memory might be a change in the strength

of previously-active synapses. Empirical support for this notion came from Bliss and Lomo's groundbreaking discovery that high frequency stimulation of the presynaptic input to the dentate gyrus led to a long-lasting increase in the postsynaptic response, a phenomenon known as LTP. We now know that the mechanism of this increased postsynaptic response comes from changes in the sensitivity of the postsynaptic membrane to transmitter release. This increased sensitivity arises from AMPA receptors being added to the postsynaptic membrane through activation of the CAMKII pathway. Synapses can also be weakened through LTD via mechanisms similar to LTP.

4.2.7: Key Terms

18.1 Memory is Classified Based on Time Course and Type of Information Stored

long-term memory, short-term memory, working memory, consolidation, recall, reconsolidation, anterograde amnesia, procedural memory, declarative memory, episodic memory, basal ganglia, retrograde amnesia, infantile amnesia, Alzheimer's disease, seizure disorders, Korsakoff's syndrome, mild cognitive impairment, amyloid fibrils, neurofibrillary tangles, ApoE4, familial, sporadic, interictal epileptiform discharges, Dravet syndrome, Morris water maze, Barnes maze

18.2 Implicit Memories: Associative vs. Nonassociative Learning

Habituation, sensitization, Aplysia, classical conditioning, unconditioned stimulus, unconditioned response, conditioned stimulus, conditioned response, engram, amygdala, hippocampus, operant conditioning, positive/negative reinforcement, punishment

18.3 Explicit Memories: Episodic and Semantic Memories

Food caching, place cells, grid cells, head direction cells, speed cells, border cells, hippocampal theta rhythm, time cells

18.4 Synaptic Mechanisms of Long-Term Memory

long-term potentiation, long-term depression, trisynaptic loop, perforant pathway, mossy fiber pathway, Schaffer collateral pathway, field/population EPSP, homosynaptic plasticity, associative plasticity, depotentiation, NDMA receptor, AMPA receptor, CAMKII, coincidence detector, silent synapse

This page titled 4.2.7: Key Terms is shared under a CC BY-NC 4.0 license and was authored, remixed, and/or curated by Ivette Merced via source content that was edited to the style and standards of the LibreTexts platform.

4.2.9: Multiple Choice

18.1 Memory is Classified Based on Time Course and Type of Information Stored

1.
Which type of memory has a timescale of seconds?

a. Sensory memory
b. Working memory
c. Long-term memory
d. Short-term memory

2 .
Which type of memory has a timescale of hours to a lifetime?

a. Sensory memory
b. Working memory
c. Long-term memory
d. Short-term memory

3.
Which is the process by which information in working memory is converted into long-term memories?

a. Consolidation
b. Recall
c. Retrieval
d. Reconsolidation

4 .
Patient H.M. had the anterior two-thirds of his medial temporal lobe removed. As a result, he suffered from ____, or the inability to form new memories.

a. dementia
b. Alzheimer's disease
c. retrograde amnesia
d. anterograde amnesia

5.
Patient H.M. displayed intact skill-based knowledge or _____, even though he had no memory of having practiced the skills that had been learned.

a. episodic memory
b. declarative memory
c. procedural memory
d. explicit memory

6 .
Which structural abnormality is associated with Alzheimer's disease?

a. Neurofibrillary tangles
b. Amyloid beta plaques
c. Brain shrinking and enlargement of the ventricles
d. All of the above

7.

Which is thought to causes the memory problems associated with temporal lobe epilepsy?

a. The seizures themselves
b. The medications used to treat the seizure
c. Interictal epileptiform discharges
d. All of the above

18.2 Implicit Memories: Associative vs. Nonassociative Learning

8 .
Which are the two main types of non-associative learning?

a. Negative and positive reinforcement learning
b. Operant and classical conditioning
c. Habituation and sensitization
d. Cued fear learning and contextual fear learning

9.
You are performing an operant conditioning experiment with a rodent, and you would like it to increase the frequency of a behavior (lever pressing). To accomplish this, you could:

a. present a positive stimulus or remove a positive stimulus after a lever press.
b. present a positive stimulus or remove a negative stimulus after a lever press.
c. present a negative stimulus or remove a negative stimulus after a lever press.
d. present a negative stimulus or remove a negative stimulus after a lever press.

10 .
In cued fear conditioning, the animal:

a. learns to pull a lever when a tone is presented.
b. learns to ignore a harmless stimulus.
c. forms an association between a tone and a shock.
d. Forms an association between the environment and a shock.

11.
In sensitization, the response to a stimulus:

a. increases.
b. decreases.
c. decreases if paired with a neutral stimulus.
d. increases if paired with a neutral stimulus.

12 .
In the experiment with Pavlov's dog, the conditioned responses is:

a. the ringing bell.
b. the food.
c. the dog.
d. salivation.

13.
In the experiment with Pavlov's dog, the conditioned stimulus is

a. the ringing bell.
b. the food.
c. the dog.
d. salivation.

18.3 Explicit Memories: Episodic and Semantic Memories

14 .
When a rodent runs along an elevated track, some hippocampal neurons fire in response to the animal being in a particular location. These neurons are referred to as:

a. place cells.
b. border cells.
c. head direction cells.
d. speed cells.

15.
These types of neurons get their name from the fact that connecting the centers of their firing fields gives a regular pattern.

a. Place cells
b. Grid cells
c. Speed cells
d. Head direction cells

16 .
Which structure includes the hippocampus proper, dentate gyrus, subiculum, presubiculum, parasubiculum, and entorhinal cortex?

a. Internal capsule
b. Basal ganglia
c. Hippocampal formation
d. Neocortex

17.
Which is an example of an episodic memory?

a. Playing a rehearsed song perfectly at your piano recital
b. Being able to recall the capital of your home state
c. Eventually ignoring a repeated harmless stimulus (noise in the city)
d. Being able to recall the details of your family vacation last summer

18 .
Which is the best description of the hippocampus?

a. A three-layered structure in the temporal lobe that encodes episodic and spatial memories
b. A six-layered structure in the neocortex that stores all learned information
c. A nucleus in the basal ganglia that encodes procedural skills
d. A small gland in the hypothalamus that secretes memory-promoting hormones

18.4 Synaptic Mechanisms of Long-Term Memory

19.
According to Donald Hebb:

a. synapses are likely not involved in information storage.
b. neurons that fire together, wire together.
c. synaptic strength does NOT change throughout life.
d. new synaptic connections are NOT formed throughout life.

20 .
Different regions of the hippocampus are connected through a series of excitatory glutamatergic pathways known as the:

a. trisynaptic loop.
b. perforant path.
c. mossy fiber pathway.

d. Schaffer collateral pathway.

21.
Repeated high frequency stimulation leads to increased synaptic strength. This increased synaptic strength is caused by:

a. internalization of AMPA receptors.
b. degradation of NMDA receptors.
c. decreased numbers of NMDA receptors at the synapse.
d. increased numbers of AMPA receptors at the synapse.

22 .
Why is the NMDA receptor considered a molecular coincidence detector?

a. Its activation only requires postsynaptic depolarization.
b. Its activation only requires glutamate.
c. Its activation requires both glutamate and postsynaptic depolarization.
d. Its activation requires silencing of AMPA receptors.

23.
Unlike long-term potentiation, long-term depression involves:

a. decreasing the numbers of AMPA receptors at the synapse.
b. delivery of AMPA receptors to the postsynaptic membrane.
c. degradation of NMDA receptors.
d. increased numbers of NMDA receptors at the synapse.

24 .
You are performing an LTP experiment and delivering high frequency stimulation to Schaffer collaterals. Which treatment when applied to the hippocampal slice would NOT interfere with LTP induction at these CA3-CA1 synapses?

a. Application of NMDA receptor inhibitors
b. Removal of Mg2+ from the extracellular bath
c. Application of CaMKII inhibitors
d. Application of AMPA receptor inhibitors

4.2.10: Fill in the Blank

18.1 Memory is Classified Based on Time Course and Type of Information Stored

1.
_____ memories have the shortest duration, and are briefly held by systems that process visual, auditory, and somatosensory information.
2 .
One type of short-term memory is _____, which refers to information that is temporarily stored, used, and then discarded.

18.2 Implicit Memories: Associative vs. Nonassociative Learning

3.
_____ refers to a diminished response to a stimulus that has been presented multiple times.
4 .
_____ stimuli like a ringing bell are stimuli that signal and become associated with the unconditioned stimulus.
5.
Hippocampal _____ cells fire preferentially when an animal is in a particular location.

18.4 Synaptic Mechanisms of Long-Term Memory

6 .
Repeated high frequency stimulation can lead to _____ , a long-term increase in synaptic strength.

Xander settled into their seat for today's Introduction to Neuroscience lecture. They were particularly excited about today's lecture because the topic was attention. People often told Xander that they were attentive to other people's feelings, that they were attentive to their schoolwork, and that they were attentive to details. So, naturally, Xander wanted to understand how attention works. Professor Jones announced that the first activity of the day was going to be a test of everyone's attention. The task was simple: watch a video on the big screen of people passing around a basketball and, after the video was finished, write down how many times a person in a white shirt passed the ball. Xander kept their eyes glued to the screen and counted every pass. When the video was over, Xander confidently wrote down their answer: "15". Professor Jones announced the correct answer and Xander was right! BUT, Professor Jones asked a strange question: "Did you see the gorilla?" Xander assumed that this was a joke, or a trick question, because there clearly wasn't a gorilla in the video. However, when Professor Jones replayed the video in slow motion, sure enough, there it was—right in the middle of the picture. Xander worried that something was wrong with their eyes, or that they weren't as attentive as they thought. How could they have missed something so obvious?

The video in this anecdote comes from a famous psychology experiments showing the limits of visual attention (if you'd like to watch the full video yourself, visit Dan Simon's website) and it illustrates the fact that much of the information in our sensory world escapes our conscious awareness. To overcome this limitation, we rely on cognitive processes such as attention and executive functions to sift through the barrage of information in order to engage in goal-directed behavior. In this chapter, we'll explore the cognitive and neural systems that underlie attention and executive function, and we'll come to appreciate the wide range of psychological processes and brain mechanisms involved in each. By the end of the chapter, you'll understand how Xander's

experience was completely normal, and how it represents a natural consequence of the limits of our attention and executive function systems.

4.2.12: What are the Different Psychological Processes Associated with Attention?

Learning Objectives

By the end of this section, you should be able to

- 19.1.1 Distinguish the variety of cognitive processes that fall under the umbrella term of “attention”.
- 19.1.2 Differentiate the multiple ways in which attention can be deployed.

Just like other complex cognitive processes, such as emotion (Chapter 13 Emotion and Mood), attention involves a wide range of abilities and networks. It’s an umbrella term that covers a variety of distinct mental experiences and brain systems. In this first section, we’ll cover some of the different cognitive operations that fall under this umbrella term. We’ll focus almost exclusively on visual attention, but it’s worth pointing out that most of the concepts that you’ll encounter here also occur in other sensory domains such as hearing, touch, and smell—each with their own distinct processes and brain systems.

Arousal, consciousness, and vigilance

“Pay attention!” That’s an expression we’ve all heard at some point in our lives. But what does it mean? We can attend to concrete information like the objects in our external environment, or to fairly abstract concepts such as our own internal train of thought, or even to someone else’s feelings. We can also find ourselves in situations where our attention seems to be working very well (e.g., when you’re laser focused on finishing a paper due the next morning!), or where we're having a hard time concentrating (e.g., sitting in an 8am lecture after not getting much sleep the night before). In this section, we’ll explore how attention can refer to quite distinct cognitive processes (including arousal, consciousness, and vigilance) that are related to our subjective experience and awareness of the internal and external world and how those experiences change over time. In 19.1 What are the Different Psychological Processes Associated with Attention?, we'll walk through the neural systems that support these processes.

When we think about attention, we might reflect on the fact that our ability to concentrate, or pay attention, changes with our overall mental state of being awake or alert. This is a concept known as arousal, and it refers to global state of “readiness” or awareness of the information that we are processing at any given moment. There are a number of factors that determine your current state of arousal including such things as sleep (did you get a full 8 hours last night?), drugs (have you had any caffeine yet today?), external forces (is that a tiger over there?), and even internal motivation (what’s your passion?).

Consciousness is a complex process that's hard to define, and maybe even harder to study neuroscientifically, but there's no getting around the fact that consciousness and attention are tightly linked. It’s difficult to come up with a single definition of consciousness (Damasio, 1999), but a good starting point is to think of it as the subjective experience and awareness of our internal and external world (Hobson, 1999). Even if it’s hard to pin down a good definition, we probably can agree on the fact that that there are certain times during the day when we are conscious of the world around us (e.g., when we're awake) and other times when we’re not (e.g., when we’re asleep or under general anesthesia). These examples point out that consciousness, like arousal, varies over time. In addition to these normal variations, there are neurological conditions in which consciousness is altered in a more profound way. Individuals who experience disorders of consciousness (Schnakers, 2020), such as persistent vegetative state or minimally conscious state, appear to lack conscious awareness of the external world, despite having relatively preserved sleep-wake cycles.

Yet another concept that often comes to mind when people hear the phrase “pay attention!” is the ability to be focused on one thing over an extended period of time, despite distractions or boredom. Sustaining attentional focus on specific information over time is referred to as vigilance (van Schie et al., 2021), and, like consciousness and arousal, it varies over time (think of a time when you were caught up in a task only to look up at a clock and realize that you forgot to eat lunch!) and even across individuals (think of a Secret Service agent who can stay hyper-focused on assessing potential threats in a crowd).

The final concept that we’ll consider in this section is selective attention. As we engage with the world in our day-to-day lives, our sensory systems are constantly bombarded by information. The sheer volume of information that we experience in each moment—even in a single sensory system such as vision—is staggering. Our brains can’t process it all equally well, and so we

constantly pick and choose the subsets of information on which we want to focus. This process is known as selective attention, and it has two complementary features. The first is that the information that we select receives enhanced visual processing in a number of ways (e.g., it's processed faster and in greater detail). The second feature, which represents the tradeoff of this enhanced processing, is that the information that we *don't* select suffers the opposite fate—it's processed more slowly and in less detail.

Although arousal, vigilance, and selective attention are different processes, they clearly interact with one another in many ways to bring information into conscious awareness. For instance, selective attention functions best when a person's arousal is "just right". That is, too little arousal or too much arousal will negatively impact our ability to select information for processing. Nevertheless, selective attention is one of the more common uses of the term "attention" in psychological research, and it's what we will focus on for much of the remainder of this chapter. It, like many of the other related processes that we've discussed, can also be broken down into different components.

Covert vs. overt orienting

An important distinction concerning our ability to select information for enhanced processing refers to the connection between where we are looking ("with our eyes") and where we are attending ("with our brains"). Normally, as we shift visual attention, we execute those shifts by simply moving our heads and our eyes to look directly at the things we want to pay attention to. This process is known as overt attention and it allows us to process the information that we want to attend using foveal vision, which is the central portion of your visual system, where you have the highest visual acuity (see Chapter 6 Vision). But this is not the only way in which we can shift attention. In fact, we also routinely shift the focus of our attention to new information without moving our eyes at all. This process is known as covert attention, and it happens more often than you might think. For example, imagine that you're sitting next to someone who's watching a funny video on their phone. You might be interested in watching the video too, but it would be rude to look directly at their phone. So instead of looking directly at their device, you pay attention out of the corner of your eye—a classic example of covert attention.

Researchers have developed a number of important paradigms for studying both overt and covert attentional selection in laboratory settings. For instance, Figure 19.2 illustrates a common experimental paradigm in which participants focus their eyes on a fixation cross in the middle of the screen and attend to a peripheral location on the screen using covert attention.

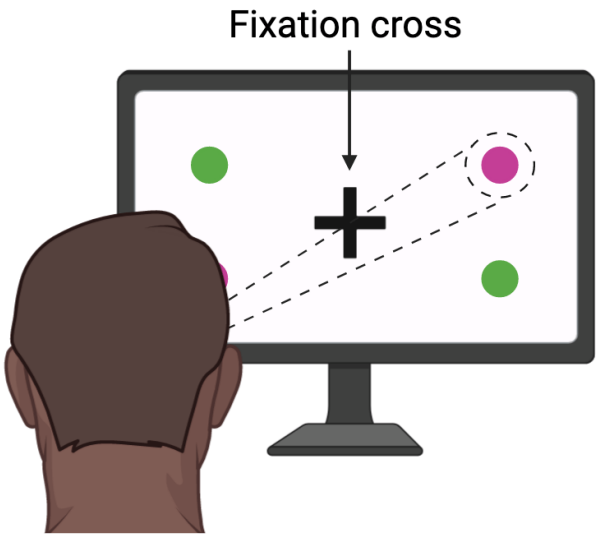

Figure 19.2 Covert attention The participant keeps their eyes focused on the central fixation cross but attends to a location, such as the purple circle, using peripheral vision.

In this case, the focus of attention is illustrated with the dotted lines and circle, even though no such dotted lines or circle appear on the screen. Using a paradigm such as this, researchers can ask participants to shift their attention from one corner of the screen to another without moving their eyes and then document how well they are able to process a piece of information (e.g., the purple circle), depending on the focus of their attention. Critically, if there are any differences in performance, they can't be due to differences in the visual input, because the exact same visual information would be processed in all cases (i.e., the information hitting the retina would be identical when you're paying attention to the upper left or upper right, assuming that you don't move

your eyes). The only difference would be the participant's mental state, namely, whether they are covertly attending to the purple circle or not.

Endogenous vs. exogenous orienting

Do we consciously decide what to pay attention to from one moment to the next? Or does the focus of our attention pinball back and forth between the dizzying array of information that hits our eyeballs at any given moment? The answer to these questions, like many choices in psychology and neuroscience, is "both". As you engage with the world, there are many situations in which you control the focus of your awareness. Perhaps you are doing this right now as you shift your eyes back and forth between this text and the pages of your notebook where you're writing down information. This deliberate process of shifting of attention from one piece of information to another is referred to as endogenous attention (sometimes referred to as top-down attentional control), and it requires conscious awareness and deliberation. But equally often in our day-to-day lives, attention is captured by a novel stimulus in the world in an automatic fashion, seemingly outside of our control. Imagine that someone unexpectedly runs by you down the hall. You look up from your reading before you even realize it, clearly shifting your attention away from what you were doing without really intending to do so. This anecdote illustrates the phenomenon of exogenous attention (sometimes referred to as bottom-up attentional control), and it also represents an important way in which our attention selects different sources of information over time.

There are a number of ways to study endogenous and exogenous shifts of attention in a laboratory environment. Posner (1980; Posner & Cohen, 1984) developed perhaps the best-known paradigm using a simple task in which participants have to detect targets that can appear at one of two locations on a screen (Figure 19.3). Participants fixate their eyes on a dot in the middle of the screen and then receive a cue telling them to focus attention (covertly!) to one side of the screen or the other. After a delay, a target appears either on the side indicated by the cue (a valid trial) or on the opposite side (an invalid trial).

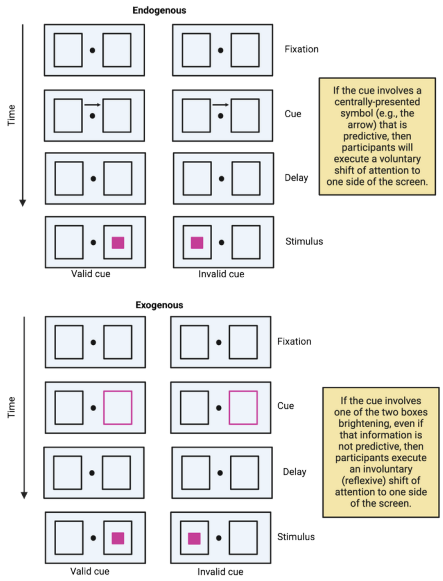

Figure 19.3 Posner cueing paradigm

One of the interesting features of this task is that the experimenter can alter the nature of the cue to involve either (a) a centrally presented stimulus that indicates the side to attend (e.g., the arrow pointing either way) or (b) a peripheral flashing light around one of the two sides of the screen. The experimenter can also vary how helpful the cue is. For instance, the cue might correctly predict the location of the upcoming target on 75% of the trials. If that's the case, it's an informative cue and it's worth using it to figure out where the target will appear. In other situations, the cue might be totally random and only predict the target location half of the time. If that's the case, then the cue isn't informative, and it wouldn't really be worth using it to figure out where the target will appear. As it turns out, by varying these two features (the type of cue and its predictability), you can elicit and then study either voluntary or involuntary shifts of attention.

If the cue involves a centrally presented letter and it's informative (i.e., it correctly predicts the location of the target more often than not), then participants will execute an endogenous (voluntary) shift of attention in order to focus awareness on the cued side. If, however, the cue involves a brightening of one of the two boxes—even when it's not informative (i.e., it's random)—then the flashing boxes will capture attention automatically using an exogenous (involuntary) shift of attention. In this second case,

participants know that the flashing boxes aren't helpful, but they just can't help themselves from shifting their focus to the side of the screen that flashes.

Visual search

Another way in which attention moves from one piece of information to another involves visual search—our ability to scan the world to search for specific objects or pieces of information. Finding an object in a crowded environment requires us to shift the focus of our awareness to many locations until we find the one that we are looking for. In some cases, the object reveals itself to us effortlessly; but in other cases, it requires significant focus and concentration. Imagine, for example, that you're trying to locate your suitcase on a crowded conveyer belt at the airport. Let's suppose that your suitcase is an uncommon color (e.g., lime green). If that's the case, then it might jump out at you immediately, regardless of how many other suitcases there are on the belt (since yours is the only one that's lime green!). This is a phenomenon known as pop out and can happen quite easily when you're searching for a single distinct feature (i.e., a singleton feature) such as a unique color or a unique shape. If, however, the only way to find your suitcase is to look for the suitcase that's blue (a common color) and that has four wheels (which also might be common). In this new scenario, you would have to expend a lot of mental energy focusing on finding a combination of the right suitcase color and the right wheel pattern. This scenario involves what we call conjunction search (i.e., searching for a combination of two individual features) and it is much more effortful (Treisman, 1988; Treisman & Gelade, 1980).

Figure 19.4 illustrates an example of a computer-based visual search paradigm. When participants search for singleton features, as in the top row, they find the target quickly (because of pop out) and the time that it takes does not depend on the number of distracting objects. When participants have to search for a combination of two features, then it takes them longer to respond (because of conjunction search), and, critically, their response times increase with each additional distractor item.

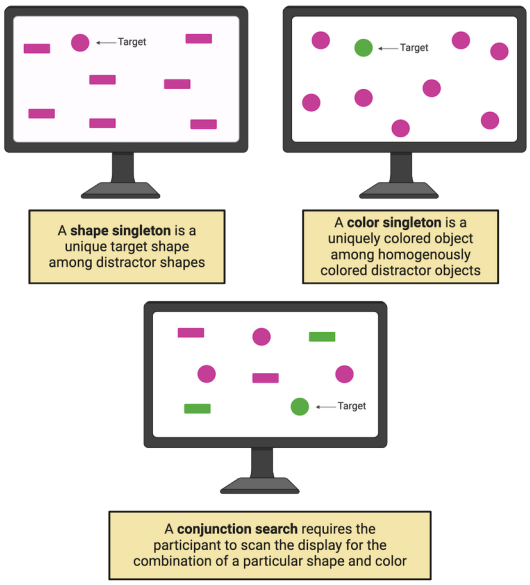

Figure 19.4 Visual search

4.2.13: How is Attention Implemented in the Brain?

Learning Objectives

By the end of this section, you should be able to

- 19.2.1 Map out the cortical and subcortical brain regions that subserve attentional operations.
- 19.2.2 Describe the differences between top-down attentional control networks and bottom-up effects of attention on visual processing regions.

The diversity of cognitive processes that we discussed in the last section is mirrored by the complex neuroanatomy that underlies those processes. Arousal, vigilance, and selective attention rely on a wide-ranging and interconnected set of regions that span many levels of the brain—structures buried deep in the brainstem all the way up through the highest levels of cortex. It is important to note that there are rich interconnections between the many brain structures described below, both anatomically and functionally. Nevertheless, we will consider each as a discrete unit in order to better isolate that structure's or system's specific role in attention. To be sure, these systems do not act completely in isolation. For simplicity, however, we'll break down some of them and review the specific roles they play in arousal and attention. Finally, we'll focus on the brain systems involved in attention here, but later, in 19.6 How Do We Use Executive Functions to Make Decisions and Achieve Goals?, we'll review the neuroanatomical structures most closely associated with executive function, such as the prefrontal cortex (PFC).

Brainstem and subcortical structures

Deep in the posterior regions of the brainstem is a cluster of nuclei known as the reticular formation (Figure 19.5) that sends signals up to the thalamus and then onto other cortical regions through a circuit called the ascending reticular activation system (ARAS).

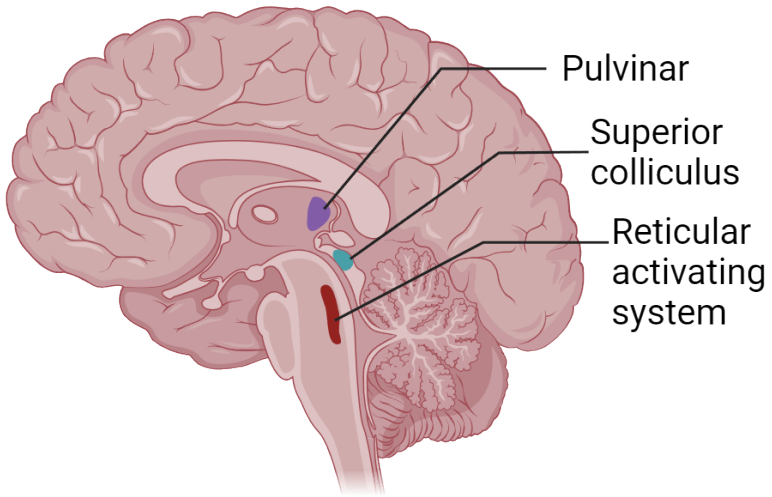

Figure 19.5 Brainstem and subcortical regions associated with arousal and selective attention

The ARAS is responsive to input from multiple sensory modalities, is involved in sleep/wake cycles, and is thought to be one of the main brain systems responsible for our overall state of arousal (see Chapter 15 Biological Rhythms and Sleep). In fact, early research demonstrated that animals with lesions through the brainstem fell into a comatose state, whereas electrical stimulation of this region can wake a sleeping animal (Bremer, 1935; Moruzzi & Magoun, 1949). Studies involving humans provide similar evidence, namely, that damage to the hindbrain, including the ascending reticular activation system, can produce a comatose state (Parvizi & Damasio, 2003). These results illustrate the crucial role of the ARAS in maintaining *arousal*, but it is also important to note that other research suggests that it plays a role in *orienting* responses as well, for instance, in our ability to disengage

and refocus attention to new sources of information (Aston-Jones & Cohen, 2005).

Moving up the brain, we find another region that's critical for attention within the midbrain, more specifically, the superior colliculus (SC). The superior colliculus is involved in visual processing and orienting behavior—especially in our ability to make eye movements towards a novel visual stimulus (Sparks, 1999). Early research argued that, because of the heavy involvement of the superior colliculus in eye movements, it was only involved in overt, but not covert attention (Wurtz et al., 1982). However, a number of more recent studies demonstrate that the superior colliculus plays an important role in covert attentional processes as well. For instance, temporarily shutting down the monkey superior colliculus (a process known as reversible deactivation) results in impairments on a motion discrimination task that requires covert attention (Desimone et al., 1990; Lovejoy & Krauzlis, 2010), whereas microstimulation of this same area improves an animal's motion discrimination ability under covert attentional conditions (Müller et al., 2005). Finally, patients with brain damage that selectively impairs the superior colliculus (as well as the basal ganglia), a condition known as progressive supranuclear palsy (PSP), demonstrate a range of motor and cognitive impairments, including an inability to shift attention from one location to another (Rafal et al., 1988).

Continuing our climb, one final subcortical structure worth mentioning is the pulvinar, located in the posterior thalamus. The pulvinar does not receive direct projections from the retina, but it nevertheless has neurons that are visually responsive (through indirect connections to the visual system). Moreover, the pulvinar has been implicated in variety of attentional functions, including filtering out distracting information and both overt and covert attentional shifts. For instance, studies involving monkeys (Desimone et al., 1990) and humans (Rafal & Posner, 1987) demonstrate that damage to the pulvinar impairs the ability to attend to a target in the presence of distracting information. Similarly, Petersen and colleagues (1992) demonstrated that temporarily inhibiting neural activity in the monkey pulvinar resulted in selective impairments in covert attentional orienting (using a variation of the Posner cueing paradigm), whereas temporarily facilitating pulvinar activity had the opposite effect, namely, improved covert attentional orienting.

There's one more attentional brain network that's worth mentioning at this point, and it's the network of brain regions involved when you are *not* focusing your attention on the external world. This network, first labelled the default mode network (DMN) by Marcus Raichle and colleagues (2001), consists of several anatomical structures including, most notably, the medial prefrontal cortex, the precuneus, cingulate cortex, and angular gyrus. Activity in this region is *reduced* when one focuses their attention on something in the external world, and in contrast, is *enhanced* when one engages in any number of internally-directed cognitive processes such as mind-wandering and reflection. The focus of the rest of this chapter is on the brain systems involved in attention to the external, rather than the internal world, but there is considerable evidence to suggest that the DMN is important for a range of cognitive processes related to internally-directed attentional functions.

Dorsal and ventral attentional networks

As we continue to ascend into the cerebral cortex, there are two networks critical for shifting our attention from one location to another (Figure 19.6). The dorsal attentional network (DAN) is responsible for voluntary or endogenous shifts of attention—especially in the context of goal-directed behavior, whereas the ventral attentional network (VAN) is responsible for bottom-up or exogenous shifts of attention—especially when reorienting to particularly novel or salient stimuli in our sensory environment (Corbetta & Shulman, 2002). To be sure, the two networks interact to determine our attentional focus, and our top-down goals impact the degree to which bottom-up information can capture attention (e.g., Kincade et al., 2005), but we will consider them separately in the discussion below.

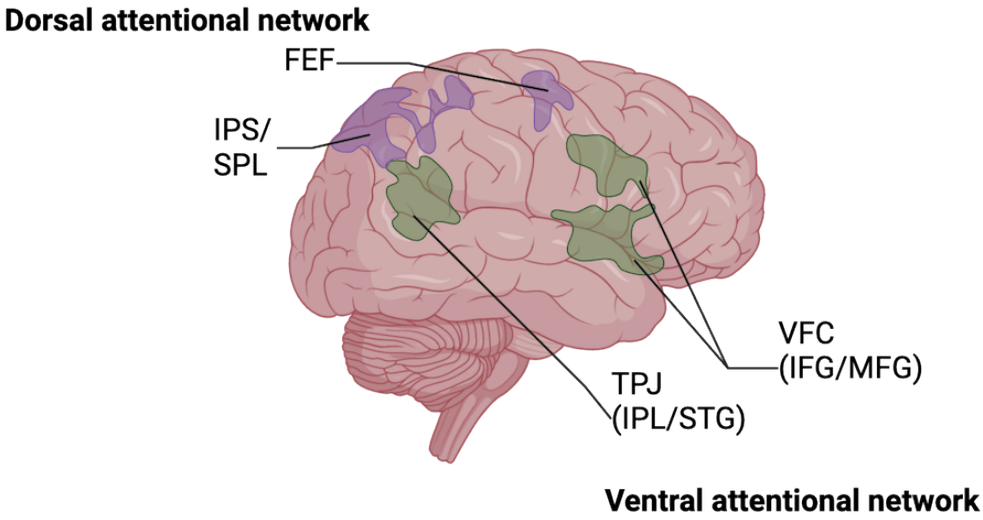

Figure 19.6 Dorsal and ventral attention networks

The dorsal attentional network is comprised of several regions, including the superior parietal lobule (SPL), the intraparietal sulcus (IPS), and the frontal eye fields (FEF). In the early 2000s, two separate research groups (Corbetta et al., 2000; Hopfinger et al., 2000) used a modified version of the Posner cueing paradigm (recall Figure 19.3) to monitor brain activity during attentional selection using fMRI (see Methods: MRI/fMRI). The nature of the task allowed them to isolate brain activity specifically associated with the attentional cue, separate from brain activity associated with processing the subsequent targets (a technique known as event-related fMRI, since it allows researchers to link brain activity to individual events over the course of a trial). Each group found that the SPL, IPS, and FEF were all strongly activated, bilaterally, during the cue period (but before the targets appeared on the screen), when participants were presumably directing covert attention voluntarily to the relevant location. These imaging results have been supported by other methodologies, such as non-invasive brain stimulation, which shows that temporarily disrupting IPS activity impairs the ability to control attentional shifts in a voluntary manner (Koch et al., 2005).

The ventral attentional network, as its name implies, involves a group of brain areas located more inferiorly within the cerebral cortex, including the temporoparietal junction (TPJ) and portions of the inferior and middle frontal gyri (collectively referred to as the ventral frontal cortex; VFC). Whereas the DAN implements voluntary shifts of attention, the VAN is thought to be essential for our ability to disengage attention from its current location and move it to a new location, for example, when an unexpected event occurs. Corbetta and colleagues (2000) examined this process using the same Posner cueing paradigm described above. Recall that in this paradigm, sometimes the cue can be invalid, meaning that the target appears on the opposite side of the screen as the cued location. On such trials, participants disengage attention automatically from the cued location and reorient to the uncued location in order to process the visual target. Therefore, isolating brain activity associated with the appearance of invalidly-cued targets will reveal brain areas associated with involuntary or reflexive shifts of attention. Across multiple studies (for a review, see Corbetta et al., 2008), Corbetta and colleagues have shown that the TPJ and VFC are engaged by such exogenous shifts of attention, and that this ventral attention network is strongly lateralized to the right hemisphere.

The dorsal and ventral attentional networks work in tandem to ensure, on the one hand, that we can voluntarily shift attention to information that is relevant for goal-directed behavior (in a top-down manner), but at the same time, that we can maintain the ability to dislodge attention from those locations when necessary, in light of important changes in our sensory world (in a bottom-up manner).

Neuroscience across species: Non-human primates: Attentional effects on sensory processing

In the previous section, we reviewed the brain systems involved in our ability to shift attention from one location to another (attentional control). But what are the consequences of those attentional shifts on brain regions involved in sensory processing? Recall from the beginning of this chapter that when we attend to something, that information benefits from enhanced processing. In this section, we'll discuss the neural signatures of that enhanced processing in brain areas ranging from subcortical structures, all the way through late visual processing areas.

Many of the studies that demonstrate the effects of selective attention on sensory processing regions once again involve the Posner cueing paradigm, which should seem quite familiar by now. In a typical study, the participant is cued to attend covertly to one location on the screen. Researchers can then record brain activity through a variety of techniques such as event-related potentials (ERP; Methods: EEG/ERP) and functional magnetic resonance imaging (fMRI; see Methods: MRI/fMRI) to investigate the changes in brain activity when the participant is attending to a specific piece of information compared to when that same information is unattended. Recall that by using covert attention, researchers can present the same stimulus display, but vary the location of attention. Thus, any observed differences in brain activity would be due to the attentional state, not to the information hitting the retina (which would be identical in both cases).

A number of studies (e.g., Mangun & Hillyard, 1991) demonstrate that visual attention amplifies visually-evoked ERPs (Figure 19.7). Event-related potentials are an averaged electrophysiological response, resulting from brain activity, that contain a number of positive and negative deflections (peaks and valleys), as shown in the figure. These deflections, or components, are typically named with a letter to indicate whether it's a positive (P) or negative (N) direction, and a number to indicate its relative position (1st, 2nd, etc.). Researchers can compare the relative magnitude of these peaks and valleys in different conditions of an experimental paradigm to make inferences about differences in underlying brain activity. In this case, the P1 and N1, which are thought to be generated by neural activity in extrastriate cortical regions (i.e., regions just beyond primary visual cortex; Clark & Hillyard, 1996), and which occur as early as ~80 milliseconds after a target appears on the screen, are affected by attention, suggesting that attended information receives preferential treatment relatively early in the course of visual processing.

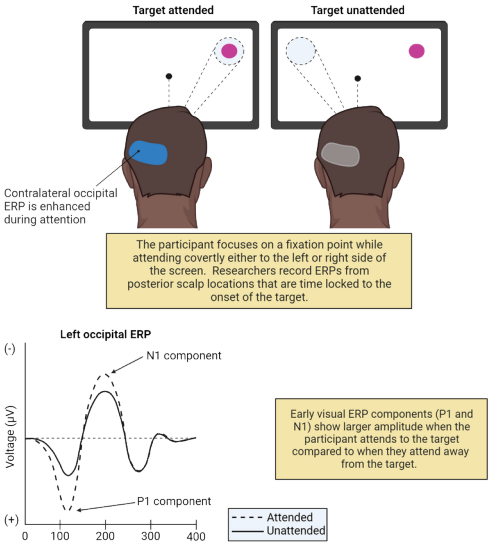

Figure 19.7 Attention effects on visually-evoked ERPs

Initial ERP studies of attentional selection typically did not find evidence of attentional modulations in primary visual cortex (also called V1), or in earlier parts of the neural pathways from your eyes to your brain (see Chapter 6 Vision). However, later work confirmed that brain regions even earlier within the visual pathways show attentional modulation, including primary visual cortex (Martinez et al., 1999) and in subcortical structures such as the lateral geniculate nucleus, which is the major relay station for visual information between the eyes and V1 (O'Connor et al., 2002). These results all point to the ability of attentional selection to enhance the neural representation of attended stimuli (i.e., strengthen the brain's response to those items) even at the earliest stages of visual processing (a concept that we'll return to later).

The effects of attentional selection are not limited to early sensory processing regions. In fact, these modulations are evident throughout the visual system even in intermediate-stage areas such as V4 (a later visual processing region along the ventral visual stream). For instance, Moran & Desimone (1985) recorded activity from individual neurons in V4 (Figure 19.8) while a monkey covertly attended to a stimulus that was either particularly effective in driving activity in the cell, or to another stimulus that was not effective. Both stimuli were presented at the same time, and both appeared in the relevant neuron's receptive field, which is the region of space in which a stimulus must occur for that neuron to respond. Thus, the retinal input was identical in both cases (remember the nature of covert attentional manipulations). Remarkably, however, the neurons responded more vigorously when the animal attended to the effective visual stimulus compared to the ineffective stimulus.

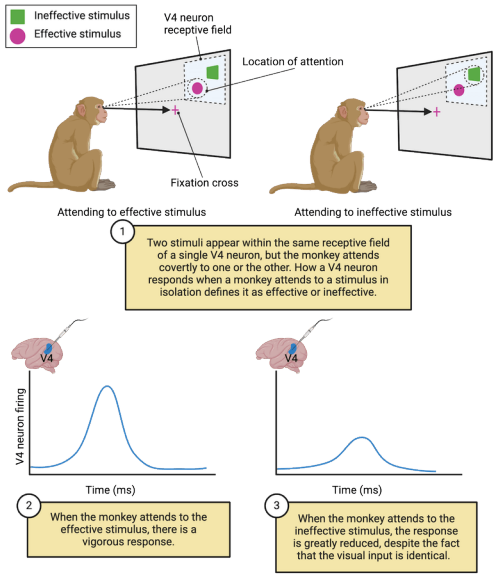

Figure 19.8 V4 firing with visual attention

Attentional modulations are evident in even later-stage visual processing areas such as the fusiform face area (FFA) and the parahippocampal place area (PPA); two brain regions in the ventral temporal cortex that are thought to be specialized for processing relatively specific categories of visual input—faces and places, respectively. O'Craven and colleagues (1999) recorded fMRI activity while participants viewed overlapping faces and houses on a computer screen (Figure 19.9). On some trials, participants attended to the faces, while in others, they attended to the houses. They found that activity was greater in the FFA when participants attended to a face and greater in the PPA when they attended to a house—providing further evidence that attentional selection enhances neural representations at multiple levels within the visual cortex. As mentioned earlier, this chapter focuses primarily on visual attention, but similar higher-level attentional modulations occur in other sensory modalities such as hearing (cf., Shinn-Cunningham, 2008).

4.2.14: What Happens to Unattended Information?

Learning Objectives

By the end of this section, you should be able to

- 19.3.1 Identify factors that impact the degree to which unattended information is processed.
- 19.3.2 Articulate the perceptual load theory and explain its relationship to debates concerning attentional selection.

So far in this chapter, we've talked mostly about the brain systems involved in selecting and processing the things that *are* the focus of your attention, without much consideration for what happens to the things that are *not* the focus of your attention at any given moment. We discussed at the beginning of the chapter that attended information benefits from enhanced sensory processing and gains access to our conscious awareness, but what is the fate of everything else? In this section, we'll unpack some of the limits to processing unattended information and discover how those limitations reveal critical bottlenecks in the brain's ability to deal with competing sources of information.

Inattentional blindness

In the beginning of this chapter, we met Xander, who was concerned that there was something wrong with their eyes because they failed to notice a gorilla in the middle of a video showing people passing a basketball (Figure 19.1). That anecdote stems from a famous experiment performed by Simon & Chabris (1999), in which participants did the exact task described earlier, namely, count the number of basketball passes performed by a group of players moving around a scene (if you'd like to watch the full video yourself, visit Dan Simon's website). In their study, roughly 50% of participants failed to notice a person in a gorilla suit walking through the scene (even when it stops in the middle of the room and beats on its chest!). They accurately counted the number basketball passes, so their failure didn't stem from a lack of attention in general. Rather, attention was so focused on the primary task (counting passes) that they were completely unaware of other (even strikingly novel!) information that passed before their eyes. As mentioned earlier, our top-down goals can affect the degree to which bottom-up information can capture attention. This demonstrates the phenomenon of inattentional blindness (originally coined by Mack & Rock, 1998) and it points out that much of the information that is present in our sensory world escapes our conscious awareness. Inattentional blindness is not limited to laboratory settings. In fact, several studies have shown that people will fail to notice a clown riding next to them on a unicycle (Hyman et al., 2010) or money dangling from a tree (Hyman et al., 2014)—even when they have to move to one side or the other in order to avoid walking into the branches with the money!

Inattentional blindness shows that we often fail to notice salient information in plain sight, provided that our attention is engaged on a different source. In a similar manner, we often fail to notice significant changes to visual information that we are processing—a phenomenon known as change blindness (for a review of the differences between inattentional blindness and change blindness, see Jensen et al., 2011). For instance, in one striking experiment, a researcher stopped pedestrians on a sidewalk to engage them in a conversion, but partway through, a large obstacle passed between the researcher and the pedestrian. Unknown to the pedestrian, the researcher who started the conversation (Researcher A) switched places with a different researcher (Researcher B) during the obstruction. Roughly half of the participants failed to notice that they were talking to a totally different person (Simon & Levin, 1998)!

In both inattentional blindness and change blindness, we are sometimes completely unaware of obvious salient and novel information. But what does our brain do with this information? Do these failures imply that we engage in little to no processing of ignored input? Or, rather, does our brain fully encode the basic sensory information but that information somehow does not gain access to conscious awareness? In the next section, we will consider an important historical debate concerning when, and how, unattended information is filtered out by the brain.

Early/late selection

Early attention researchers clearly understood that not all information is processed equally but wrestled with the best way to characterize the nature of selective attention. In the 1950s, Broadbent (1958) developed a model (Figure 19.10) that envisioned information processing as proceeding along a series of stages that go from rudimentary (e.g., edge and color detection) to

complex (e.g., whole object descriptions, memory matching, etc.). After information passes through these various stages, it can then gain access to higher-level executive functions (e.g., decision making) and conscious awareness. In the model, you see channels (represented by arrows) that reflect different sources of information (these could be different locations in space, different objects, etc.).

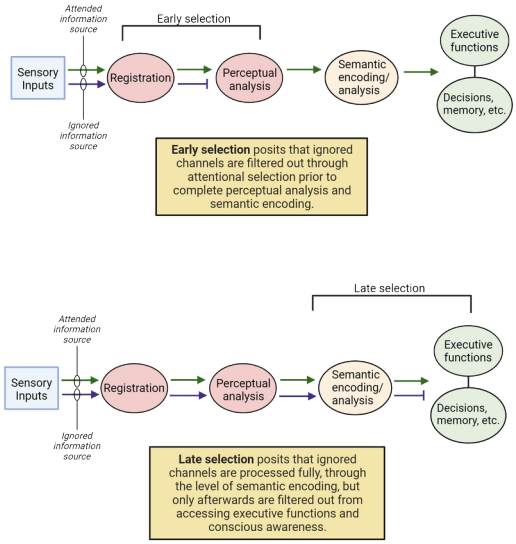

Figure 19.10 Broadbent's model of selective attention

Broadbent (1958) argued that attention works like a filtration system and that unattended sources of information are filtered out relatively early in the game, prior to complete processing, a concept known as early selection. Many sources of evidence are consistent with this view. For instance, Cherry (1953) presented participants with speech over headphones and asked them to repeat back what they heard in one ear specifically (different speech was presented to each ear). This is a difficult task known as dichotomous listening, but people can do it quite well with a little training. The interesting thing about these dichotomous listening paradigms wasn't what people were able to report about the speech that they were attending. Rather, after the experiment was over, the researchers asked questions about the speech that was unattended and found that participants might be able to remember lower-level (i.e., basic or sensory) features of the speech such as the pitch or gender of the speaker, but often failed to notice higher-level (i.e., conceptual or semantic) features of the speech such as the language (German vs. English) or whether it was forward vs. backwards speech. Apparently, relatively basic information processing occurred for the unattended information, but higher-level information processing related to the meaning (i.e., semantics) of the speech did not, consistent with early selection.

Not all studies are consistent, however, with the notion of early selection. In fact, other research (e.g., Deutsch & Deutsch, 1963) suggests that all sources of information proceed through relatively late stages of semantic processing, and that only then does attention filter out unattended sources from engaging with executive functions or conscious awareness—a concept known as late selection. Early evidence of late selection also comes from dichotomous listening tasks. For instance, Moray (1959) showed that when a participant's name is presented to the unattended ear, they will reliably notice it and switch the focus of their attention to that ear. You've probably experienced this phenomenon yourself. If you're in a crowded room with many people talking and you're focused on having a conversation with one person, then you probably won't know much about the other conversations going on around you. But, the second someone says your name, it will capture your attention—even if you unaware of everything else that person was saying up until that point. This phenomenon is sometimes referred to as the Cocktail Party Effect and it suggests that, at least in some cases, unattended information is processed to a relatively high level before it is filtered out through attention (you must have processed the meaning, or semantics, of the other conversation to know that they said your name). Interestingly, not all names are the same—other studies (Howarth & Ellis, 1961) showed that a person's own name captured attention more easily than another person's name, further supporting the idea that higher-level semantic features of unattended information (e.g., personal relevance) were being processed.

So, does the attentional filter operate early or late? A classic "either-or" question that has been debated for many years in psychological circles. As with most such questions, and as we'll see in the next section, the answer is probably "both".

Science as a process: Perceptual load and neural correlates

Does selective attention filter out information early (prior to higher-level semantic processing), or late (after such processing has occurred)? Various attempts to accommodate both answers within Broadbent's (1958) information processing framework have been proposed over the years (e.g., Treisman, 1960). However one of the most successful attempts to integrate these two viewpoints comes from the perceptual load theory (Lavie & Tsal, 1994; Lavie, 1995). According to this theory, attention is a limited capacity resource (i.e., there's not enough to go around) that must be allocated strategically to different sources of information. This allocation happens dynamically, depending on a variety of factors, including how much of a strain any given task puts on information processing systems (i.e., perceptual load). When we perform a relatively difficult task (high load), we expend considerable attentional resources to complete it, but when we perform a relatively easy task (low load), we need not engage as much of the attentional currency. The theory also posits that any leftover attentional resources that aren't engaged by the attended task will automatically be deployed to task-irrelevant information.

The perceptual load theory makes several interesting predictions about how much information processing occurs for unattended sources. For instance, the theory argues that if you are engaged in a relatively easy task, then significant attentional resources will be "left over" to be applied to unattended information, which will therefore be processed quite fully and appear to reflect late selection. If, however, you are engaged in a relatively difficult task, then the limited attentional resources that are left over and allocated to unattended information will result in quite impoverished processing and appear to reflect early selection. A real-world example might be the degree to which you notice billboards along the side of the road. If you are driving in very difficult conditions (bad weather, difficult terrain, etc.), you will be so focused on the central task of driving that you will not have any leftover attentional resources to process the billboards. If, however, you are driving in relatively easy conditions, then driving will not consume all of your attentional resources, and the leftover resources will be deployed to unattended information on the side of the road such as the billboards.

There is a large body of evidence to support the perceptual load theory. For instance, Miller (1991) showed that when participants attended to a central letter on a computer screen and ignored surrounding letters, the distracting letters influenced response times more so when the task was easy (low load) compared to when it was hard (high load). Functional MRI research also shows that perceptual load influences the degree to which visual information processing occurs for unattended sources of information. For instance, Schwartz and colleagues (2005) conducted an fMRI experiment in which participants attended to a stream of upright and inverted “t”s in the middle of a computer screen and ignored a flashing checkerboard pattern in the periphery (Figure 19.11). In some cases, participants performed a relatively easy (low load) task—responding to red “t”s, whether they were upright or inverted (recall that searching for a singleton feature such as color requires little effort). In other cases, participants performed a much harder (high load) version of the task—responding to upright blue “t”s or inverted yellow “t”s (i.e., a conjunction search, which is more difficult). The researchers in this study took advantage of the fact that visual areas exhibit retinotopic organization, which means that the spatial arrangement of information on the retina corresponds to the spatial arrangement of the neurons that process that information in each visual area. Thus, they were able to disentangle brain activity from V1, V2, etc.

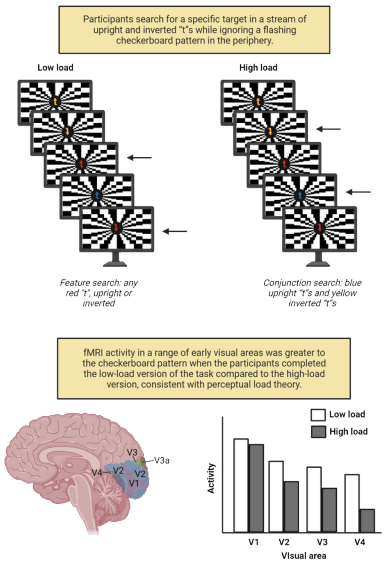

Figure 19.11 Perceptual load theory and neural correlates Checkerboard pattern: By Sven Hermann, CC BY-SA 4.0, https://commons.wikimedia.org/w/inde...urid=124163044

Schwarz and colleagues (2005) found that the irrelevant checkerboard pattern produced significantly greater brain activity in a range of early visual areas in the low load condition compared to the high load condition (Figure 19.11). Note that the visual displays were identical in both the high and low load cases, but since (according to the perceptual load theory) greater attentional resources would automatically be deployed to the unattended checkerboard under low load compared to high load conditions, there would more extensive neural processing of the checkerboard pattern during the easy version of the task compared to the hard version. Converging ERP evidence (Handy et al., 2001) shows that early visually-evoked potentials mirror the fMRI results, with greater P1 component amplitude to unattended distractors under low perceptual load relative to high perceptual load (see Methods: ERP, Methods: MRI/fMRI).

4.2.15: What is the Relationship between Attention and Eye Movements?

Learning Objectives

By the end of this section, you should be able to

- 19.4.1 Articulate the connections between planned eye movements and covert orienting according to the premotor theory of attention.
- 19.4.2 Evaluate the contribution of brain regions involved in programming eye movement to covert selective attention.

Earlier, we distinguished between overt attention, which involves performing a rapid eye movement from one point of fixation to another (a saccade) in order to bring information into central vision, and covert attention, which involves shifting the focus of your attention mentally without eye movements. The existence of these two separate methods of deploying attention might suggest that eye movements and covert attentional shifts are distinct processes. However, several researchers have suggested that eye movements and covert attentional shifts are tightly linked. In fact, the premotor theory of attention argues that covert attentional shifts are nothing more than planned, but unexecuted, eye movements. In this section, we'll discuss the major theory behind that line of reasoning and review experimental evidence for how the brain systems involved in programming saccades may also play a critical role in covert attentional orienting.

The premotor theory of attention

The relationship between eye movements and covert attention have been the subject of debate for decades (for recent reviews, see Craighero & Rizzolatti, 2005; Hunt et al., 2019). One suggestion is that covert attentional shifts are, quite simply, planned eye movements that are never executed. An early version of this argument was labelled the oculomotor readiness hypothesis (Klein, 1980), but more recent formulations have been dubbed the premotor theory of attention (Rizzolatti et al., 1987). As mentioned, the central premise of this theory is that attentional shifts are subthreshold eye movements and, by extension, that the neural systems involved in programming saccades are responsible for covert shifts of attention.

Rizzolatti and colleagues (1987) provided early behavioral support for this theory. In their study, participants covertly attended to a location on either the left or right side of a computer screen. As in other covert attention studies, when the target appeared at an attended location, participants responded faster compared to when it was presented at an unattended location. However, there was an interesting twist in their results. If the target appeared at an uncued location farther in the same direction as the attended location, there was less of a penalty than when it appeared at an uncued location on the opposite side of the screen—even if both unattended locations were equidistant from the original attended location. They argued that shifting attention to an unattended location on the opposite side of the screen as the original cue required planning an entirely new eye movement, and therefore there was a larger cost in those situations compared to an unattended location in the same direction of the original cue, which only required a modification of the existing planned eye movement.

Neuroscience across species: Non-human primates: Frontal eye field stimulation

In addition to behavioral experiments linking covert attention and eye movements, neurophysiological studies also provide strong support for the premotor theory of attention. Recall that the dorsal attentional network (Figure 19.6) is responsible for voluntary shifts of attention (including covert shifts of attention), and that one of the key regions in the dorsal network is the frontal eye field (FEF), which is located near the junction of the precentral gyrus and the middle frontal gyrus. As the name implies, the FEFs are critical for planning and executing saccadic eye movements. Electrical stimulation of the FEF elicits eye movements (Bruce et al., 1985), and damage disrupts such movements (e.g., Braun et al., 1992). It is not surprising, therefore, that proponents of the premotor theory of attention have speculated that the FEF plays an important role in covert attentional orienting.

In an ingenious set of experiments, Tirin Moore and his colleagues examined this issue by stimulating neurons in the FEF and

then observing the effects of that stimulation on performance in an attention task (Moore & Fallah, 2001). When you stimulate neurons in the FEF, the neurons produce eye movements to a specific location in space. That location is referred to as the motor field of the neuron. Moore & Fallah mapped out the motor field of individual FEF neurons in a macaque using suprathreshold stimulation (i.e., electrical current strong enough to produce an eye movement). Figure 19.12 shows the design of their experiment.

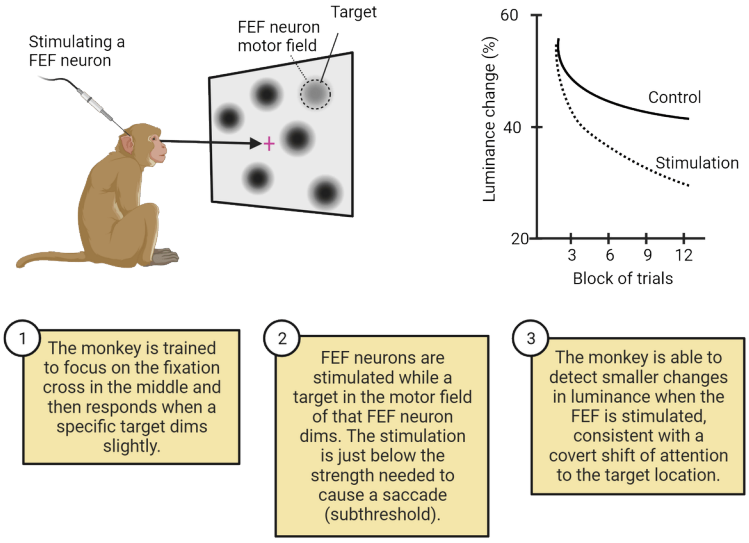

Figure 19.12 Frontal eye field stimulation Data based on findings of: Moore & Fallah. 2001. Control of eye movements and spatial attention. PNAS, 98: 1273-1276

Once the researchers determined the motor field of a neuron, they then trained the animal to covertly attend to a spatial location inside of that motor field. The animal's task was to respond when a light in the attended location dimmed slightly (the researchers measured the minimum amount of dimming that the animal could reliably detect). On some trials, the researchers delivered subthreshold stimulation to the FEF neurons (i.e., stimulation below the threshold necessary to elicit a saccade). They found that over the course of several blocks of trials, the animal was able to detect more subtle changes in luminance when the FEF was stimulated compared to the control condition (i.e., no stimulation). Critically, the improved performance only occurred for targets that appeared in the motor field of the neuron and not for targets that appeared at other locations on the screen. This suggests that activation of the FEF elicited a covert orienting response to the motor field of the neuron, consistent with the premotor theory of attention.

Converging support for the premotor theory of attention comes from a range of studies, including reversible deactivation (Bollimunti et al., 2018), fMRI (Nobre et al., 2000), and noninvasive brain stimulation studies involving both TMS (Morishima et al., 2009; Fernandéz et al., 2022) and tDCS (Kanai et al., 2012). Nevertheless, there is still debate within the neuroscientific community over the value of the theory in terms of a general explanation of the connection between covert attention and eye movements (for recent critical reviews, see Hunt et al., 2019 and Smith & Schenk, 2012), with some researchers arguing that attention and eye movements are fundamentally independent systems that complement one another, depending on the complexities of our natural environment.

People behind the science: Spotlight on Tirin Moore

Tirin Moore (Figure 19.13) is a professor of neurobiology at the Stanford University School of Medicine and an investigator of the Howard Hughes Medical Institute. In his career, he has pioneered study of the relationship between FEF activation and covert selective attention (Moore & Armstrong, 2003; Moore & Fallah, 2001), earning him honors such as induction into the National Academy of Medicine and the National Academy of Sciences. One of his early, groundbreaking findings was that stimulating the frontal eye field, even at lower levels that do not cause eye movements, induces covert attentional shifts. His subsequent work has elegantly demonstrated the tight coupling between attentional control, eye movement, and working memory systems in the prefrontal cortex.

4.2.16: How Do Clinical Disorders Affect Attentional Function?

Learning Objectives

By the end of this section, you should be able to

- 19.5.1 Articulate the different neuropsychological conditions associated with impaired attentional operations, as well as the varieties of each.
- 19.5.2 Explain the relationship between ADHD and forms of attentional disruption that result from brain damage.

Much of our discussion thus far has focused on attentional function in the healthy, typically developing brain. There are, however, a number of neuropsychological and neurodevelopmental disorders that provide unique insights into the brain systems involved in attention. In this section, we'll review a few such disorders to see how they disrupt the normal operations of the attentional system, and how they inform our theories of attention in the healthy brain.

Neglect and extinction

One of the most striking disruptions of attentional function after brain damage is a condition known as spatial neglect (also commonly referred to as visual neglect, hemispatial neglect, or hemineglect). The key feature of patients with this disorder is an inability to attend, or orient, to information from one side of space (Halligan et al., 2003; Parton et al., 2004; Rafal, 1994). Typically, the impacted side of space is contralesional, which means that if the patient has damage to the right side of the brain, then the left (opposite side) of the world will be ignored. Information on the same side as the brain damage (ipsilesional) is often, though not always (Kim et al., 1999), spared. Neglect patients engage with the world seemingly unaware of the presence of information on the contralesional side. They fail to notice objects and people on that side. They might only shave or apply makeup to half of their face. They might even leave half of the food on their plate, or only dress half of their body.

Not all neglect patients experience their problems in the same way. We'll see later that they vary in *kind*, with different manifestations depending on the type of information that's ignored. But they also vary in *degree*, ranging from mild to severe. In its mildest form, neglect may manifest itself as extinction (Driver & Vuilleumier, 2001; Riddoch, 2010), which refers to a situation in which patients fail to attend to contralesional visual input, but only when simultaneous input is also present in the ipsilesional visual field. In other words, if you present an extinction patient with information on just one side (even the contralesional, or "bad", side), they will be aware of it, and respond to it. However, if you present them with information simultaneously on both sides (double simultaneous stimulation), then they will only be aware of the information presented ipsilesionally (i.e., the "good" side; see Methods: Lesions).

Clinical features of neglect and extinction

The hallmark symptom of neglect is a failure to attend, or orient, to contralesional information. Most often, this results from damage to the right side of the brain, which means that the left side of the world is typically impaired. Clinicians diagnose this disorder in a number of ways; often using relatively simple pen-and-paper tests, like those shown in Figure 19.14

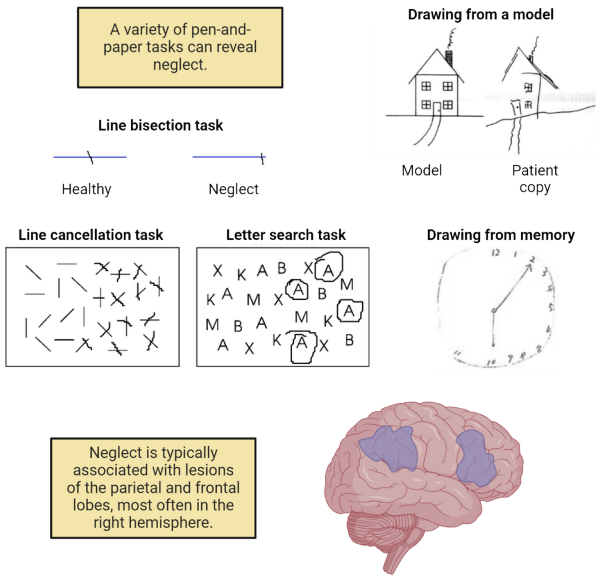

Figure 19.14 Hemispatial neglect Clock image by Dhru4you - Own work, Public Domain, https://commons.wikimedia.org/w/inde...curid=12227682; Letter search test recreated from Eliran t, CC BY-SA 4.0, https://commons.wikimedia.org/w/inde...urid=107312572; Line cancellation test recreated from Eliran t, CC BY-SA 4.0, https://commons.wikimedia.org/w/inde...urid=107312575; Half-line marking recreated from By Eliran t, CC BY-SA 4.0, https://commons.wikimedia.org/w/inde...urid=107589001; Drawing from a model from: O'Reilly et al., "6.5: Spatial attention and neglect in the "Where/how" pathway in O'Reilly, R. C., Munakata, Y., Frank, M. J., Hazy, T. E., and Contributors (2024). Computational Cognitive Neuroscience. Wiki Book, 5th Edition. https://compcogneuro.org" CC BY 4.0

For instance, if you ask a neglect patient to make a mark in the middle of a horizontal line (a line bisection task), they will place their mark too far to the ipsilesional (typically the right) side. They think that they have split the line in half, but in fact, they are unaware of the left-most part of the line, and so they fail to recognize the true midpoint. In a similar task, patients might look at a sheet of paper with a scatter of lines and be asked to make a mark through all the lines that they see (a line cancellation task). Similar to the line bisection task, patients will cross out most of the lines on the right side of the page but miss most, if not all, of the lines on the left side.

Another rather basic diagnostic test involves drawing (Figure 19.14). If you ask a typical neglect patient to copy a picture that's in front of them, or if you ask them to draw a picture from memory, they will either fail to include details from the left side of the image, or in some cases, they'll include all the details but misplace them on the right side. They recognize the objects, but they fail to notice, or be aware of, information on one side of the image.

You might think that these previous examples could be easily explained by a lower-level visual impairment. For instance, maybe the patients are blind to one side of the visual world (a condition known as hemianopia). This is not the case, however, as visual examinations demonstrate that neglect patients have preserved lower-level visual processing, and they even show activation in striate and extrastriate brain regions for the information that they fail to attend (Rees et al., 2000). In fact, hemianopic patients don't exhibit the problems that you see in Figure 19.14 because they *know* they have a visual impairment, and they adjust accordingly (e.g., by turning their head so that everything falls into their sighted regions). Patients with neglect lack that insight into their condition, a condition known as anosagnosia. That is, they not only miss out on half of the world, but they are *unaware* that they are missing anything.

Neglect typically results from unilateral damage to the posterior and inferior parietal cortices but can also occur after frontal or subcortical lesions (Figure 19.14; Mort et al., 2003). Damage to either side of the brain can produce neglect, although it is more common after right-sided brain damage (Bowen et al., 1999). Despite this variability, notice that these regions overlap considerably with the dorsal and ventral attentional networks reviewed in 19.2 How is Attention Implemented in the Brain?. In fact, a number of theorists have argued that neglect is best characterized by a disruption of these two key attentional control networks (Corbetta & Shulman, 2011).

Unconscious processing of neglected information

Patients with neglect are unaware of information presented on the contralesional side of space. But is it better to characterize their condition as a problem of conscious awareness, or a problem of perceptual processing? Another way to think about this is to consider neglect in light of our earlier review of early and late selection in 19.3 What Happens to Unattended Information?. Some

evidence suggests that neglected information is subjected to a relatively high level of semantic processing (late selection). For instance, Marshall & Halligan (1988) asked a patient to look at two houses arranged vertically so that the left side of each house fell into the neglected side of space. The right half of each house was identical, but the left side of one of the houses appeared to be on fire. The patient failed to notice any differences between the two houses (because the important differences were on the neglected side of space), but when asked where she would like to live, she routinely selected the house that was not on fire (even though she could not articulate a reason)! This finding has not been consistently replicated (e.g., Bisiach & Rusconi, 1990), but other lines of research suggest that neglect and extinction patients process semantic-level information about sensory input that's ignored. For instance, Berti and Rizzolatti (1992) presented an extinction patient with a double simultaneous stimulation task in which the two objects belonged to the same semantic category but looked very different perceptually (two different cameras seen from different angles), or two objects that looked perceptually similar, but belonged to different semantic categories (a spoon and a key). The patient was able to correctly categorize whether the two belonged to the "same" or "different" categories, even though they were unaware of the object presented contralesionally in the first place.

Different manifestations of neglect

Earlier, we defined neglect as a failure to attend, or orient, to one side of space. That was a somewhat general definition of the condition, and it intentionally glossed over an important aspect that we haven't considered so far, namely, that we can carve up space in many different ways. For instance, we can talk about the left and the right side of the environment around us, but we can also talk about the left and right sides of individual objects in that environment. Similarly, we can talk about space in terms of the external perceptual world, or in terms of our own internal "mental" space. These two examples illustrate the complexity of defining the exact spatial nature of neglect and give a preview of some of the different manifestations of the disorder.

In a classic neuropsychological study, Bisiach and Luzzatti (1978) asked two neglect patients to form a mental picture of the central square in their hometown of Milan, Italy. In one case, they were asked to imagine that they were on the East side looking West and to name all of the buildings that they could see in their "mind's eye". In this case, they mostly named landmarks on the North side of the square (which corresponded to the right side of their mental image) and reported very few buildings on the South side. Interestingly, when they were asked to flip their point of view (i.e., imagine standing on the West side facing East), they did just the opposite. That is, they named mostly buildings from the South side of the square (which now lined up with the right side of their mental image) and very few buildings from the North side. This demonstrates that neglect not only occurs for the external perceptual world, but can also occur for our own internal mental representations of space (representational neglect). Perceptual and representational neglect typically co-occur (Bartolomeo, 2002), but each can occur without the other (Ortigue et al., 2006), a phenomenon in neuropsychology known as a double dissociation.

Neglect can also manifest itself in different spatial frames of reference. For instance, neglect can occur for relatively close (Halligan & Marshall, 1991) or far (Vuilleumeir et al., 1998) regions of space. It can also occur for the left and right side of individual objects, a phenomenon known as object-based neglect (Robertson, 2004; Figure 19.15). If you ask a patient with object-based neglect to circle all of the "A"s on a piece of paper where the letters are clustered into two groups or "objects", they might circle the "A"s from the right side of *each cluster*, rather than just the "A"s on the right side of the page. Similarly, if they are asked to copy a scene, they might draw objects from the whole picture, but leave out details from the left side of each element. Marshall & Halligan, (1993) demonstrated that when a patient attempted to copy a single potted plant containing two flowers, they only copied the right half of the plant. Interestingly, when the patient was shown the top half of the same picture presented in isolation (which created two separate flowers), they copied the right sides of each flower! The anatomical correlates of each of these subtypes are not fully understood, although there are ongoing efforts to understand the distinct neural systems that give rise to each manifestation (for a review, see Buxbaum, 2006).

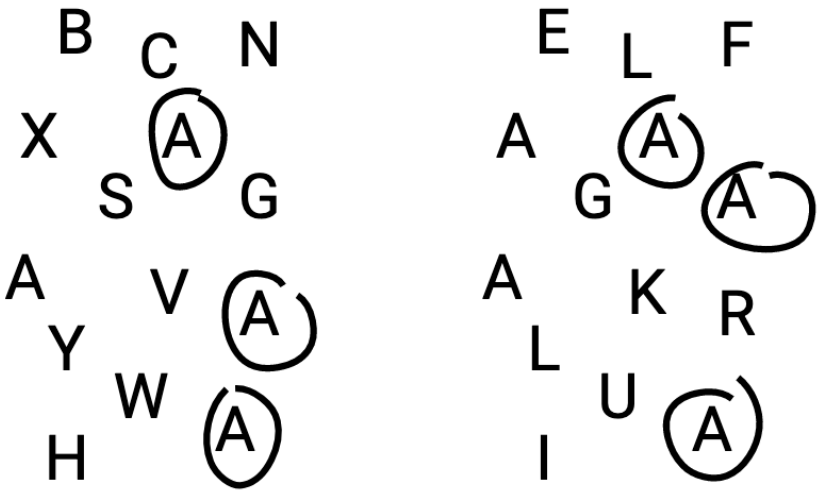

Figure 19.15 Object-based neglect Instructions: "Circle all the As you can find above." Result from a patient with left object-based neglect. Patients with object-based neglect fail to attend to one side of individual objects. In this case, they ignore the letters on the left side of each grouping.

Treatment options for neglect patients

Spatial neglect is relatively common after right hemisphere brain damage (upwards of 50%; Buxbaum, 2004), but spontaneously resolves in a portion of those cases (Farne et al., 2004). For many individuals, however, the symptoms persist indefinitely, which presents significant challenges for daily life. Researchers have explored a range of methods to reduce symptom severity ranging from modest behavioral interventions to drug therapies and brain stimulation (for recent reviews, see Luauté et al., 2006; Umeonwuka et al., 2022).

One intervention strategy involves the use of prism adaptation (PA; Rossetti et al., 1998; Figure 19.16), in which patients wear specially designed goggles that shift their visual input in one direction (typically, that makes neglected information on the left side appear farther to the right). Rossetti and colleagues showed that a brief period of PA training (roughly 5 minutes) resulted in reduced neglect severity on a range of behavioral tests (e.g., line cancellation) that lasted for several hours. A recent meta-analysis suggests that this relatively low-cost and non-invasive form of therapy yields substantial benefits (Chen et al., 2022).

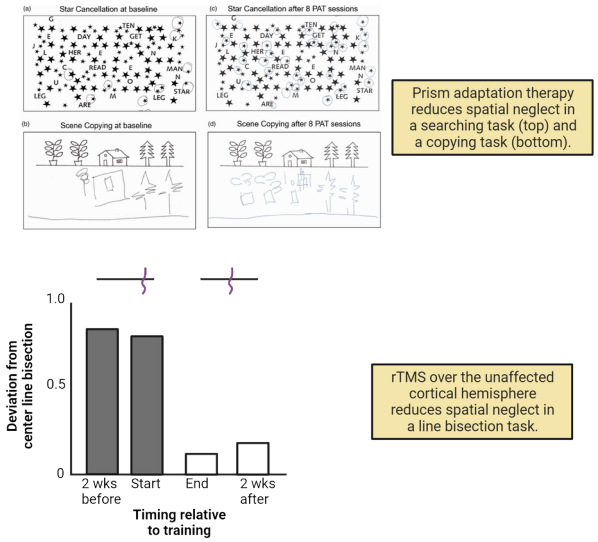

Figure 19.16 Examples of treatment for neglect Task images from: Chen P, Lander V, Noce N, Hreha K. Prism adaptation treatment for spatial neglect post brain tumour removal: A case report. Hong Kong Journal of Occupational Therapy. 2020;33(1):25-29. doi:10.1177/1569186120921472 CC BY NC 4.0. Data on bottom inspired by: Brighina, F., Bisiach, E., Oliveri, M., Piazza, A., La Bua, V., Daniele, O., et al. (2003). 1 Hz repetitive transcranial magnetic stimulation of the unaffected hemisphere ameliorates contralesional visuospatial neglect in humans. Neurosci. Lett. 336, 131–133. doi:10.1016/S0304-3940(02)01283-1

Another promising, although more intense, therapeutic option for neglect is caloric vestibular stimulation (CVS). This process involves inserting cold or warm water into the ear, which produces rapid involuntary sideways eye movements known as nystagmus. If cold water is delivered to the left ear in a patient with right brain damage, then it will cause the eyes to drift towards the left ear (the neglected side) followed by rapid eye movements back to center. It only takes a few minutes but reduces neglect symptoms significantly for several days following the intervention (Rubens, 1985; Rode et al., 1992).

One final technique that has been used to treat spatial neglect is transcranial magnetic stimulation (TMS; Müri et al., 2013). TMS delivers electric currents that can either boost or suppress cortical excitability in specific brain regions using a coil located on the person's scalp (see Methods: rTMS). The rationale behind its application in neglect stems from an influential theory of attention developed by Kinsbourne (1987) known as the hemispheric rivalry hypothesis. According to the theory, each brain hemisphere competes to pull your attention to the contralateral side, and neglect results from an unfair playing field after damage to one hemisphere, resulting in attention being drawn disproportionately to the ipsilesional side by the intact hemisphere. If this theory is correct, then suppressing brain activity in the intact hemisphere might level the playing fields, which would restore the balance of attentional pulls to each side. Several lines of evidence support this model, for instance, Brighina and colleagues (2013; Figure 19.16) suppressed brain activity in the contralesional parietal cortex of several neglect patients over the course of two weeks and found that it reduced neglect symptoms significantly and that the effects lasted beyond the TMS regimen.

Spotlight on ADHD

Developmental Perspective: Disorders such as neglect and extinction result from trauma to the brain such as a stroke or tumor, but there are other neurological conditions that are relevant to our discussion of attention. In fact, one of the most common neurodevelopmental disorders is Attention Deficit Hyperactivity Disorder (ADHD), which affects approximately 10% of all children (Bitsko et al., 2022). The hallmark features of ADHD are hyperactivity, impulse control, and (as its name implies), difficulty paying attention. The neuroanatomy of ADHD is not fully understood, but studies show that children with ADHD have lower gray and white matter volume relative to neurotypical children, particularly in prefrontal regions of the brain, as well as structural differences in regions such as the caudate nucleus and cerebellum compared to children without ADHD (Bush, 2010; Shaw et al., 2006; Valera et al., 2007). Functional brain imaging studies complement these findings, showing that activity in several of the regions linked to ADHD (e.g., the caudate and ventral striatum) is reduced (Kappel et al., 2015; Lei et al., 2015). In addition, specific neurotransmitter systems are thought to be play a role in ADHD, including dopamine and norepinephrine. In fact, one of the most common forms of treatment for ADHD involves the drug methylphenidate (Ritalin), which blocks the reuptake of norepinephrine and dopamine (effectively increasing the amount of these neurotransmitters available). Drug therapies are not the only treatment options available, however. In fact, behavioral

approaches such as exercise and play therapy might be just as effective as drugs in treating ADHD. Some researchers have argued that reduced play behavior increases the risk of developing ADHD (Siviy & Panksepp, 2011), and that play and exercise interventions significantly improve ADHD symptoms (Vysniauske et al., 2020). These studies highlight an important feature of ADHD, which is that the mechanisms responsible for the underlying processes may well change across the lifespan. Indeed, the fMRI studies mentioned above showed that striatal activity reductions were more pronounced in children with ADHD compared to adults with ADHD (Kappel et al., 2015; Lei et al., 2015). Similarly, ADHD medications such as methylphenidate differentially affect cortical function in juvenile vs. adult rats (van der Marel et al., 2014), highlighting the fact that developmental perspectives are critical for understanding this complex disorder. Finally, studies suggest that males are more likely to be diagnosed with ADHD than females (Mowlen et al., 2019), and that the primary symptoms experienced by males and females with ADHD can differ markedly (Gershon, 2020). It is therefore also important to incorporate biological sex differences into any meaningful discussion of the disorder.

The diagnostic criteria for ADHD (American Psychiatric Association, 2022) refers to concepts such as not following through on instructions, difficulties organizing tasks, and problems with waiting your turn or interrupting other people. Those might sound like problems related to paying attention. However, they are also distinct aspects of our ability to plan and execute behaviors in a way that allows us to achieve our goals, which, as we'll learn in the next section, constitute the cognitive processes associated with executive function. It is sometimes difficult to distinguish between the concepts of attention and executive function, and in the case of ADHD, many researchers would argue that the key symptoms might be more appropriately characterized as problems with executive function (Rubia, 2018). We'll unpack these related processes more in the next section.

4.2.17: How Do We Use Executive Functions to Make Decisions and Achieve Goals?

Learning Objectives

By the end of this section, you should be able to

- 19.6.1 Give examples of different higher-level cognitive operations that enable us to weigh options and make decisions and the tasks used to assess those functions.
- 19.6.2 Localize the prefrontal brain regions responsible for the various aspect of higher-level cognitive operations.

We'll wrap up this chapter by considering the suite of cognitive processes that allow us to plan out and successfully engage in behaviors that help us to reach our goals, to maintain or shift focus on important tasks as the need arises, and to keep us from acting impulsively or inappropriately. Collectively, these refer to executive function, and we'll review the different pieces that make up this complex aspect of higher cognition, as well as the brain systems that underlie those processes.

Components of executive function (and their associated tests)

Executive function is a fairly dense and complicated topic, but it involves a host of processes such as setting goals and making concrete plans to achieve those goals ('What do I need to do to get an "A" on my lab writeup?"), being able to switch back and forth between competing tasks ("How am I going to juggle my psychology paper due next Monday and my Art History test next Tuesday?"), and monitoring yourself to know whether things are going well or not ("I made a lot of mistakes on that quiz—what can I do differently next time?"). It also involves our ability to suppress the urge to do things that either won't help you succeed or that would be inappropriate ("Don't look at another student's test."). Each of these represents a distinct aspect of our ability to coordinate information to make decisions and achieve goals, and while they overlap with some of the processes that we've already covered (such as top-down attentional control), they represent a different aspect of higher-level cognition.

We often cycle between multiple activities in our day-to-day lives (e.g., checking text messages while trying to read your textbook), and our ability to make those shifts is known as task switching (Monsell, 2003). Shifting back and forth between activities is effortful, and, critically, it levies a toll on our performance. That is, any time you switch between tasks, your performance will suffer in terms of speed, accuracy, or both. Switching between tasks makes you slower on each, compared to staying focused on just one or the other. This is known as a switch cost and it has been demonstrated in numerous experiments dating back to the early 20th century (Jersild, 1927). Rogers and Monsell (1995) developed a standard paradigm for examining these effects. They presented participants with letters and numbers on a computer screen and then cued them on each trial to decide whether the letters were vowels or consonants, or whether the numbers were odd or even. They found that on trials where the participant had to switch from one task to the other, they were consistently slower than on trials where they did not switch. Another classic paradigm for studying task switching is called the Wisconsin Card Sorting Test (WCST; Berg, 1948; Figure 19.17). In this task, participants receive a stack of cards with different colored shapes on them. They sort the cards into piles based on one feature (e.g., shapes or colors), but after some amount of time, the experimenter changes the sorting rule without telling them and they have to determine the new rule on their own (using trial-and-error) in order to respond correctly. This requires them to task switch and, like the previous paradigm, entails a switch cost.

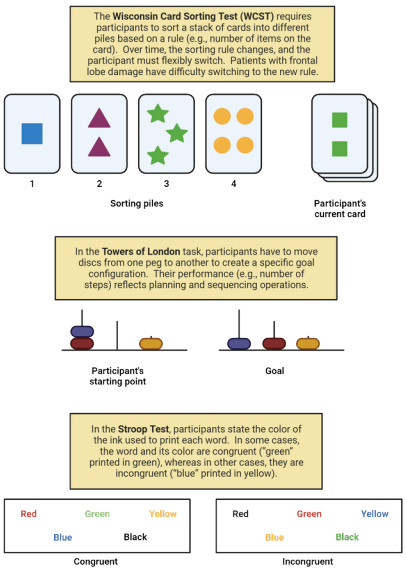

Figure 19.17 Tasks relying on frontal cortical function

A separate core component of executive function is our ability to break down complicated tasks into separate pieces, and then to arrange those pieces in a logical order to achieve our goals. This could involve simple tasks like brushing your teeth or more complicated, long-term activities like planning a wedding. In either case, we need to think about sequencing the behaviors in a way that will yield success. One method for studying these planning and sequencing processes is through a task developed by Shallice (1982) called the Tower of London (ToL) game (Figure 19.17). In this task, participants rearrange discs on a row of pegs. Their goal is to recreate a pattern that the experimenter shows them, and the rule is that they can only move one disc at a time. Researchers can vary the difficulty of the problem on each trial, and by examining the number (and kind) of moves that a person makes, as well as their speed, they can assess various components of planning and sequencing behavior.

A third critical aspect of executive function relates to inhibitory control, which generally refers to our ability to suppress thoughts or behaviors. We might need to suppress a response because it's inappropriate in the current context (yelling at the referee for your child's soccer match), or because it's a change from our normal, well-rehearsed routine (turning the opposite way on your commute home to run an unscheduled errand). In either case, we have to exercise mental effort in order to avoid the wrong choices. A number of tasks are used to study inhibitory control, with perhaps the most famous one being the Stroop task (Stroop, 1935; Figure 19.17). This task requires participants to look at a set of words on a paper or on a computer screen and selectively attend to, and report, the color of each word. They are told not to read the words out loud, but reading is a relatively automatic process, and so it requires a great deal of inhibitory control to say the color of the ink, rather than the word itself—especially when the words conflict with the ink color (e.g., the word "red" printed in blue). Another classic approach for studying inhibitory control is the Go/No-Go task (Lappin & Eriksen, 1966). The basic feature of this task is that participants are told to press a button ("Go") when they see one type of cue, and withhold a button press ("No-Go") when they see a different type of cue. Depending on how rare the No-Go cues are, it can be quite difficult to suppress the response, and therefore this task is an effective measure of inhibitory control processes. These tasks not only have value in experimental research, but are also important tools in many clinical settings. For instance, the Stroop tasks is commonly used to track and monitor the progression of neurodegenerative diseases such as Alzheimer's disease (Hutchison et al., 2010).

We'll briefly touch on two other aspects of executive function, which are the ability to *update* and *monitor* information that's relevant to your current task or your long-term goals. These processes are actually implemented in distinct ways, such as working memory, which allows us to not only *retain* important bits of information in a temporary buffer, but also to *manipulate* those bits as a task requires. We won't discuss working memory in detail here (see Chapter 18 Learning and Memory), but we also monitor and update our own actions and assess how effective they are in allowing us to accomplish our goals. This is described as self-monitoring and it can operate on different time scales, from immediate ("did I just call you the wrong name?") to long-term ("am I saving enough to buy a car next year?)". One way to study short-term self-monitoring experimentally is to use a Flanker Task (Eriksen & Eriksen, 1974), in which a participant has to discriminate a central letter ("X" vs "S") that's surrounded by flanking letters that should be ignored. Sometimes the flanking letters are the same as the central letter (congruent) and sometimes they are the opposite letter (incongruent). People are slower and tend to make mistakes on incongruent trials, and by observing how their behavior changes after they recognize their mistake (error monitoring), you can study these self-reflection and updating processes. For instance, people typically respond more slowly but more accurately after an error, suggesting that they are updating their criteria for making a response.

Mapping executive function to the brain

Executive functions are carried out by a wide range of brain systems, most notably the prefrontal cortex (PFC; Figure 19.18).

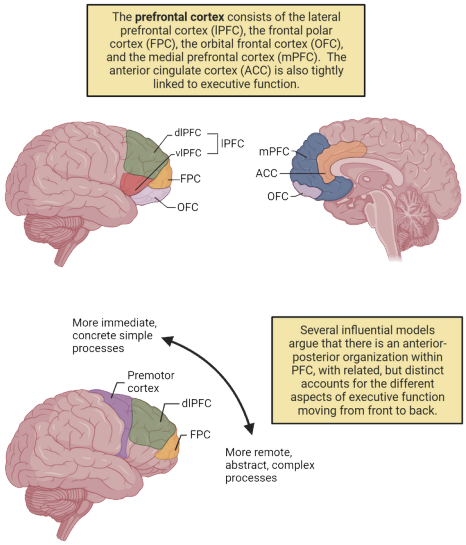

Figure 19.18 Brain regions associated with executive function

Anatomically, the prefrontal cortex can be broken down into several regions including the lateral prefrontal cortex (just anterior to the motor and premotor regions), the orbital frontal cortex and frontal pole (just in front of and below to the lateral prefrontal cortex), and the medial prefrontal cortex (located on the interior wall of each hemisphere). When researchers refer to the medial prefrontal cortex in the context of executive function, they also commonly include the anterior cingulate cortex, which lies just posterior to medial PFC and superior to the corpus callosum. The lateral prefrontal cortex is also commonly divided further into dorsolateral prefrontal cortex (dlPFC) and ventrolateral prefrontal cortex (vlPFC).

Activity in each of these brain regions has been linked to the different executive functions discussed above using functional brain imaging (Methods: fMRI/MRI) and electrophysiological (Methods: EEG/ERP) techniques. For instance, fMRI studies show that that the WCST engages the dlPFC (Monchi et al., 2001) and vlPFC (Lie et al., 2006; for a review, see Nyhus & Barceló, 2009) and structural MRI evidence suggests that PFC volume correlates with performance in the task (Yuan & Raz, 2014). Other fMRI studies, using related task-switching paradigms, find activity in regions such as the ACC (Ravizza & Carter, 2008) and premotor cortex (Slagter et al., 2006). Planning and sequencing tasks such as the ToL reliably engage the dlPFC (van den Heuvel et al., 2003) and ACC (Lazeron et al., 2000), and non-invasive brain stimulation to the left dlPFC improves performance on the ToL task (Kaller et al., 2013). Tasks that involve inhibitory processing are associated with activity throughout the prefrontal cortex (for two recent reviews, see Banich, 2019; Hung et al., 2018). Finally, the ACC and mPFC have been closely linked to self- and error-monitoring tasks through electrophysiological markers such as the error-related negativity (Falkenstein et al., 1991; Gehring et al., 2018), which is a negative ERP component that occurs within the first ~100ms after a participant makes a mistake in a variety of tasks (e.g., the Flanker task) and is thought to be generated by the ACC (Dehaene et al., 1994). Functional MRI studies provide converging evidence for a critical role of the ACC in error-monitoring (e.g., Iannaccone et al., 2015).

It is important to note that while the bulk of the research discussed thus far focuses on human and non-human primates, there is in fact a wealth of research suggesting a link between executive function and prefrontal cortex in other species. Using analogs of many of the paradigms describe above, researchers have established a critical role of the rodent prefrontal cortex in executive functions such as task and set switching (e.g., Bortz et al., 2023; Ragozzino, 2007), spatial and olfactory working memory (e.g., Wang et al., 2023), the Flanker task (e.g., Fisher et al., 2020), and error monitoring (e.g., Olguin et al., 2023).

Although there is clear consensus that the prefrontal cortices are critical for many of the above-mentioned aspects of executive function, there is considerable debate about how to best characterize the division of labor within PFC. There isn't a single agreed-upon mapping between different executive functions and different brain regions (to paraphrase an old expression, if you ask 5 neuroscientists how executive functions are organized in the PFC, you'll get 6 opinions!). Nevertheless, two relatively popular models of PFC organization (Badre & D'Esposito, 2009; Koechnlin & Summerfield, 2007; for a recent review, see Badre & Nee, 2018) propose related hierarchical organizations going from anterior to posterior PFC, albeit with slightly different properties

in each case (Figure 19.18). In both models, the basic premise is that more anterior regions of the PFC are tightly linked to temporally remote, abstract, and higher-level aspects of executive function and control, whereas more posterior regions are more tightly linked to immediate, concrete, and sensory-driven aspects of executive function and control. To be sure, this glosses over some major differences between the two, but it provides a first glance at one potential way to break down this large network of prefrontal regions into smaller units. Other organizational schemes suggest, for example, hemispheric differences related to things such as task-switching vs. monitoring (Ambrosini et al., 2019), or for different types of working memory content (D'Esposito et al., 1998). However, several recent reviews (Friedman & Robbins, 2021; Menon & D'Esposito, 2021) suggest that it might be better to conceive of cognitive control and executive function as emerging from a set of overlapping networks that all involve the PFC, rather than focusing on the specific roles of individual regions.

Effects of brain damage on executive function

Proper executive functions rely on the integrity of the prefrontal cortex (for a review, see Alvarez & Emory, 2006). For instance, patients with frontal lobe lesions are often impaired on the WCST (Milner, 1963; Goldstein et al., 2004) and will continue to apply an old sorting rule, even when it has changed (a phenomenon known as perseveration), and even when they know that it has changed. Monkeys with prefrontal lesions (Dias et al., 1996) are also impaired in an analog of the WCST, suggesting that the role of the frontal cortex in executive function is not specific to humans. Similar findings occur in rats (Birrell & Brown, 2000; McGaughy et al., 2008) and further suggest that norepinephrine plays a critical role in this process. This fits well with the fact that a number of common treatments for executive dysfunction such as ADHD (e.g., Adderall) involve blocking the reuptake of norepinephrine (recall 19.5 How Do Clinical Disorders Affect Attentional Function?).

Task switching paradigms reveal deficits after frontal lobe damage (e.g., Kumada & Humphreys, 2006; Rogers et al., 1998), as do tasks that involve planning and sequencing behaviors. Performance on the ToL game is impaired after damage to prefrontal regions (for a review, see Nitschke et al., 2017). Patients will sometimes perseverate on previous moves or attempt to break the rule of only moving one disc at a time. Moreover, they do not engage in strategic planning or sequencing, but rather often attempt to solve the task using "trial and error" approaches. Petrides & Milner (1982) showed a similar phenomenon using a self-ordered pointing task (SOPT), which requires patients to look at a set of objects on a computer screen and point to one that they choose. Then, on each subsequent trial, the researchers rearrange the objects and the patient has to point to a new object that they haven't already selected. This task relies on several aspects of executive function including working memory and sequencing since the patient needs to remember the objects that they have already selected even though they appear at new locations on the screen each trial, and, critically, damage to the frontal lobes impairs performance.

Damage to the prefrontal cortex and anterior cingulate cortex will also impact inhibitory control processes. For instance, Perret (1974) argued that left frontal lesions selectively impair performance on the Stroop test, although not all researchers agree with this claim (e.g., Stuss et al., 2001). Impairments on other related inhibitory control tasks have been linked to right frontal lobe damage (Aron et al., 2003) and lateral prefrontal and orbitofrontal lesions in monkeys selectively impair non-affective (i.e., non-emotional) and affective (i.e., emotional) inhibitory control processes, respectively (Dias et al., 1997).

Disruptions of inhibitory control after brain damage are not restricted to laboratory-based paradigms such as the Stroop test. In fact, patients with frontal lobe damage can exhibit much more striking failures in inhibitory control that affect their behavior outside of the laboratory. For instance, one of the most famous early case studies of damage to the frontal lobes involved Phineas Gage. Gage suffered a severe accident as a railroad construction worker, when a large tamping iron triggered an explosion and sent the metal rod through his skull, damaging significant portions of his frontal lobe, particularly his orbitofrontal cortices. Figure 19.19 shows Gage holding the rod, as well as a modern reconstruction of the brain damage that he suffered (Damasio et al., 1994).

Figure 19.19 Phineas Gage "By Polygon data is generated by Database Center for Life Science(DBCLS)[3]. - Ratiu P, Talos IF, Haker S, Lieberman D, Everett P. The tale of Phineas Gage, digitally remastered. J Neurotrauma. 2004 May;21(5):637-43. PMID: 15165371 [1]Polygon data is from BodyParts3D[2]., CC BY-SA 2.1 jp, commons.wikimedia.org/w/inde...curid=44466317

Gage survived the incident and was relatively unaffected in many aspects of cognition, however historical accounts suggest that his emotion regulation and inhibitory control processes were significantly impacted. He seemed to lack the ability to inhibit socially inappropriate behaviors and his associates described him as rude, irreverent, and profane after the accident (Harlow, 1848). An even more dramatic example of this lack of inhibition is evident in environmental dependency syndrome (originally labelled utilization behavior; Lhermitte, 1983), in which patients with frontal lobe damage (particularly the right OFC; Besnard et al., 2011) cannot help themselves from picking up and using objects in their environment, even if it is not appropriate to the situation. Lhermitte (1986), for instance, described a patient who picked up medical instruments placed before her and immediately began performing a medical exam on the researcher (e.g., taking his blood pressure and examining his throat with a tongue depressor). Another patient started to hang a picture on the researcher's wall, having spotted a hammer and nail on a nearby table. In each of these cases, the patient lacked the ability to inhibit behaviors, and moreover, failed to recognize that the action was inappropriate in that context.

Dopamine, Schizophrenia, and Executive Function

In addition to focusing on the role of brain regions such as the PFC in executive function, there has been considerable interest in the role of specific neurotransmitter systems in these processes, particularly (but not exclusively) dopamine (Ott & Nieder, 2019; Robbins & Arnsten, 2009). Dopaminergic neurons in the midbrain project to the PFC through the mesocortical dopamine pathway, and a variety of studies have demonstrated an important role for this pathway in executive functions (Figure 19.20).

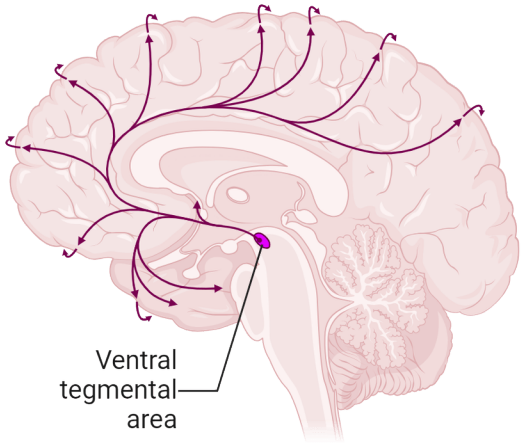

Figure 19.20 Mesocortical dopamine system

For instance, depleting dopamine availability in rats (Simon et al., 1980) and primates (Brozokski et al., 1979) results in working memory deficits. Similarly, PET studies (Takahashi et al., 2008) demonstrate that moderate dopamine levels in PFC correlated with optimal performance on the WCST (suggesting that an inverted-U shape represents the optimal levels of dopamine availability in PFC; Weber et al., 2022). Pharmacological intervention studies in humans showed that participants who received sulpiride (a dopaminergic receptor antagonist) performed worse on planning and sequencing tasks such as the ToL and other task switching paradigms (Mehta et al., 1999).

Disruptions in the dopaminergic and frontal systems can impact executive functions, as described above, but they can also lead to mental illness as in the case of schizophrenia, which affects roughly 1 in every 200 adults. The hallmark features of schizophrenia fall into one of two groupings: positive symptoms (e.g., delusional thought and hallucinations) and negative symptoms (e.g., decreased motivation or and reduced emotional expressiveness). In addition to positive and negative symptoms, executive function impairments and frontal lobe abnormalities are also present in the disorder, and these executive function impairments may, in fact, be more predictive of functioning and quality of life for individuals with schizophrenia than either their positive or negative symptoms (Bowie & Harvey, 2006). For instance, people with schizophrenia perform worse on the WCST compared to healthy individuals (Polgár et al., 2010). Planning and sequencing tasks such as the ToL are also negatively impacted by schizophrenia (Sponheim et al., 2010), as are inhibitory control tasks such as the Stroop task (Westerhausen et al., 2011). Structural brain imaging studies show a general decline in frontal lobe gray matter volume in schizophrenic patients (e.g., Andreasen et al., 2011). Functional brain imaging studies similarly show that schizophrenic patients typically show reduced activity in the frontal lobes (hypofrontality) when engaged in executive control tasks such as the WCST (Riehemann et al., 2001) and the ToL (Andreasen et al., 1992), or even when at rest (Hoshi et al., 2006).

Schizophrenia is a highly heritable disorder and there is strong evidence to suggest that genes which encode dopamine receptors may play a key role (Pantelis et al., 2014). Moreover, the most common treatments for the disorder involve antipsychotic drugs that target dopamine systems in the brain, and, in addition to reducing the positive symptoms of the disorder, these medications often result in demonstrable improvements in executive function (e.g., Bilder et al., 2002). It is important to note, however, that there is some debate concerning the use of antipsychotic medications for long-term care of individuals with schizophrenia (Gaebel et al., 2020), as well as the extent to which such drugs are effective at treating the cognitive symptoms of the disorder (Spark et al., 2022). In addition, more recent work suggests that other neurotransmitters, such as GABA and serotonin, may also play key roles in the disorder, and there is widespread recognition that current models of schizophrenia cannot focus solely on dopaminergic systems in the brain (e.g., Yang & Tsai, 2017).

View this Interactive Content online

The concepts of arousal, vigilance, and selective attention are all tightly related aspects of our brain's ability to bring certain pieces of information into conscious awareness and maintain that information over time. When considering selective attention more closely, we start to see the complexities involved in shifting the focus of our awareness, and to appreciate how those shifts involve a number of factors, including the degree to which we make those shifts voluntarily, as well as how those shifts line up with where we're looking.

19.2 How is Attention Implemented in the Brain?

Attentional mechanisms exist across much of the brain, including brainstem and subcortical structures involved in general arousal, cortical networks for voluntary and reflexive shifts of attention in the dorsal and ventral attention networks, respectively, and the consequences of attentional selection on sensory processing systems as early as the lateral geniculate nucleus and stretching into later, higher-level visual processing regions.

19.3 What Happens to Unattended Information?

Unattended sources of information do not benefit from the same enhanced processing as attended sources, but they are nevertheless processed by the relevant sensory systems in the brain. Historically, attention researchers debated whether the filtering of such information occurred relatively early or late along the sensory pathways. More recent work argues that such distinctions may represent a false dichotomy and that the degree to which attention filters out unattended sources varies dynamically based on factors such as task difficulty and perceptual load.

19.4 What is the Relationship between Attention and Eye Movements?

There is considerable evidence to support the idea that shifts of attention, even when made covertly, engage some of the same perceptual and control systems involved in eye movements. This has led a number of researchers to argue for a premotor theory of attention, in which covert attentional orienting results from planned, but unexecuted saccades. Microstimulation studies in animals show that weak electrical currents applied to a key aspect of the dorsal attentional network—the frontal eye field—result in improved behavioral performance and enhanced neural processing in posterior brain regions, consistent with this premotor theory of attention.

19.5 How Do Clinical Disorders Affect Attentional Function?

A variety of clinical disorders have informed our understanding of the neural basis of attention, including spatial neglect and ADHD. The former provides key insights into the ways in which the brain constructs spatial representations of the world and

deploys attentional resources. The latter provides a window into the tight coupling between attentional operations and executive function.

19.6 How Do We Use Executive Functions to Make Decisions and Achieve Goals?

Our ability to plan out and execute behaviors to achieve goals encompasses a group of cognitive processes collectively referred to as executive function. These processes rely heavily on the prefrontal cortex and on dopamine systems in the brain, although the precise neuroanatomical correlates of these functions are still debated. Finally, patients with damage to the frontal lobe and individuals with schizophrenia provide converging evidence concerning the role of the prefrontal cortex in these processes.

4.2.19: Key Terms

19.1 What are the Different Psychological Processes Associated with Attention?

Arousal, consciousness, vigilance, selective attention, overt attention, covert attention, endogenous attention, exogenous attention, visual search, pop out, conjunction search

19.2 How is Attention Implemented in the Brain?

Ascending reticular activation system, superior colliculus, progressive supranuclear palsy, pulvinar, default mode network, dorsal attentional network, ventral attentional network, fusiform face area, parahippocampal place area

19.3 What Happens to Unattended Information?

Inattentional blindness, change blindness, early selection, late selection, dichotomous listening paradigm, cocktail party effect, perceptual load theory, low/high load, retinotopic

19.4 What is the Relationship between Attention and Eye Movements?

Saccade, premotor theory of attention, motor field

19.5 How Do Clinical Disorders Affect Attentional Function?

Spatial neglect, contralesional, ipsilesional, extinction, double simultaneous stimulation, line bisection task, line cancellation task, hemianopia, anosagnosia, representational neglect, double dissociation, object-based neglect, prism adaptation, caloric vestibular stimulation, nystagmus, transcranial magnetic stimulation, hemispheric rivalry hypothesis, attention deficit hyperactivity disorder

19.6 How Do We Use Executive Functions to Make Decisions and Achieve Goals?

Executive function, task switching, switch cost, Wisconsin Card Sorting Test, sequencing, Tower Of London Task, inhibitory control, Stroop Task, Go/No-Go Task, working memory, self-monitoring, Flanker Task, error monitoring, error-related negativity, perseveration, self-ordered pointing task, environmental dependency syndrome, schizophrenia, positive symptoms, negative symptoms, hypofrontality

This page titled 4.2.19: Key Terms is shared under a CC BY-NC 4.0 license and was authored, remixed, and/or curated by Ivette Merced via source content that was edited to the style and standards of the LibreTexts platform.

4.2.21: Multiple Choice

19.1 What are the Different Psychological Processes Associated with Attention?

1.
When might a visual search process be effortless and quick?

a. When the object being searched for is asymmetrical
b. When the object being searched for has a distinct color or shape
c. When the object being searched for is a combination of color and shape
d. When the object being searched for is far away

2 .
Which of the following is a characteristic of endogenous attention?

a. It requires conscious awareness and deliberation
b. It involves the automatic capture of attention by novel stimuli
c. It refers to the phenomenon of bottom-up attentional control
d. It is the process of focusing on external stimuli effortlessly

3.
Normally, consciousness varies with sleep-wake cycles. Which of the following situations shows that the two can be dissociated?

a. Individuals who are under anesthesia but who are not awake
b. People who cannot control the content of their dreams
c. Patients with narcolepsy
d. Patients in a persistent vegetative state

19.2 How is Attention Implemented in the Brain?

4 .
What is one of the main functions of the ascending reticular activation system (ARAS)?

a. Activating retinal neurogenesis
b. Generating upward (ascending) saccades
c. Controlling working memory
d. Regulating sleep/wake cycles

5.
Which of the following is an impairment associated with progressive supranuclear palsy (PSP)

a. Visual neglect for the left visual field
b. Hemianopia for the left visual field
c. Deficits in shifting attention from one location to another
d. Representational neglect

6 .
Which of the following tasks would be most impacted by temporarily disrupting activity in the monkey superior colliculus?

a. Deciding whether a banana is ripe based on a conjunction search involving color and texture
b. Maintaining arousal during portions of the day normally associated with sleep
c. Deciding whether a predator in peripheral vision is moving towards or away from them
d. Recognizing places in their local visual environment

7.

If someone scanned your brain while you were daydreaming, without any specific task or goal in mind, which brain network would be mostly likely engaged?

a. The default mode network
b. The dorsal attentional network
c. The representational neglect network
d. The error monitoring network

8 .
Imagine that you are closely watching a computer monitor at the Department of Motor Vehicles that will cue you whether you should go to the customer service agent just to the left or to the right of the monitor for your appointment. Which brain network would most likely be engaged by the computer monitor in this situation?

a. The default mode network
b. The fusiform face area
c. The dorsal attentional network
d. The ventral attentional network

19.3 What Happens to Unattended Information?

9.
What does the phenomenon of inattentional blindness suggest about the influence of top-down attentional goals on our perception?

a. Top-down attentional goals have no impact on blindness
b. Little of the sensory information in our visual world escapes our conscious awareness
c. Bottom-up information is immune to intentional blindness
d. Much of the sensory information in our visual world escapes our conscious awareness

10 .
How does task difficulty affect the allocation of attention, according to the perceptual load theory?

a. Low load tasks require less attention
b. High load tasks require more attention
c. Both A and B
d. None of the above

11.
In the context of visual processing, to what does the term “retinotopic organization” refer?

a. The correspondence of the spatial arrangement of information on the retina and in visual brain regions
b. The correspondence of the temporal arrangement of information on the retina and in visual brain regions
c. The spatial arrangement of the retina relative to the cornea
d. The synchronization of neural firing across rods and cones on the retina

12 .
Imagine you are in a bustling coffee shop, and you are trying to focus on a conversation with a friend at your table. Simultaneously, there is background noise, including nearby conversations, the barista's activities, and the hum of coffee machines. In this real-world dichotic listening situation, which of the following statements is true?

a. You can easily filter out the background noise and focus solely on your friend's conversation because dichotic listening is not perceptually difficult
b. You may catch a few words or sounds from the nearby conversation, but your attention is primarily on your friend
c. Your attention is evenly distributed between your friend's conversation and the various background sounds because dichotomous listening tasks are low perceptual load
d. You are equally likely to attend to both the background noise and your friend's conversation

13.
In the context of attention and perceptual load, which of the following real-life scenarios best illustrates a situation with low

perceptual load?

a. Identifying and tracking a red circle on a computer screen that's crowded with one red circle and many blue circles
b. Watching a critically acclaimed foreign film with subtitles at lunchtime in the campus dining hall
c. Navigating through a crowded airport while checking departure screens, listening to announcements, and maneuvering through the crowd
d. Solving a complex mathematical problem with multiple variables and equations

14 .
One example of the cocktail party effect is when you are at a crowded party, you might hear someone across the room say the name of your high school even if you weren't paying attention to their conversation. Which of the following predictions would be true about this effect based on the perceptual load theory?

a. If the conversation that you're currently in is boring, then you'll be less likely to hear the name of your high school because fewer attentional resources will be available
b. If the conversation that you're listening to is especially interesting, then you'll be more likely to hear the name of your high school, because additional attentional resources will be devoted to the current conversation
c. If the conversation that you're listening to is especially interesting, then you'll be less likely to hear the name of your high school, because additional attentional resources will be devoted to the background conversations
d. If the conversation that you're currently in is boring, then you'll be more likely to hear the name of your high school because more attentional resources will be available

19.4 What is the Relationship between Attention and Eye Movements?

15.
What is a saccade?

a. A rapid eye movement to change the point of fixation
b. A planned, but unexecuted eye movement
c. Both A and B
d. None of the above

16 .
Which of the following statements is true concerning the premotor theory?

a. The motor cortex is primarily responsible for deploying attention
b. Attentional systems develop prior to motor systems
c. There is a link between covert attention and some aspects of motor programming in the brain
d. The premotor cortex is associated specifically with the arousal component of attention

17.
An early formulation of the premotor theory of attention was dubbed which of the following?

a. The oculomotor retinotopy hypothesis
b. The perceptual load hypothesis
c. The oculomotor readiness hypothesis
d. The perceptual readiness hypothesis

19.5 How Do Clinical Disorders Affect Attentional Function?

18 .
In the context of spatial neglect, to what does the term "contralesional" refer?

a. Brain damage that contradicts a medical diagnosis
b. Brain damage that results in problems with the opposite side of space
c. Brain damage that, contradictorily, results in problems with the same side of space
d. A medical diagnosis that is contraindicated

19.

According to the hemispheric rivalry hypothesis, how does neglect arise after damage to one hemisphere?

a. Damage allows for the revival of the hemisphere drawing attention
b. Attention is drawn disproportionately to the contralesional side
c. Attention is drawn disproportionately to the ipsilesional side
d. Neglect rivals perception in terms of attentional detail

20 .
You are a neurologist examining a neglect patient who has damage to the right parietal cortex. Which symptom is most likely to occur in the patient?

a. Dividing a line by putting the midway point too far to the left (i.e., the neglected side)
b. Failing to eat the food on the ipsilesional side of their plate
c. Dividing a line by putting the midway point too far to the right (i.e., the non-neglected side)
d. Crossing out all of the lines on the contralesional side of a piece of paper

21.
Which of the following is the best description of a difference between someone with hemianopia and spatial neglect?

a. Neglect patients are typically anosagnosic, but hemianopic patients are typically not
b. Hemianopic patients are typically anosagnosic, but neglect patients are typically not
c. Hemianopia typically results from right parietal lobe damage, whereas neglect typically results from left parietal damage
d. Hemianopia can occur in different frames of reference, whereas neglect can only occur in one frame of reference

19.6 How Do We Use Executive Functions to Make Decisions and Achieve Goals?

22 .
How does task switching affect performance compared to staying focused on a single task?

a. Performance on each task will become faster and/or more accurate
b. Performance on each task will become slower and/or less accurate
c. People over time will be able to perform faster saccades
d. People over time will be able to perform slower saccades

23.
Which of the following scenarios best describes the behavior of a patient with environmental dependency syndrome?

a. A musician who repairs a musical instrument that fell off the wall of their home office
b. A musician who mounts a musical instrument to the wall of their home office
c. A musician who plays a musical instrument mounted to the wall during a doctor's appointment
d. A musician who plays a musical instrument behind a wall during an orchestra audition

24 .
How would a drug that elevates dopamine above normal levels in the prefrontal cortex affect performance on the Towers of London task?

a. It would result in worse color naming
b. It would result in better color naming
c. It would result in better planning and sequencing
d. It would result in worse planning and sequencing

4.2.22: Fill in the Blank

19.1 What are the Different Psychological Processes Associated with Attention?

1.
Unlike searching for an object with a single distinct feature, _____ search involves two distinct features and requires a lot more mental energy.
2 .
Many animals such as owls cannot move their eyes within their sockets. If an owl was immobilized so that it could not move its head or neck, _____ attentional shifts would be affected.

19.2 How is Attention Implemented in the Brain?

3.
The frontal eye field is part of the _____ attentional network.

19.3 What Happens to Unattended Information?

4 .
The phenomenon in which we fail to notice a significant alteration to visual information that we are consciously processing is known as _____.

19.5 How Do Clinical Disorders Affect Attentional Function?

5.
In neglect patients, representational neglect occurs not only for the external perceptual world, but also for _____ representations of space.

19.6 How Do We Use Executive Functions to Make Decisions and Achieve Goals?

6 .
_____ describes the process of assessing and updating our own actions to evaluate their effectiveness in achieving goals.

4.2.23: Learning, Genes, and Adaptation

Learning Objectives

1. Describe several definitions of learning which vary depending on theoretical perspective.
2. Discuss the claim that behavior is not random, but orderly and lawful.
3. Describe the fundamental law that governs the organization of behavior and the origin of that natural law.
4. Explain the similarities and differences between information in genes and learned information.
5. Discuss the nature-nurture continuum.
6. Describe examples of "biological preparedness" or biological constraints on learning.

Overview

In this section, we examine learning and how it contributes to the adaptive organization of mind and behavior. To understand learning within its broader biological context, it is important to compare it with genetic information, the other major source of information that organizes behavior into adaptive patterns. Learning refers to behavioral change as a result of experience, but learning is not a single, unitary phenomenon. Instead there are many types of learning which are specialized to adapt to various features of the environment and to solve a variety of adaptive problems. In other words, learning evolved in many forms to serve a range of adaptive functions. Learned and genetic sources of information interact to organize behavior into adaptive patterns. The relative contribution of each varies with the species and the behavior in question.

Learned and Genetic Sources of Information Shape Adaptive Behavior

Learning is defined differently by different psychologists depending upon the theoretical emphasis of the psychologist. Strict behaviorists rejected explanations of behavior that involved reference to internal mental processes. Instead, they emphasized the measurable relations between observable behaviors and observable stimuli. Consequently, behaviorists usually define learning as a change in behavior as a result of experience (excluding changes due to fatigue or other special circumstances). Cognitive psychologists, partially in reaction against strict behaviorism, are more likely to define learning as acquisition of information as a result of experience. From an evolutionary perspective, learning can be thought of as the acquisition of information during the lifetime of the individual animal. This last phrase differentiates learned information from genetic information which is acquired over the evolutionary history of the species.

Behavior is not random. Instead, like all of nature, behavior follows natural laws. An evolutionary perspective applied to learning emphasizes the role of learning as a means of achieving successful adaptation. Certainly, the ability to learn new behaviors in response to new situations encountered in the environment is valuable to survival and therefore increases the chances for reproduction and the transmission of one's genes into future generations, including genes for learning itself. This consideration is important because it suggests how and why learning evolved. It also suggest why behavior is orderly and lawful. Behavior is organized to promote survival and reproduction. This outcome is an inevitable product of the forces of evolution, most notably, natural selection. Thus, learning itself is an evolved property of nervous systems. The properties and laws of learning have evolved and are consistent with the primary law of evolution, natural selection. Learning reflects this law so that learned information organizes behavior in ways that serve an animal's biological fitness in the "struggle for existence" (to the extent that this is not true for any individual animal or human, we recognize some form of behavioral or psychological pathology). In section 10.2, we discuss in more detail how different forms of learning contribute to adaptation and improve biological fitness to particular features of the environment.

Figure 4.2.23.1: Dusky Langur infant and mother. In the first few months the infant is constantly breast-fed. The mother must teach her infant to eat leaves, as shown in this photo. (Image and caption adapted from Wikimedia Commons; File:Dusky Langur infant learning to eat leaves.jpg; https://commons.wikimedia.org/wiki/F...eat_leaves.jpg; by: Roughdiamond21; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

Behavior, and other traits of organisms, ultimately are organized by information. Just like a builder needs information in the form of structural plans to construct a building, information is required to build and operate an organism, including the guidance of its movement, its behavior. In short, behavior is not random, but orderly and lawful, because it is organized by information selected and filtered by two processes. Learning is one source of the information that organizes behavior into adaptive patterns. The laws of learning tend to organize learned behavior in ways that serve adaptation to the environment. This is because the laws of learning themselves are evolved properties of brains, and natural selection shaped these laws into adaptive form so that learned behavior tends to increase survival and reproduction. The second informational source for the adaptive organization of living things is in genes, already discussed briefly above, and in some detail in Chapter 3 on evolution and genetics. From earlier discussion, we know that genetic information is filtered over countless generations by natural selection and other processes of evolution (see Chapter 3) so that the information transmitted across generations in genes generates traits that, in general, contribute to survival and reproduction (genetic abnormalities are, of course, an exception). In short, information is required to organize living things and their functioning. This information comes from two sources: 1) genes and genetic evolution; and 2) learning and laws of learning (in those organisms that are capable of learning).

Let's compare these two sources of information which organize behavior into forms which help an animal adapt to environmental demands (see Table 10.1.1 below).

First, genetic information is available to all living organisms on earth, but learned information is available only to species whose brains are equipped with properties that make learning possible. Do flies learn? Do cockroaches? Do frogs? If they do, how much do they learn, how readily do they learn? How important is learning in the life of a frog compared to how important learning is in the life of a dog, a chimpanzee, or a human? In general, learning is more characteristic of the brains of the more complex animals, especially the mammals. Nevertheless, learning does occur even in many invertebrates (animals without backbones, such as insects or squid and octopus; I once visited the lab of a psychologist at the University of Hawaii who was studying learning in bees). Usually, however, the more complex the animal's brain, the more likely it is that the animal has well developed capacities for learning--capacities for the acquisition of information during its individual lifetime.

Secondly, genetic information has been acquired and transmitted generation after generation over the entire genetic history of the species. For example, think of flies, or pelicans. As you know from your own personal observation, flies are very good at flying. And so are pelicans. They ride the air currents perfectly and skim the ocean only inches above it, their paths rising and falling with the tops of breaking waves. As the wave rises they rise just enough to stay inches above the wave while flying at perhaps 30 miles per hour or more. When the pelican dives to catch a fish, it tucks its wings just at the right moment, and it rarely misses its target. How do these birds (and flies) know how to fly at all, and to fly and dive so well?

Figure 4.2.23.2: Brown pelican tucking its wings as it dives for a fish. Genetic information controls the complex, precisely timed movements involved (Image from Wikimedia Commons; File:Brown pelican (Pelecanus occidentalis occidentalis) diving.jpg; https://commons.wikimedia.org/wiki/F...is)_diving.jpg; By Charles J. Sharp, Sharp Photography; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

Over the evolutionary history of these diverse species (one an insect, the other a large bird), natural selection has preserved the genetic information that allows flies and pelicans to fly (they don't learn it); and it is just the right information needed to organize the complex movements of flight in these two very different species.

How did the "right" information, information that so perfectly organizes the movements required for flight, get into fly DNA and pelican DNA? Of course, the answer is natural selection. The wrong information has been weeded out over thousands of generations by natural selection, leaving for reproduction to future generations only the "correct" information, the information that guides with precision the complex movements required for flight in these two species. Note that this involves an information acquisition process, but it is species-wide and takes place over the thousands and thousands of generations that make up the genetic and evolutionary history of each species. The primary mechanism for acquisition of genetic information, the "correct" (i.e., adaptive) genetic information, is natural selection. Its method of transmission is heredity.

By contrast, learned information is acquired not over the genetic history of the species, but during the short lifetime of the individual animal. This is useful because some changes in the environment that may impact chances for survival and reproduction (successful adaptation) may be temporary or highly specific or even unique to the experience of only one or a few individuals within a species. Such changes are far too rapid and too specific to one or a few individuals for the relatively slow processes of natural selection to operate. For example, learning where the local water holes are would certainly be very useful to a lion during the dry season. Dependence upon genetics for this type of information isn't likely to work very well. Learning mechanisms are required.

Figure 4.2.23.3: Lioness drinking from small water hole on the African savannah. Information about location of water on the savannah changes too rapidly to be incorporated into genes and therefore must be learned (Image from Wikimedia Commons; File:Lioness drinking.jpg; https://commons.wikimedia.org/wiki/F...s_drinking.jpg; By James Wagner; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

In sum, the mechanisms of information acquisition are different for genetic information (the law of natural selection and the laws of heredity) and for learning (the laws of learning; see below), but both result in information acquisition. In the healthy organism this information facilitates adaptation to the environment (with some exceptions as when learning goes awry; an example would be behavioral pathologies such as drug addiction where drugs such as amphetamine, by virtue of their chemical structure, activate pleasure circuits in the brain when they shouldn't be activated, thereby reinforcing harmful drug-taking behaviors; see chapter on psychoactive drugs).

Thirdly, the mode of coding and storage is different for genetic information compared to learned information. Remember, DNA forms a molecular code for coding and storage of genetic information. Learned information is coded and stored in memory systems in brains. We don't yet know all the details of the coding and storage mechanisms in learning. Early theories proposed a molecular storage mechanism in brain proteins. This led to memory transfer experiments in the 1970's wherein an animal was taught something, like a conditioned response to a signal, and then killed, and its brain ground up in a malt mixer; the liquid brain was centrifuged to extract brain proteins or RNA molecules, which were then injected into the brains of untrained recipient animals. These animals were then tested to see if they showed the conditioned response to the signal, that is, to see if they had memory for something they had not experienced themselves. Some positive results were reported by some labs; but most labs could not get the memory transfer effect and this line of research disappeared after a few years. Current research suggests that changes in existing synapses, making them more or less responsive, and/or formation of new synapses, stores learned information in memory. We will cover the details of synaptic change in section 10.4.
