PHYSIOLOGICAL PSYCHOLOGY

Ivette Merced
Irvine Valley College

Physiological Psychology (IVC PSYCH003)

This text is disseminated via the Open Education Resource (OER) LibreTexts Project (https://LibreTexts.org) and like the thousands of other texts available within this powerful platform, it is freely available for reading, printing, and "consuming."

The LibreTexts mission is to bring together students, faculty, and scholars in a collaborative effort to provide an accessible, and comprehensive platform that empowers our community to develop, curate, adapt, and adopt openly licensed resources and technologies; through these efforts we can reduce the financial burden borne from traditional educational resource costs, ensuring education is more accessible for students and communities worldwide.

Most, but not all, pages in the library have licenses that may allow individuals to make changes, save, and print this book. Carefully consult the applicable license(s) before pursuing such effects. Instructors can adopt existing LibreTexts texts or Remix them to quickly build course-specific resources to meet the needs of their students. Unlike traditional textbooks, LibreTexts' web based origins allow powerful integration of advanced features and new technologies to support learning.

LibreTexts is the adaptable, user-friendly non-profit open education resource platform that educators trust for creating, customizing, and sharing accessible, interactive textbooks, adaptive homework, and ancillary materials. We collaborate with individuals and organizations to champion open education initiatives, support institutional publishing programs, drive curriculum development projects, and more.

The LibreTexts libraries are Powered by NICE CXone Expert and were supported by the Department of Education Open Textbook Pilot Project, the California Education Learning Lab, the UC Davis Office of the Provost, the UC Davis Library, the California State University Affordable Learning Solutions Program, and Merlot. This material is based upon work supported by the National Science Foundation under Grant No. 1246120, 1525057, and 1413739.

Any opinions, findings, and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the National Science Foundation nor the US Department of Education.

Have questions or comments? For information about adoptions or adaptions contact info@LibreTexts.org or visit our main website at https://LibreTexts.org.

The LibreTexts name, logo, and book covers are trademarked by LibreTexts, Inc. (a 501(c)(3) not-for-profit organization) and protected against unauthorized use.

TABLE OF CONTENTS

Licensing

1: Part I- Foundations of Physiological Psychology

1.1: What is Physiological Psychology?

1. What are the Divisions of Biopsychology?

1.2: History and Introduction to Physiological Psychology aka Neuroscience

1.2.1: History of Biopsychology

1.3: Connecting Biology to Behavior

1.4: Comparative Neuroscience

1.4.1: Introduction

1.4.2: How Do We Choose A Model System?

1.4.3: How Do We Compare Brains?

1.4.4: How Do Brains Vary in Size?

1.4.5: How Do Connections Differ Across Species?

1.4.6: How Can Diverse Species Help Us Make Inferences about Human Neurobiology?

1.4.7: How Can Brain Organoids Help Us Make Inferences about Brain Evolution?

1.4.8: Section Summary

1.4.9: Key Terms

1.4.10: References

1.4.11: Multiple Choice

1.4.12: Fill in the Blank

1.5: Functional Anatomy- Nervous System Anatomy -Functional Anatomy of the Cerebral Cortex and Spinal Cord

1.5.1: Nervous System Tissue

1.5.2: Nervous System Structure and Terminology

1.5.3: Nervous System Development

1.5.4: The Central Nervous System

1.5.5: The Peripheral Nervous System

1.5.6: Communication and the Endocrine System

1.6: Structure and Function of the Nervous System- Cells and Anatomy

1.6.1: Introduction

1.6.2: Building a Nervous System

1.6.3: Organization of the Nervous System

1.6.4: The Central Nervous System- CNS

1.6.5: The Brain- Structure and Function

1.6.6: The Peripheral Nervous System - PNS

1.6.7: Section Summary

1.6.8: Key Terms

1.6.9: References
1.6.10: Multiple Choice (IVETTE DELETE OR KEEP?)
1.6.11: Fill in the Blank IVETTE DELETE OR KEEP?
1.6.12: Genetics and Evolution
1.6.13: Neurophysiology
1.6.13.1: Introduction
1.6.13.2: Neural Communication
1.6.13.3: Neural Circuits
1.6.13.4: Principles of Bioelectricity
1.6.13.5: Mechanisms of Neural Signaling
1.6.13.6: Our Deep but Still Incomplete Understanding of Neural Signaling
1.6.13.7: Section Summary
1.6.13.8: Key Terms
1.6.13.9: References
1.6.13.10: Multiple Choice IVETTE KEEP OR DELETE?
1.6.13.11: Fill in the Blank

1.7: Neuronal Communication
1.7.1: Neurons and their Basic Functions
1.7.2: Neurons Generate Voltage Changes to Code Information
1.7.3: Synaptic Transmission

1.8: Basic Neurochemistry
1.8.1: Introduction
1.8.2: General Neurochemistry Principles
1.8.3: Neurotransmitters Made from Amino Acids
1.8.4: Neurotransmitters Made from Fats
1.8.5: Section Summary
1.8.6: Key Terms
1.8.7: References
1.8.8: Multiple Choice
1.8.9: Fill in the Blank

1.9: Neurodevelopment
1.9.1: Introduction
1.9.2: Gastrulation and Formation of the Neural Tube (Neurulation)
1.9.3: Growth and Development of the Early Brain
1.9.4: Synapse Formation and Maturation
1.9.5: Experience Dependent Plasticity
1.9.6: Section Summary
1.9.7: Key Terms
1.9.8: References

1.9.9: Multiple Choice
1.9.10: Fill in the Blank

1.10: Neuroimmunology
1.10.1: Introduction
1.10.2: Cells and Messengers of the Immune System
1.10.3: What Does Your Immune System Have to Do with Your Behavior?
1.10.4: How Does the Brain Talk to the Immune System?
1.10.5: What Do Immune System Signals Do Once They Reach the Brain?
1.10.6: Section Summary
1.10.7: Key Terms
1.10.8: References
1.10.9: Multiple Choice
1.10.10: Fill in the Blank

1.11: Research Methods- Histology Imaging and Stimulating- Histology Review
1.11.1: Introduction to Research in Biological Psychology
1.11.2: Non-Invasive Techniques- Structural Imaging
1.11.3: Non-Invasive Techniques- Direct Functional Imaging Techniques
1.11.4: Non-Invasive Techniques- Indirect Functional Imaging Techniques
1.11.5: Other Non-Invasive Techniques
1.11.6: Invasive Techniques
1.11.7: Ethical Considerations

2: Part II- Sensory and Motor Systems
2.1: Senses Overview

2.2: Vision
2.2.1: Introduction
2.2.2: An Overview of the Visual System
2.2.3: The Retina
2.2.4: Visual Processing Begins in Bipolar, Horizontal, Amacrine and Ganglion Cells
2.2.5: The Thalamus and Primary Visual Cortex
2.2.6: Extrastriate Cortex
2.2.7: Unsolved Questions In Visual Perception
2.2.8: Section Summary
2.2.9: Key Terms
2.2.10: References
2.2.11: Multiple Choice
2.2.12: Fill in the Blank
2.2.13: Vision

2.3: Hearing, Balance, and the Chemical Senses
2.3.1: Introduction

2.3.2: Acoustic Cues and Signals
2.3.3: How Does Acoustic Information Enter the Brain?
2.3.4: How Does the Brain Process Acoustic Information?
2.3.5: Balance- A Sense of Where You Are
2.3.6: Section Summary
2.3.7: Key Terms
2.3.8: References
2.3.9: Multiple Choice
2.3.10: Fill in the Blank
2.3.11: Introduction
2.3.12: The Chemical Senses are Several Distinct Sensory Systems
2.3.13: The Gustatory System
2.3.14: The Olfactory System
2.3.15: Chemethesis, Spices, and Solitary Chemosensory Cells
2.3.16: Influences That Shape Perception of Smell and Flavor
2.3.17: Section Summary
2.3.18: Key Terms
2.3.19: References
2.3.20: Multiple Choice
2.3.21: Fill in the Blank
2.3.22: Hearing

2.4: Taste and Smell

2.5: Touch, Pain, and Movement

2.5.1: Introduction
2.5.2: Somatosensory Receptors
2.5.3: Somatosensation in the Central Nervous System
2.5.4: Pain and Itch
2.5.5: Pain Relief
2.5.6: Section Summary
2.5.7: Key Terms
2.5.8: References
2.5.9: Multiple Choice
2.5.10: Fill in the Blank
2.5.11: Introduction
2.5.12: The Physiological Actions Implementing Movement – Contraction of Muscles
2.5.13: Eliciting Contractions from Lower Levels – Lower Motoneurons and Reflex Arcs
2.5.14: Our Brain Gets Involved – Responsibilities of Upper Motor Systems
2.5.15: Section Summary
2.5.16: Key Terms
2.5.17: References

2.5.18: Multiple Choice
2.5.19: Fill in the Blank
2.5.20: Touch

2.6: Motor Control
2.6.1: Classification of Muscle Types and Functions
2.6.2: Synaptic Control of Movement- Neuromuscular Junction and Motor Units
2.6.3: Spinal Reflexes
2.6.4: Motor Circuitry- Neural Structures and Pathways
2.6.5: Impact of Disease States and Neural Damage on Motor Control

2.7: Psychophysical Methods
2.8: Sensation vs Perception
2.9: Gestalt Principles of Perception

3: Part III- Rhythms, Drives, and Motivation
3.1: Biological Rhythms, Sleep, and Homeostasis
3.1.1: Introduction
3.1.2: What Are Circadian Rhythms?
3.1.3: Where Are Rhythms in the Brain?
3.1.4: Regulation of Sleep
3.1.5: Disorders of Sleep and Circadian Rhythms
3.1.6: Circadian Rhythms and Society
3.1.7: Section Summary
3.1.8: Key Terms
3.1.9: References
3.1.10: Multiple Choice
3.1.11: Fill in the Blank
3.1.12: Introduction
3.1.13: Principles of Homeostasis
3.1.14: Neural Control of Blood Oxygenation Levels
3.1.15: Neural Control of Core Body Temperature
3.1.16: Neural Control of Feeding Behavior
3.1.17: Neural Control of Drinking Behavior
3.1.18: Section Summary
3.1.19: Key Terms
3.1.20: References
3.1.21: Multiple Choice
3.1.22: Fill in the Blank
3.1.23: Consciousness
3.1.24: What is Sleep?
3.1.25: Stages of Sleep

3.1.26: The Brain and Sleep
3.1.27: Theories of Sleep
3.1.28: Sleep Disorders
3.1.29: Maintaining Water Balance
3.1.30: Triggering Drinking Behavior - Osmometric and Volumetric Thirst
3.1.31: Ingestive Behavior Basics
3.1.32: Digestion and the Hormonal Control of Metabolism
3.1.33: Hunger - Theories, Detectors, and the Hypothalamus
3.1.34: Ingestive Behavior in Context
3.2: Homeostasis
3.3: Sexual Behavior and Development
3.3.1: Introduction
3.3.2: Understanding Sexual Reproduction and Sexual Dimorphism
3.3.3: Mechanisms of Sexual Determination and Differentiation
3.3.4: Sex Differences in Brain and Behavior- Genetic, Hormonal, and Environmental Mechanisms
3.3.5: Sex Differences in Brain Circuits and Susceptibility to Psychiatric Disease
3.3.6: Section Summary
3.3.7: Key Terms
3.3.8: References
3.3.9: Multiple Choice
3.3.10: Fill in the Blank
3.3.11: Sex Hormones, Sexual Motivation, and Reproductive Behaviors
3.3.12: Sexual Development, Anatomy and Physiology
3.3.13: Differences of Sexual Development
3.3.14: Gender
3.3.15: Sexual Orientation
3.3.16: Sex Differences and Evolutionary Interpretations
3.4: Evolution, Genes and Behaviors
3.4.1: Evolution of Minds and Behavior
3.4.2: Evolution - Mechanisms and Evidence
3.4.3: Human Evolution
3.4.4: Evolutionary Theories in Psychology
3.4.5: DNA, Chromosomes, and Gene-Environment Correlations
3.4.6: The Nature-Nurture Question
3.4.7: Epigenetics in Psychology
3.4.8: Human Genetics
3.4.9: Genes and Behavior
4: Part IV- Cognition and Emotion
4.1: Intelligence

4.1.1: Overview of Brain Mechanisms in Intelligence, Language, and Cognition
4.1.2: Cognition, Intelligence, and Language as Psychological Adaptations
4.1.3: High Intelligence-Nature or Nurture; Learning Disabilities
4.1.4: Cognition- Categories, Concepts, Schemas and the Brain
4.1.5: Brain Mechanisms and Intelligence

4.2: Learning, Memory, and Attention

4.2.1: Introduction
4.2.2: Memory is Classified Based on Time Course and Type of Information Stored
4.2.3: Implicit Memories- Associative vs. Nonassociative Learning
4.2.4: Explicit Memories- Episodic and Semantic Memories
4.2.5: Synaptic Mechanisms of Long-Term Memory
4.2.6: Section Summary
4.2.7: Key Terms
4.2.8: References
4.2.9: Multiple Choice
4.2.10: Fill in the Blank
4.2.11: Introduction
4.2.12: What are the Different Psychological Processes Associated with Attention?
4.2.13: How is Attention Implemented in the Brain?
4.2.14: What Happens to Unattended Information?
4.2.15: What is the Relationship between Attention and Eye Movements?
4.2.16: How Do Clinical Disorders Affect Attentional Function?
4.2.17: How Do We Use Executive Functions to Make Decisions and Achieve Goals?
4.2.18: Section Summary
4.2.19: Key Terms
4.2.20: References
4.2.21: Multiple Choice
4.2.22: Fill in the Blank
4.2.23: Learning, Genes, and Adaptation
4.2.24: Types of Learning and Biological Adaptation
4.2.25: Introduction to Memory and the Brain
4.2.26: Synaptic Mechanisms of Learning and Memory
4.2.27: Brain Mechanisms of Memory Disorders
4.2.28: Localization of Types and Stages of Memory
4.2.29: Hormones, Learning, and Memory

4.3: Language and the Brain

4.3.1: Introduction to Language
4.3.2: Broca's Area, Wernicke's Area, and Additional Language-Processing Areas in the Brain
4.3.3: Other Brain Models of Spoken and Written Language
4.3.4: Handedness, Language, and Brain Lateralization

4.3.5: The Right Hemisphere's Contribution to Language
4.4: Attention and Executive Function
4.5: Stress and Emotion
4.5.1: Introduction
4.5.2: What Is Stress?
4.5.3: Neural Mechanisms and Circuitry of the Stress Response
4.5.4: Interindividual Variability and Resilience in Response to Stress
4.5.5: Clinical Implications of Stress
4.5.6: Section Summary
4.5.7: Key Terms
4.5.8: References
4.5.9: Multiple Choice
4.5.10: Fill in the Blank
4.5.11: Introduction
4.5.12: Foundational and Contemporary Theories of Emotion
4.5.13: What Category of Feelings Are Considered as the “Basic Emotions”?
4.5.14: What Is the Contribution of Brain Structures in Emotional States?
4.5.15: Mood and Emotional Disorders Associated with Depression
4.5.16: Section Summary
4.5.17: Key Terms
4.5.18: References
4.5.19: Multiple Choice
4.5.20: Fill in the Blank
4.5.21: The Neurological Bases of Emotions
4.5.22: Valence of Emotions
4.5.23: Fight or Flight
4.5.24: Social Neuroscience
4.5.25: Stress and health
4.6: Emotion and Mood
5: Part V- Drugs, Disorders, and Brain Health
5.1: Psychopharmacology
5.1.1: Introduction
5.1.2: Basic Principles of Pharmacology
5.1.3: Psychotherapeutics
5.1.4: Neural Circuitry of Drug Reward
5.1.5: Neurobiology of Addiction
5.1.6: Section Summary
5.1.7: Key Terms
5.1.8: References

5.1.9: Multiple Choice
5.1.10: Fill in the Blank
5.2: Psychopharmacology and Psychoactive Drug Classification
5.3: Mechanisms of Psychoactive Drug Action
5.4: Substance Use and Addiction - Theories, Brain Mechanisms, and Treatment
5.5: Specific Drug Effects, Misuse, and Risks
5.6: Psychotherapeutics
5.7: Clinical Applications- Addiction, Developmental Disorders, Anxiety, Affective Disorders
5.8: Other Neuropsychiatric Disorders
5.8.1: Biological Factors in Psychological Disorders- An Introduction
5.8.2: Biological Basis of Mood Disorders- Major Depressive and Bipolar Disorders
5.8.3: Biological Basis of Anxiety Disorders
5.8.4: Biological Basis of Schizophrenia Spectrum Disorder
5.9: Clinical ConsiderationsL- Brain Injury and Brain Pathology
6: Answer Key
6.1: Chapter 1
6.2: Chapter 2
6.3: Chapter 3
6.4: Chapter 4
6.5: Chapter 5
6.6: Chapter 6
6.7: Chapter 7
6.8: Chapter 8
6.9: Chapter 9
6.10: Chapter 10
6.11: Chapter 11
6.12: Chapter 12
6.13: Chapter 13
6.14: Chapter 14
6.15: Chapter 15
6.16: Chapter 16
6.17: Chapter 17
6.18: Chapter 18
6.19: Chapter 19
6.20: Supplemental Content
6.20.1: Chapter 3- Population Evolution (and the Modern Synthesis)
6.20.2: Chapter 3- Phenotypic Variation and Population Genetics
6.20.3: Chapter 3- Adaptive Evolution
6.20.4: Chapter 3- Modern Primates and Their Evolution

6.20.5: Chapter 3- Material Culture
6.20.6: Chapter 10- Computer Models and Learning in Artificial Neural Networks
6.20.7: Chapter 10- Acetylcholine, Enriched Experience, and Memory
6.20.8: Chapter 10- Memory Types and Stages
6.20.9: Chapter 10- The Psychology of Memory Encoding, Storage, and Retrieval
6.20.10: Chapter 10- Psychological Factors Affecting Learning, Memory, and Forgetting
6.20.11: Chapter 14- Traditional Models of Human Intelligence
6.20.12: Chapter 14- Problem Solving, Categories and Concepts
6.20.13: Chapter 14- The Brain and Evolution of Cognition
6.20.14: Chapter 14- Mirror Neurons, Theory of Mind, Social Cognition, and Neuroscience of Its Disorders
6.20.15: Chapter 15- A Gene Essential for Speech
6.20.16: Chapter 15- The Origins of Language

1.1: WHAT IS PHYSIOLOGICAL PSYCHOLOGY?

Learning Objectives

1. Describe the field of biopsychology, its areas of focus, and other names for the field.
2. Discuss a common myth about the brain and why it is false.
3. Describe several brain imaging methods.
4. Discuss materialism (physicalism) and determinism as assumptions underlying biopsychology.
5. Describe the principle of brain organization referred to as "the localization of function."

Overview

Physiological Psychology is the study of biological mechanisms of behavior and mental processes. It examines the role of the nervous system, particularly the brain, in explaining behavior and the mind. This section defines biopsychology, critically examines a common myth about the brain, and briefly surveys some of the primary areas of research interest in biopsychology.

Biopsychology - The Interaction of Biology and Psychology

Psychology is the scientific study of behavior and mental processes in animals and humans. Modern psychology attempts to explain behavior and the mind from a wide range of perspectives. One branch of this discipline is biopsychology which is specifically interested in the biological causes of behavior and mental processes. Biopsychology is also referred to as biological psychology, behavioral neuroscience, physiological psychology, neuropsychology, and psychobiology. The focus of biopsychology is on the application of the principles of biology to the study of physiological, genetic, evolutionary, and developmental mechanisms of behavior in humans and other animals. It is a branch of psychology that concentrates on the role of biological factors, such as the central and peripheral nervous systems, neurotransmitters, hormones, genes, and evolution on behavior and mental processes.

Biological psychologists are interested in measuring biological, physiological, or genetic variables in an attempt to relate them to psychological or behavioral variables. Because all behavior is controlled by the central nervous system (brain and spinal cord), biopsychologists seek to understand how the brain functions in order to understand behavior and mental activities. Key areas of focus within the field include sensation and perception; motivated behavior (such as hunger, thirst, and sex); control of movement; learning and memory; sleep and biological rhythms; and emotion. With advances in research methods, more complex topics such as language, reasoning, decision making, intelligence, and consciousness are now being studied intensely by biological psychologists.

Do humans use only 10% of their brains?

The frequently repeated claim that humans use only 10% of their brains is false. The exact origin of this myth is unknown, but misinterpretations of brain research are likely to blame. In experiments with animal brains during the 1800's through the early 1900's, Marie-Jean-Pierre Flourens and Karl Lashley destroyed and/or removed as much as 90% of the brain tissue of their animal subjects. Nevertheless, these animals could still perform basic behavioral and physiological functions. Some who read these results made the incorrect assumption that this meant that animals were using only 10% of their brains. Subsequently, this interpretation was generalized to humans (Elias and Saucer, 2006). Furthermore, prominent psychologists and researchers, such as Albert Einstein, Margaret Mead, and William James, were also quoted as saying that humans are using only a small portion of their brain (Elias and Saucer, 2006), fueling the 10% myth.

Due to advances in biopsychology and other related fields, we now have a greater understanding of the complexity of the brain. We may not be using our brains as efficiently as possible at all times, but we are using the entirety of our brain as each part contributes to our daily functioning. Studies of humans with brain damage have revealed that the effects of brain damage are correlated with where the damage is and how extensive it is. In other words, where damage occurs determines what functions are impacted and more damage has more of an effect. This reflects a key organizational principle of the brain: the localization of function. This principle means that specific psychological and behavioral processes are localized to specific regions and networks

of the brain. For example, we now know that damage to an area of the brain known as the primary visual cortex, at the very back of your head in the occipital lobe, will result in blindness even though the rest of your visual system, including your eyes, is functioning normally. This syndrome is known as cortical blindness, to distinguish it from blindness that is caused by damage to the eyes. We now know that damage to a small area less than the size of a quarter at the very base of your brain results in disruption of feeding and regulation of body weight. Damage to another area of the brain located near your temples disrupts your ability to form new memories for facts and events, while leaving your ability to learn new motor tasks (such as skating or riding a bike) completely unaffected. Damage to another brain area causes face blindness, or prosopagnosia, a disorder in which the afflicted individual can still see normally except that they cannot recognize familiar faces, even the faces of close family members or even their own face in a photograph.

In the pages that follow in this textbook, you will learn many amazing things about the brain, and the nervous system in general. Get ready for many surprises as we explore the 3 pounds of brain tissue between our ears that make up the most complex piece of matter in the known universe. In this book, we examine some of what scientists now know about this astonishing organ, the brain, and how it functions to produce mind and behavior.

The Brain

The most important organ controlling our behavior and mental processes is the brain. Therefore, biopsychologists are especially interested in studying the brain, its neurochemical makeup, and how it produces behavior and mental processes (Wickens, 2021).

Figure 1.1.1: Photo of the left side of a human brain. Front is at the left. The massive cerebral cortex hides many subcortical brain structures beneath. Note the folds on the surface of the cerebral cortex. This folding increases in mammal species with increasing complexity of the brain of the species and is thought to originate from the "cramming" of more cortical tissue into the skull over evolutionary time. (Image from Wikimedia Commons; File:Human brain NIH.png; https://commons.wikimedia.org/wiki/F..._brain_NIH.png; image is from NIH and is in the public domain.).

Modern technology through neuroimaging techniques has given us the ability to look at living human brain structure and functioning in real time. Neuroimaging tools, such as functional magnetic resonance imaging (fMRI) scans, are often used to observe which areas of the brain are active during particular tasks in order to help psychologists understand the link between brain and behavior.

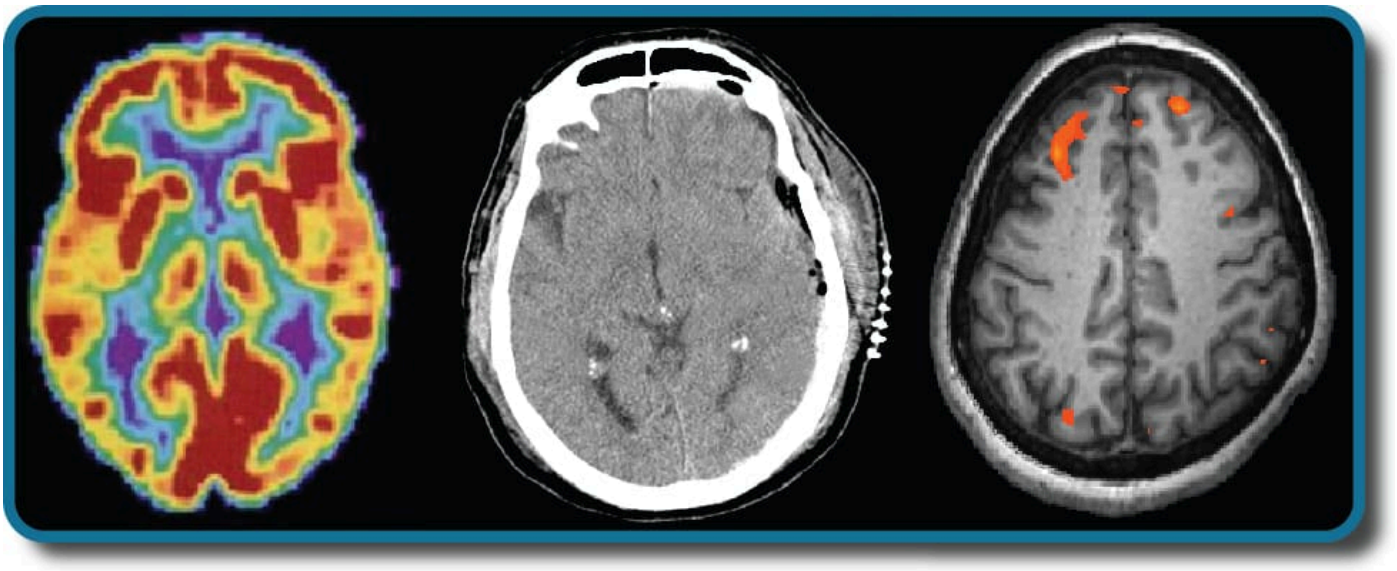

Figure 1.1.2: Brain Imaging Techniques (Copyright; author via source)

Different brain-imaging techniques provide scientists with insight into different aspects of how the human brain functions. Three types of scans include (left to right) PET scan (positron emission tomography), CT scan (computed tomography), and fMRI (functional magnetic resonance imaging). (credit “left”: modification of work by Health and Human Services Department, National Institutes of Health; credit “center": modification of work by "Aceofhearts1968"/Wikimedia Commons; credit “right”: modification of work by Kim J, Matthews NL, Park S.)

Magnetic resonance imaging (MRI) scans of the head are often used to help psychologists understand the links between brain and behavior. As will be discussed later in more detail, different tools provide different types of information. A functional MRI, for example, provides information regarding brain activity while an MRI provides only information about structure.

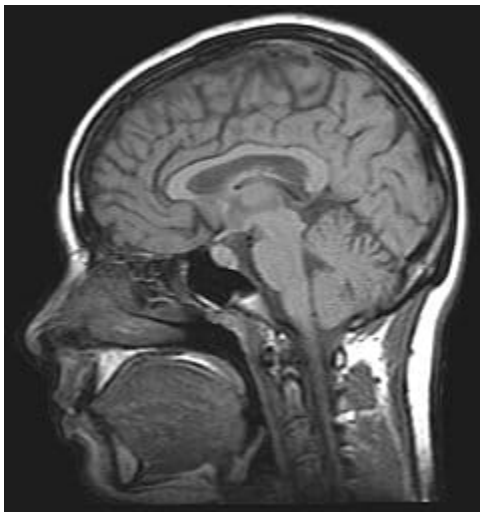

Figure 1.1.3: MRI of Human Brain (public domain; via Wikimedia Commons)

A Scientific Model of the Universe: Two Basic Assumptions

The modern scientific view of the world assumes that there are at least two fundamental properties of the universe. The first assumption common to most scientists is that the entire universe is material or physical, composed exclusively of matter (including so-called dark matter) and energy (including electromagnetic energies such as light, heat, ultraviolet, and various other radiant energies, as well as other physical energies and forces such as electrical, gravitational, nuclear, and so forth). The entire universe is governed by physical laws. This view of the universe is called **materialism or physicalism**--the view that everything

that exists in the universe consists of matter, energy, and other physical forces and processes.

Most important to biopsychology is the application of this principle to psychology and psychological processes. If everything in the universe is physical, then applied to psychology, including biopsychology, this means that the mind, our mental processes and subjective mental experiences, must also be entirely physical processes in an entirely material brain. Using this fundamental assumption of the modern scientific view of the universe, this means that the mind is entirely material, dependent upon the physical activities of an entirely material organ, the brain. On this view, the mind is what the brain does, and the brain and its processes are completely physical, material, just matter and energy in highly specific and organized form. This does not mean that all matter is conscious, nor does it mean that the mind is just energy. The key idea is that the matter and energy must be organized in a particular way. That is, a mind, consciousness, can only emerge from matter, energy, and physical processes if they are organized in a very specific and complex form--that form that we know as a brain and its physical operations. Where did brains come from and how did they acquire the specific organization of matter and energy needed to make a conscious mind within them? The scientific answer is evolution.

Although this is the view among most biological psychologists, there are a few who believe, like many students do, that the brain, along with the rest of life, was created by a divine being and that therefore the mind has divine origins. Typically, this belief is accompanied by the assumption that the mind is not physical, but that it is akin to the soul and the soul is believed to be non-material. Belief that the mind is non-material and therefore independent of the physical brain and its physical processes is known as **mind-body dualism or mind-brain dualism,** which literally means that the mind and the functioning of the brain (assumed to be entirely physical) are two (dual) separate processes, completely independent of one another. The origin of dualism is often attributed to the 17th century French philosopher and mathematician, Rene Descartes. If this view were true, then we would expect that brain damage would have no effect on the mind. However, brain damage does affect the mind and the specific location of the damage produces more or less specific, fairly predictable, effects on the mind, modifying the mind and behavior in various ways. Examples of this are coma due to head injury; the effects of Parkinson's disease on movement after the disease damages areas of the brain known as the basal ganglia; changes in personality and emotion due to injury to the front of the brain, specifically the frontal lobes; memory loss in Alzheimer's Disease; and so on. Though you don't have to accept the assumption of physicalism when studying the brain if your religious beliefs are contrary to the idea, nevertheless it is important that you be aware of the assumption of physicalism/materialism that most biological psychologists accept, at least as a working hypothesis, if not a philosophical position, as they do their brain research.

The second major assumption among most scientists is **determinism**--the belief that all events in the universe have prior causes and that these causes are external to the human will. This implies that humans do not have free will. Instead human behavior is caused by events external to us such as our upbringing, our social and cultural environment, by our brain structure and functioning, and by our genes and our evolution as a species. In some versions of this viewpoint, since we do not have control over many of the factors in our environment, our genes, and our evolution as a species, our brain function and thus our behavior is actually controlled by causes outside of our control. On this view, free will is an illusion that arises from our awareness of our mental processes as we make choices based on our selection of various behavioral options that we see open to us, but what we often fail to realize is that those choices are determined by many factors beyond our awareness and control (Koenigshofer, 2010, 2016). Free will vs. determinism is an issue that is far from being resolved and remains controversial even among scientists, including biological psychologists. Investigation by biological psychologists of the brain processes involved in choice and decision-making is ongoing and may eventually shed light on this difficult issue. Again, it is not necessary for you to be a determinist to study the brain, but it is important for you to be aware of the doctrine of determinism as you consider the implications of brain research as you progress through this textbook and your course in biological psychology.

1. What are the Divisions of Biopsychology?

Learning Objectives

Learning Objectives
By the end of this section, students will be able to:

1. **Define neuroscience and describe its relationship to behavior and mental processes.**
2. **Explain the role of biopsychology as an integrative discipline within neuroscience.**
3. **Identify and describe key divisions of neuroscience (e.g., neurophysiology, neuroanatomy, neuropharmacology, developmental neuroscience, cognitive neuroscience, computational neuroscience, neurology, social neuroscience, and educational neuroscience).**
4. **Summarize how knowledge from these divisions contributes to understanding human behavior and mental processes.**
5. **Discuss examples of how different branches of neuroscience inform biopsychology's study of the brain and behavior.**

Overview

Biopsychology, often called Physiological Psychology is an integrative branch of Psychology dedicated to understanding the biological foundations of behavior and mental processes. Neuroscience itself is the broad scientific study of the nervous system, its structure, development, chemistry, and function. As research in this field has advanced, it has become increasingly clear that the ways we think, feel, and act are deeply connected to the activity of neurons and neural circuits in the brain.

Biopsychology draws on discoveries from many specialized divisions of neuroscience to build a comprehensive picture of how the brain supports behavior. For example, neurophysiology examines how neurons communicate, while neuroanatomy maps the structures that make up the nervous system. Neuropharmacology studies how substances such as medications or chemicals affect brain function, and developmental neuroscience explores how the nervous system forms and changes over time. Cognitive neuroscience links mental processes to brain activity, and computational neuroscience uses modeling and computer simulations to study information processing in the nervous system. Fields like neurology, social neuroscience, and educational neuroscience contribute clinical, social, and educational insights that deepen our understanding of brain and behavior relationships.

By integrating these perspectives, biopsychology provides a powerful framework for investigating how biological systems shape human experience. This interdisciplinary approach not only advances scientific knowledge but also informs real world applications from treating neurological disorders to improving learning environments and understanding social behavior.

Biopsychology - An Integrative Discipline

Neuroscience is the scientific study of the nervous system in all its complexity. As research in this field has advanced, it has become increasingly clear that human behavior and mental processes, the central focus of psychology, are deeply linked to the activity of the brain and its networks. Neuroscience is not limited to one area of biology; rather, it draws from and contributes to multiple biological disciplines, including anatomy, biochemistry, molecular biology, and physiology, to explore how neurons and neural circuits develop, communicate, and function. At the same time, neuroscience investigates cognition, our ability to think, reason, remember, and learn, revealing how these biological systems give rise to the behaviors and mental experiences that shape human life.

Within this broad field, biopsychology stands out as a specialized area that directly connects the workings of the nervous system with behavior and mental processes. Often referred to as behavioral neuroscience, biopsychology focuses on understanding the biological foundations of how we act, feel, and think. It is not a stand alone field; instead, it integrates knowledge from multiple divisions of neuroscience to build a clearer picture of how brain structures and functions influence behavior.

Several key branches of neuroscience contribute to this understanding. Neurophysiology examines how neurons function and communicate through electrical and chemical signals, providing insight into how information travels within the nervous system. Neuroanatomy focuses on the structure and organization of the brain and other parts of the nervous system, helping us map specific functions to specific regions. Neuropharmacology studies how substances, including medications and chemicals, affect neural activity and behavior, offering important knowledge for treating disorders or enhancing brain function. Developmental neuroscience explores how the brain and nervous system form and change from conception through adulthood, shedding light on the mechanisms that drive growth and adaptation.

Other specialized areas further enrich biopsychology. Cognitive neuroscience links thought processes such as memory, attention, and decision making to underlying neural activity. Computational neuroscience combines biology, psychology, mathematics, and computer science to model and simulate the brain's information processing functions. Neurology focuses on diagnosing and treating disorders of the nervous system, giving biopsychology clinical insights into how injuries and diseases affect behavior. Social neuroscience investigates how the brain processes social information and how interactions with others shape our thoughts and actions. Finally, educational neuroscience or neuroeducation seeks to bridge research on brain function with practical strategies for improving teaching and learning in classrooms.

By integrating findings from all these areas, biopsychology offers a comprehensive and continually evolving perspective on the connection between biology and behavior. This interdisciplinary approach not only deepens our scientific understanding of the mind and brain but also has far reaching applications, from developing treatments for neurological disorders to enhancing learning and fostering healthier social interactions.

Summary

Chapter Summary: Biopsychology as an Integrative Discipline

In this section, we explored biopsychology—often referred to Physiological Psychology and its central role in connecting the biology of the nervous system with human behavior and mental processes. Neuroscience, the scientific study of the nervous system, has revealed that every thought, emotion, and action is deeply intertwined with activity in the brain. It draws on many areas of biology, including anatomy, biochemistry, molecular biology, and physiology, to explain how neurons and neural circuits function. Beyond structure and function, neuroscience also illuminates higher processes such as memory, learning, decision making, and problem solving.

Biopsychology builds on these foundations by focusing specifically on the biological basis of behavior. It is not an isolated field but rather an integrative discipline that relies on knowledge from many branches of neuroscience. Throughout the chapter, we examined how these branches contribute unique perspectives:

- Neurophysiology reveals how neurons communicate through electrical and chemical signals.
- Neuroanatomy maps the structures of the nervous system and links them to specific functions.
- Neuropharmacology studies how substances influence neural activity and behavior.
- Developmental neuroscience examines how the brain forms, grows, and adapts across the lifespan.
- Cognitive neuroscience connects mental processes such as memory and attention to neural activity.
- Computational neuroscience models information processing in the brain through mathematical and computer-based approaches.
- Neurology provides clinical insights into disorders of the nervous system.
- Social neuroscience studies how the brain processes social information and how others influence our thoughts and actions.
- Educational neuroscience applies our understanding of brain processes to improve teaching and learning.

By bringing these areas together, biopsychology offers a comprehensive view of how biological systems give rise to the rich complexity of human behavior. This chapter highlighted how each discipline contributes to a larger understanding of the brain, laying the groundwork for future exploration in areas such as cognition, intelligence, mental health, and applied neuroscience.

1.2.1: History of Biopsychology

Learning Objectives

1. Discuss the history of biopsychology.
2. Discuss the important contributors to biopsychology and the contributions each made.
3. Explain the current direction of biopsychology.

Overview

Biopsychology as a scientific discipline is relatively new. However, early philosophers such as Hippocrates wrote about the importance of biological factors in human behavior. In this section, we will examine the emergence of biopsychology as a scientific field. We will further outline important events and contributions to biopsychology, beginning with early philosophers and their understanding of the biological aspects of behavior and mental processes. We then examine a number of more recent historical figures who made major contributions to the development of biological psychology and discuss their contributions to the discipline. Lastly, we will look at current directions in the field.

Biopsychology as a Discipline

Biopsychology as a scientific discipline emerged from a variety of scientific and philosophical traditions in the 18th and 19th centuries. Although the exact date of inception of biological psychology is unknown, there have been a number of milestones in its emergence. William James in his book, *The Principles of Psychology* (1890), argued that the scientific study of psychology should be grounded in an understanding of biology (Walinga, 2014). Like many early psychologists, James had extensive training in physiology.

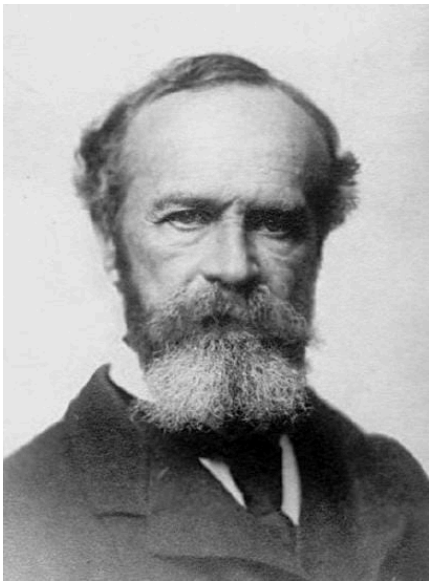

Figure 1.2.1.1: William James. (Public Domain; via Wikimedia Commons)

In *An Outline of Psychobiology,* Knight Dunlap used the term "psychobiology" to explain the role of biology in behavior. In 1949, Donald Hebb wrote his influential book, *The Organization of Behavior*, where he introduced the first comprehensive theory on how the brain might create and control complex psychological functioning, such as thought, memories, emotions and perceptions. In other words, even before biopsychology was formally recognized as a branch of psychology or as a discipline, the connection between psychology and biology was recognized. With case studies such as Phineas Gage and invention of methods such as the electroencephalogram (EEG) and computed tomography (CT or CAT) scans, scientists began to link the brain to specific behavior and cognition as biopsychology as a discipline began to emerge.

The Origins of Biopsychology

It is important to examine the historical path of our understanding of the brain and its role in our behavior and mental processes. Examining the history of biopsychology allows us to understand its development over time, highlighting instances where researchers were wrong about the nature of brain-behavior relationships and revealing what we have yet to explain (Saucier and Elias, 2006). Studying the history of a scientific discipline gives us a roadmap of where we have traveled from and in what direction we need to go.

Early Views of Brain and Behavior

Early philosophers, such as Aristotle (384-322 B.C.E.), believed that one's mind resided in the heart. He believed that since our blood started from the heart, the soul also originated there. Plato (428-347 B.C.E.) argued that the executor of reason was the heart and our animalistic desires and emotions were controlled by the liver (Gross, 1987). Many ancient cultures, including the Chinese, Indian, and Egyptian also shared the same belief (Carlson, 2014). When the Egyptians embalmed a person, the heart was saved and buried with the individual but the brain was discarded (Klein and Thorne, 2006). However, there were early Greeks, such as Hippocrates (460-377 B.C.E.) , who believed that it was the brain and not the heart where the locus of the mind resided. He wrote: "It ought to be generally known that the source of our pleasure, merriment, laughter, and amusement, as of our grief, pain, anxiety, and tears is none other than the brain. It is specially the organ which enables us to think, see, and hear.....It is the brain too which is the seat of madness and delirium, of the fears and frights which assail us" (Gross, 1987, p. 843-844).

During the 3rd Century B.C., in Alexandria, a science museum was established. Since human dissection was practiced in that city for centuries, the anatomical study of the human body flourished (Gross, 1987). Two neuroanatomists, Herophilos and Erasistratos, contributed to our knowledge of the human brain. Herophilos distinguished the cerebellum (at the very base of the back of the brain) and the cerebrum (the two cerebral hemispheres). He hypothesized that since the cerebellum was denser than the other parts of the brain, it must control the muscles (a guess of impressive accuracy). And he provided the first clear description of the cavities within the brain known as ventricles (Figure 1.2.1). Erasistratos continued the work of Herphilos and proposed that human intelligence was related to the number of convolutions (ridges) in the brain; the more convolutions an individual's brain had, the more intelligent that person would be.

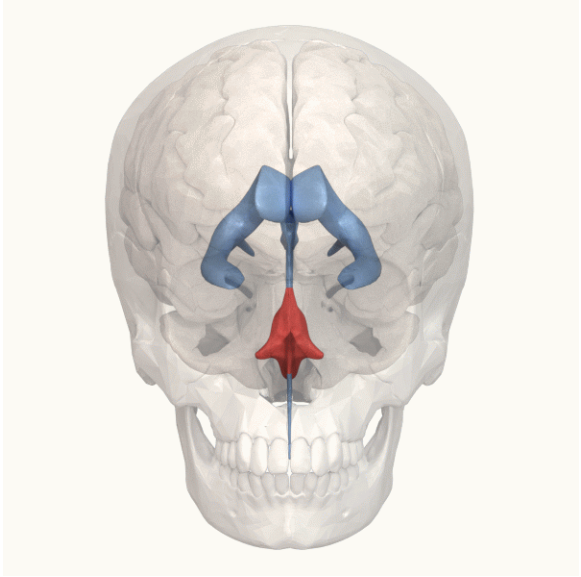

Figure 1.2.1.2: Human Ventricles (CC BY-SA 2.1; BodyParts3D by DBCLS via Wikimedia Commons)

During the Roman Empire, the Greek anatomist Galen (A.D. 130-200) dissected the brains of sheep, monkeys, dogs, pigs, among other non-human mammals (Carlson, 2014). He believed the brain to be the site of sensation and thought, and the controller of movement (Gross, 1987). He stated that spinal cord was an extension of the brain and chronicled the relationship between the spinal nerves and specific muscles each controlled. For the next advance in understanding spinal function, we must await Bell and Magendie in the 19th Century.

Middle Ages

Figure 1.2.1.3: Drawing of Ibn-Sina. (Public Domain; via Wikimedia Commons)

Avicenna (980-1037 C.E.) was a Persian physician who some regard as the father of modern medicine. He recognized biological psychology in his treatment of illnesses that involved emotions (Syed, 2002). In his book, *The Canon of Medicine (Qanun: Law of Medicine)*, Avicenna dedicated three chapters to neuropsychiatric disorders where he defined madness (Junun) as originating in the middle part of the brain. He discussed a condition similar to schizophrenia, which he called Junun Mufrit, characterized by agitation, behavioral and sleep disturbances, giving inappropriate answers to questions, and an occasional inability to speak. Avicenna also discovered the cerebellar vermis, which he simply called the vermis, and the caudate nucleus. Both terms are still used in neuroanatomy today (Mohamed, 2008). He further explained that "humidity" inside the head contributed to mood changes and when this moisture inside the brain goes beyond limits, the brain loses control over its rationality and mental disorders appear (Haque, 2004). Lastly he presented detailed knowledge about skull fractures and their surgical treatments (Aciduman, Arda, Ozakturk, and Telatar, 2009). He also discussed phenomena such as insomnia, mania, hallucinations, nightmares, dementia, epilepsy, stroke, paralysis, vertigo, melancholia, and tremors (Mohamed, 2008). He was also the first person to associate mental deficits with deficits in the brain's middle ventricle or frontal lobe (Mohamed, 2008).

Renaissance

By the beginning of the 16th century, Andreas Vesalius, founder of modern anatomy, rekindled interest in neuroscience (Gross, 1987). Through his dissection of human cadavers, Vesalius found problems with the Galenic view of anatomy (which emphasized three major systems--the heart, brain, and blood--and the importance of a balance between four bodily fluids--blood, phlegm, and black and yellow bile). Vesalius published seven books, with the fourth and seventh books devoted to the nervous system (Van Laere, 1993). Vesalius outlined seven pairs of 'brain nerves', each with a specialized function. In his seventh book which was solely devoted to the brain, he successfully describes the cerebral membranes, the ventricular system, and the cerebrum (Van Laere, 1993). Other scholars furthered Vesalius' work by adding their own detailed sketches of the human brain.

René Descartes (1596-1650) proposed the reflexive theory in terms of our behavior (Elias and Saucier, 2006). This theory explained reflexive behavior as an "external stimuli [that] would move the skin, in turn moving the filaments, releasing the animal spirits and innervating the muscles" (Elias and Saucier, 2006, p 6). His mechanical explanation of movement without conscious intervention allowed for scientific study of behavior. Furthermore, his theory encouraged using animal models to study biological bases of behavior (Cobb, 2002). He also studied the physiology of the brain, proposing the theory of dualism (the view that mind and brain are separate) to tackle the issue of the brain's relation to the mind. He suggested that the pineal gland was where the mind interacted with the body after recording the brain mechanisms responsible for circulating cerebrospinal fluid (Elias and Saucier, 2006).

Figure 1.2.1.4: Descartes Drawing - Reflexive role of pain in contracting muscle. (Public Domain; via Wikimedia Commons)

Discoveries of the 19th Century

Localization of Function

Starting in early 1800's, a series of researchers began to catalog different brain parts and their presumed role in behavior. In 1811, Jean-Cesar Legallois (1770-1840) discovered that when he destroyed tissue in the medulla, a procedure called lesioning, there was an immediate cessation of respiration (Elias and Saucier, 2006). Charles Bell (1774-1842) and Francois Magendie (1783-1840) discovered the different function of spinal cord nerves where the ventral roots transmitted motor impulses and posterior roots received sensory input (Bell-Magendie Law). Given the specialization found in spinal cord nerves, Bell recommended that further investigation of the the entire nervous system should examine functional and anatomical segregation (Elias and Saucier, 2006).

Taking on the challenge, Franz Joseph Gall (1758-1828) and Johann Spurzheim (1776-1832) formulated phrenology where measurement of the skull was used to determine personality characteristics of an individual. Gall made the claim that here were twenty-seven distinct cognitive abilities that could be localized on the cortex of the human brain (the cortex composing the outermost part of the brain). He believed that the design of the brain changed as each of us developed certain characteristics and this resulted in corresponding changes in the skull. Where the skull rises, one can see excellence in the human qualities associated with the underlying brain and where there were depressions in the skull, human defects were represented (Lau, Loi and Abdullah, 2021). Measuring the skull by using a technique called cranioscopy would allow the scientist to detect deformation and bumps on the skull which would outline the person's personality (Elias and Saucier, 2006).

In 1848, John Martyn Harlow treated Phineas Gage and documented his case. Gage, who was a railroad worker, had his frontal lobe pierced by an iron tamping rod in a blasting accident. He survived the trauma but suffered extensive damage to his left prefrontal cortex (Macmillan, 2001). Through Gage's case study, Harlow showed the connection between the prefrontal cortex damage, executive functioning, and personality changes.

In 1861, Paul Broca (1824-1880) presented a case where a young man had sustained damage to the left frontal lobe and as a result was unable to produce spoken speech. However, the patient was able to comprehend speech and had average intelligence. After his death, Broca performed an autopsy and determined that the patient had a lesion in the frontal lobe in the left cerebral hemisphere. Broca collected similar cases of damage to the left frontal lobe with the patient losing their ability to speak (Lau, Loi and Abdullah, 2021). One such case was Phineas Gage who lost his speech after his accident. Broca published his findings from the autopsies of twelve patients in 1865. Today, we recognize Broca's Area in the frontal lobe as a critical region in speech production. His work inspired others to perform careful autopsies with the aim of linking more brain regions to sensory and motor functions.

Carl Wernicke (1848-1904) further developed the theory of the specialization of specific brain structures in language comprehension and production. He wrote a paper in 1874, suggesting that housed in the left temporal lobe was an auditory comprehension center. He stated that when this area, now known as Wernicke's area, was damaged, the individual could not comprehend other's speech or use words correctly (Elias and Saucier, 2006). The concept of "localization of function", specific functions residing in specific parts of the brain, was established the end of the 19th century. Respiration and the medulla and the roles of Broca's and Wernicke's areas in language are examples of this concept.

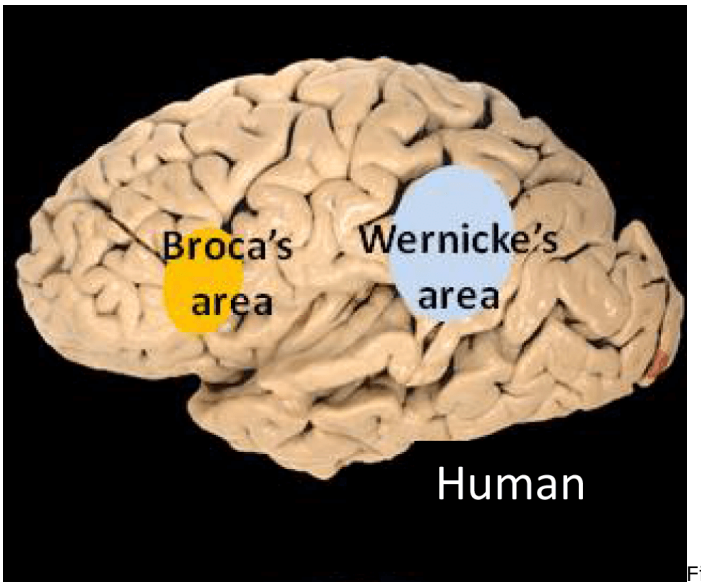

Figure 1.2.1.5: The two language areas of the brain. (Public Domain; via Wiki media Commons)

The Neuron

The last monumental neurological discovery of the 19th century was the identification of the specific structural unit responsible for these brain functions, the neuron. Studies of the brain became more sophisticated after the invention of the microscope and the development of a staining procedure by Camillo Golgi during late 1873 (Elias and Saucier, 2006). Golgi (1843-1926) was a histologist (one who studies the cellular structure of tissue) and a physician (Klein and Thorne, 2006). He used a silver chromate salt to reveal the intricate structures of single neurons (Elias and Saucier, 2006). Through this technique, he was able to reveal that the neuron has three distinct structures: dendrite, cell body, and axon (Elias and Saucier, 2006). Furthermore, he revealed that the axon can be short or very long, enabling the cell body to send messages to neurons far away. Therefore the axon must be the output carrier for the neuron. This technique is called the Golgi stain, named in his honor.

The Golgi stain technique was used by Santiago Ramón y Cajal to outline the neural connections in the brain (Elias and Saucier, 2006). While Golgi believed that neurons were fused together to form a continuous circuit, Cajal demonstrated that neurons are not physically connected but do have a mechanism for communicating (Elias and Saucier, 2006). This led to the formation of the **neuron doctrine**, the hypothesis that the functional unit of the brain is the neuron, also known as a nerve cell. Today, the field accepts neuronal theory which states that the nervous system is made up of individual nerve cells called neurons (Klein and Thorne, 2006).

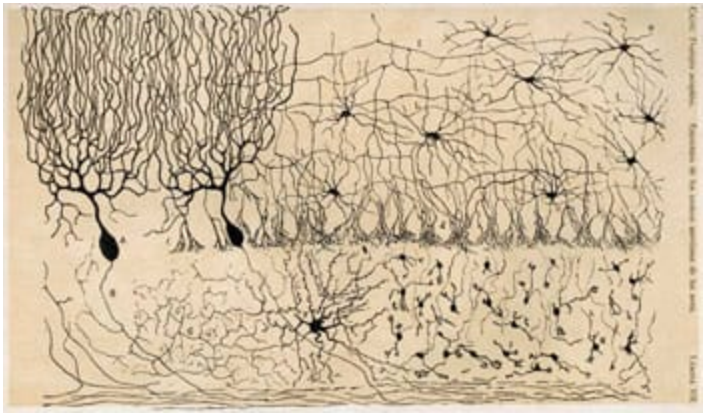

Figure 1.2.1.6: Ramon y Cajal's Drawing of A Neuron. (Public Domain; via Wikimedia Commons)

Golgi and Ramón y Cajal shared the Nobel Prize in Physiology or Medicine in 1906 for their extensive observations, descriptions, and categorizations of neurons throughout the brain. Golgi was praised for his staining technique and Cajal for developing the neuron doctrine.

One of the most important questions given Cajal's neuron doctrine was the mechanism for communication between neurons. The role of electricity in nerves and electrical communication between neurons was first observed in dissected frogs by Luigi Galvani. In 1780, he showed that an electrical stimulus applied to the motor nerve of a frog's nerve cell produced a twitch. This experiment suggested that electricity was an important functional element of the nervous system (Klein and Thorne, 2006).

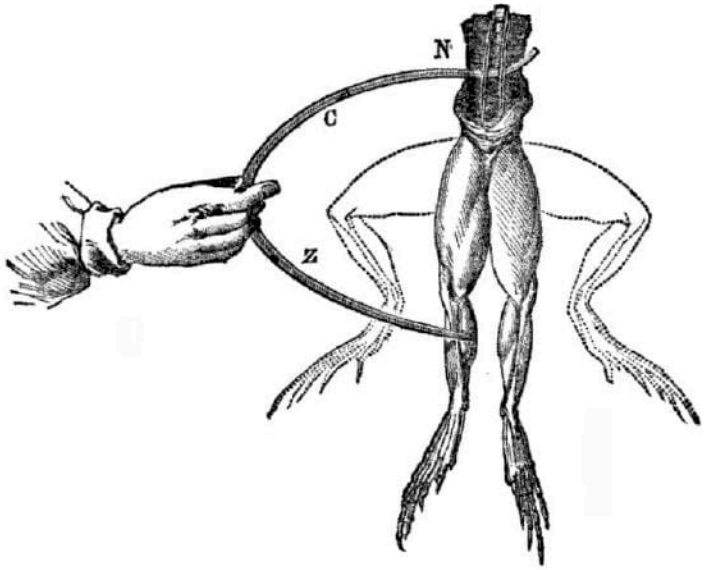

Figure 1.2.1.7: Drawing showing Galvani's Frog Leg Electricity Experiment. (Public Domain; via Wikimedia Commons)

Discoveries of the 20th Century

The Synapse

Charles Scott Sherrington (1857-1952) accepted Cajal's neuron doctrine and set out to discover the point of functional contact between neurons. He called this connection point the **synapse**, which means "binding together" (Klein and Thorne, 2006). His discovery was made by studying spinal reflexes in dogs. Confirming Galvani's electrical theory, he demonstrated the electrical transmission between neurons (Elias and Saucier, 2006). He received the Nobel Prize in 1932 for his research. A German pharmacologist and physician, Otto Loewi (1873-1961), investigated chemical communication between neurons. He removed the heart of two frogs and placed them in separate containers, each one filled with a chemical solution that allowed the hearts to continue to beat. He stimulated the vagus nerve of the first heart which slowed down its beating. He shared the solution from the first heart's container with the second heart and the beating of the second heart also slowed. He concluded that when he

stimulated the vagus nerve of the first heart, a chemical was released to slow down its beating and when the solution from the first heart's container was shared with the second heart, the chemical directed the second heart to also decrease its beating (Klein and Thorne, 2006). He originally called this chemical vagusstoff, referring to its secretion after the stimulation of vagus nerve. This chemical was later identified as a **neurotransmitter**, acetylcholine (ACh). ACh was originally identified in 1915 by Henry Hallett Dale. However, Loewi is credited with establishing its role in chemical communication between nerve cells (Klein and Thorne, 2006).

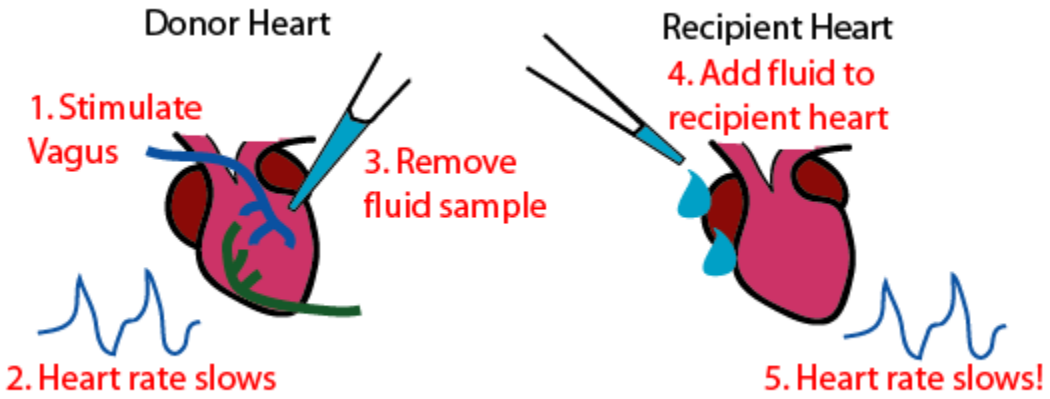

Figure 1.2.1.8: Loewi's experiment, describing the existence of Vagusstoff. (CC BY-SA 3.0; via Wikimedia Common)

Today, dozens of neurotransmitters have been identified in the brain. After acetylcholine, noradrenaline (now known as norepinephrine) was discovered in the 1940's, followed by dopamine and serotonin in the next decade and gamma-aminobutyric acid (GABA), glutamate, and glycine in the 1960's (Wickens, 2021). Later discoveries of neuropeptides, neuromodulators, and certain gases have added to the complexity of chemical communication in the brain. Our understanding of the impact and role of these chemical messengers and their effect on behavior and mental processes has given rise to the field of **psychopharmacology**.

Neural Conduction

Previous research had clearly demonstrated that electrical impulses played a role in neural communication. But the finer details of how this was occurring had not been discovered (Wickens, 2021). A series of discoveries led to our present understanding of neural conduction.

In 1902 and again in 1912, Julius Bernstein (1836-1917) was the first researcher to discover the **action potential** - the unique electrical signal traveling the length of an axon (Elias and Saucier, 2006). Additionally, he demonstrated that this electric conduction was due to change in **ionic concentration** of the cell's intracellular fluid. However, given the microscopic size of the cell, it was difficult to measure and study mammalian cells. In 1936, John Z. Young, an Oxford biologist, located a neuron in the body of a squid. The axon was nearly 1 mm in diameter which was 100 to 1,000 times larger than a mammalian axon and could be studied for about six hours after its dissection (Elias and Saucier, 2006). In 1952, two Cambridge University physiologists, Alan Hodgkin and Andrew Huxley published a set of papers describing their research on the **giant squid axon**. Much of our understanding of neural functioning came from the giant squid. Hodgkin and Huxley created a technique to measure electrical changes of the neuron by inserting an electrode inside and one positioned outside of the neuron without damaging it. This enabled them to measure **changes in electrical charge** when the neuron was at rest and when it produced an action potential (Wickens, 2021). A detailed discussion of both concepts, resting and action potential will follow in future chapters.

Studying Brain Activity and Brain Imaging

With the invention of machines such as the electroencephalograph (EEG), CT scan, and magnetic resonance imaging (MRI), scientists were able to peak into the activity and images of patients' brains while they were alive and engaged in mental activity. In 1924, Hans Berger recorded the first human brain EEG. This machine allowed researchers to study the overall electrical activity of the brain. In 1953, Kleitman and Aserinsky discovered Rapid Eye Movement (REM) using EEG on sleeping subjects. Today EEGs

are helpful in diagnosing epilepsy and sleep disorders. Many credit their work as the beginning of modern study of sleep. The first image of the brain by CT scan was in 1971 by Godfrey Hounsfield. He used the CT scan to locate a brain tumor (Wells, 2005). CT scans can be used to locate brain tumors, injury, or atrophy. However, the CT scan uses Xrays to provide an image of the brain which could pose risk to brain tissue. Magnetic resonance imaging (MRI) was also used in 1970's to give pictures of the brain. An MRI does not use Xrays and is therefore found to be a safer method for producing human brain scans.

In 1950, positron emission tomography (PET) scans were used to look at brain activity or communication in a living patient. Researchers were able to look at different parts of the brain in different situations. In other words, they could look at real time activity of the brain as the person laughed or was scared to see what ares of the brain lit up. This gave an indication of what areas of the brain maybe responsible for different emotions or behaviors. The problem with PET scans was that an individual receiving a PET scan had to drink or be injected with a mildly radioactive substance, called a tracer. Once in the bloodstream, the amount of tracer in any given region of the brain can be monitored. As brain areas become more active, more blood flows to that area. A computer monitors the movement of the tracer and creates a rough map of active and inactive areas of the brain during a given behavior. PET scans show little detail, are unable to pinpoint events precisely in time, and require that the brain be exposed to radiation. In 1990s, a group in Bell Laboratories invented functional Magnetic Resonance Imaging (fMRI). This machine shows changes in brain activity over time by tracking blood flow and oxygen levels. The fMRI provides more detailed images of the brain's structure, as well as better accuracy in time, than is possible in PET scans.

Today, these instruments have greatly contributed to our understanding of the brain and its function in behavior and cognition. With their high level of detail, MRI and fMRI are often used to compare the brains of healthy individuals to the brains of individuals diagnosed with psychological disorders. This comparison helps determine what structural and functional differences exist between these populations.

Today

In April 2013, the BRAIN (Brain Research through Advancing Innovative Neurotechnologies) Initiative was launched. The focus of this initiative was to advance our understanding of the human brain. In the fiscal year 2020, 10.1 billion U.S. dollars has been allocated to neuroscience studies (Mikulic, 2021). Different institutions, agencies and foundations such as Food and Drug Administration, Defense Advanced Research Projects Agency, have joined in this effort.

1.3: Connecting Biology to Behavior

Learning Objectives

1. Discuss the Case of Phineas Gage and its contribution to biological psychology.

Overview

While experiments are necessary to establish cause and effect relationships, in-depth studies of unique individuals or groups of people who share an experience can be used to inform our understanding of things that we can not study experimentally. Surgical errors, extreme mistreatment, and tragic accidents are impactful events that can alter individuals significantly, providing unique opportunities to study the effects of experiences which can not be ethically studied experimentally. There have been a number of these case studies which have revealed the role of different parts of the brain on our thinking and behavior. One such case is Phineas Gage. Gage lived 12 years after a rod pierced his skull, damaging his left frontal lobe. Researchers were able to gather information about his functioning before and observe his cognitive ability and personality after the accident. His case enabled the field to understand the role of frontal lobe in personality and mental processes.

The Tale of Phineas Gage

Figure 1.3.1: Phineas Gage Portrait After His Accident. (Public Domain; via Wikipedia Common)

The case of Phineas Gage is worthy of expanded coverage as his tragic accident establishes a clear connection between the brain and who we are. Gage, a 25-year-old man, was employed in railroad construction at the time of the accident. As the company's most capable employee, with a well-balanced mind and a sense of leadership, he was directing a rock-splitting workgroup while preparing the bed of the Rutland and Burlington Railroad south of Cavendish, Vermont, USA. At 4:30 PM on September 13, 1848, he and his group were blasting a rock, and Gage was assigned to put gunpowder in a deep hole inside it.

The moment he pressed the gunpowder into the hole with a bar, the friction caused sparks, and the powder exploded. The resulting blast projected the meter-long bar, which was 1.25 inches in diameter and weighed about 13.2 pounds, through his skull at high speed. The bar entered his left cheek, destroyed his eye, passed through the left front of his brain, and left his head at the top of the skull on the right side. Gage was thrown on his back and had some brief convulsions, but he woke up and spoke in a few minutes, walked with a little help, and sat in an ox cart for the 0.7-mile trip to where he was living.

Figure 1.3.2: The injury of Phineas Gage With Frontal Lobe shown in Red. (Public Domain; via Wikimedia Common)

About 30 minutes after the accident, a doctor arrived to provide medical care. Gage had lost a lot of blood, and the next days that followed were quite difficult. The wound became infected, and Phineas was anemic and remained semi-comatose for more than two weeks. He also developed a fungal infection in the exposed brain that needed to be surgically removed. His condition slowly improved after doses of calomel and beaver oil. By mid-November he was already walking around the city.

The Consequences

For three weeks after the accident, the wound was treated by doctors. During this time, he was assisted by Dr. John Harlow, who covered the head wound and then reported the case in the Boston Medical Surgery Journal. In November 1849, invited by the professor of surgery at Harvard Medical School, Henry Jacob Bigelow, Harlow took Gage to Boston and introduced him to a meeting of the Boston Society for Medical Improvement .

In his reports, Harlow described that the physical injury profoundly altered Gage's personality. Although his memory, cognition, and strength had not been altered, his once gentle personality slowly degraded. He became a man of bad and rude ways, disrespectful to colleagues, and unable to accept advice. His plans for the future were abandoned, and he acted without thinking about the consequences. And here was the main point of this curious story: Gage became irritable, irreverent, rude and profane, aspects that were not part of his way of being. His mind had changed radically. His transformation was so great that everyone said that “Gage is no longer himself.”

As a result of this personality change, he was fired and could no longer hold a steady job. He became a circus attraction and even tried life in Chile, later returning to the United States. However, there is something still little known about Gage: his personality changes lasted for about four years, slowly reverting later. As a proof of this, he worked as a long-haul driver in Chile, a job that required considerable planning and focus skills. He died on May 21, 1861, 12 years after the accident, from an epileptic seizure that was almost certainly related to his brain injury.

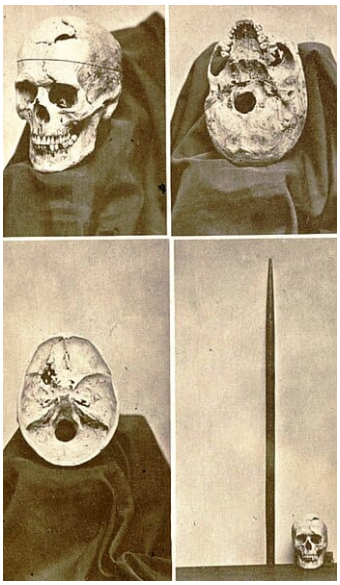

Figure 1.3.3: Frontispiece, showing multiple views of the exhumed skull, and tamping iron, of brain injury survivor Phineas Gage (Public Domain; via Wikimedia Commons

After his body was removed from its grave, Gage's mother donated his skull to Dr. Harlow who in turn donated it to Harvard University.

The Legacy

Gage's case is considered to be one of the first examples of scientific evidence indicating that damage to the frontal lobes may alter personality, emotions, and social interaction. Prior to this case, the frontal lobes were considered silent structures, without function and unrelated to human behavior. Scottish neurologist, David Ferrier, was motivated by this fact to investigate the role of frontal lobes in brain function. Ferrier removed the frontal lobes in monkeys and noted that there were no major physiological changes, but the character and behavior of the animals were altered. In other words, he confirmed the role of the frontal lobes that was suggested by Gage's accident in an experiment with a non-human animal.

Knowledge that the frontal lobe was involved with emotions continued to be studied. The surgeon Burkhardt in 1894 performed a series of surgeries in which he selectively destroyed the frontal lobes of several patients in whom he sought to control psychotic symptoms, being the modern prototype of what was later known through Antonio Egas Moniz as psychosurgery. Today, it is well understood that the prefrontal cortex of the brain controls the organization of behavior, including emotions and inhibitions.

Folkloric as it may be, but nonetheless remarkable, the contribution of Phineas Gage's case should not be overlooked, as it provided scientists the baseline for the promotion of studies in neuropsychiatry, and a source of inspiration for world medicine. In 2012, a team of neuroscientists used computer tomography of Gage's skull with typical brain MRI scans to simulate how extensive Gage's brain damage was. They confirmed that most of the damaged area was the left frontal lobe. However, surrounding areas and their neural network were also extensively severed. And it is not just the researchers who keep coming back to Gage. Medical and psychology students still learn about Gage from their history lessons. Neurosurgeons and neurologists still sometimes use Gage as a reference when evaluating certain cases. The final chapter of his life also offers us a thought-provoking discovery about cases of massive brain damage, indicating that rehabilitation may be possible.

Summary

Phineas Gage made a huge contribution to our understanding of the frontal lobe damage and its subsequent change in personality. Furthermore, his case expanded knowledge in neurology in several areas, including the study of brain topography in behavioral disorders, the development of psychosurgery, and finally the study of brain rehabilitation. Also, Gage's case had a tremendous influence on early neuropsychiatry. The specific changes observed in his behavior pointed to theories about the localization of brain function and correlated with cognitive and behavioral sequelae, thereby acquainting us with the role of the frontal cortex in higher-order actions such as reasoning, behavior and social cognition. In those years, while neuropsychiatry was in its infancy, Gage's extraordinary story served as one of the first pillars of evidence that the frontal lobe is involved in personality,

which helped solidify his remarkable legacy in world medical history.

The study of the nervous system draws its vitality from the study of brains and behaviors of diverse species. Comparative neuroscience is the study of human and nonhuman animals to better understand brain structure, function, evolution and development across diverse species. A cursory overview of findings in the field of neuroscience shows that diverse model systems contributed to our present day understanding of neurobiology. Much of what we know about action potentials was discovered in squids, for example (Schwiening, 2012). Hodgkins and Huxley won the Nobel Prize for their work on squids, which they chose, in part, because their axons were relatively large, making them relatively easy to study. Hubel and Wiesel also won the Nobel prize for their pioneering work on cats. Cats were chosen because they rely heavily on their acute vision in day-to-day life and the study of their neurobiology led to breakthroughs in our understanding of vision (Daw, 2009). The use of rats generated many insights in the field of neurobiology of learning and memory. Rats were chosen because they are easy to study in a lab setting and also can learn a variety of tasks. Beyond these conventional research models, species with unique adaptations and behaviors such as naked mole rats, bats, and voles are used to study the basis of behaviors and specializations. We will touch on these and investigate the neural basis of sensory physiology, echolocation, social bond formation, and biparental care (Moss and Sinha, 2003; Striedter, 2005; Buffenstein et al., 2012). Comparative neuroscience integrates findings across model systems to extract principles of biological organization that are applicable to diverse species while enhancing our understanding of species-specific adaptations (Striedter, 2016). Ethical limits on the ability to directly study humans and some animals has led comparative neuroscientists to study processes in a range of species, as well as in organoids.

The study of diverse species is important because we can distill basic principles of biological organization that are broadly applicable across biological systems. In addition to building our appreciation of this diversity across species, this chapter will focus on features that make the human brain stand out relative to others. Several features of the human brain appear

unique when compared with many other mammals. For example, the human brain is relatively large compared with many other species. Also, some neural structures supporting language appear uniquely human. Moreover, the lifespan is long and extended in humans relative to many other species. While many features such as these appear unique to humans, the field of comparative neuroscience has been marked by conflict in that it has variably focused on differences versus similarities between humans and other species. This chapter recapitulates this theme. Specifically, we discuss how many of the features which are often thought to be distinctively human come to be observed in other species. Therefore, the quest to identify neural features that are unique to humans continues to be a venue of active research.

In the sections that follow, we will provide an overview of topics, methods, and approaches in comparative neuroscience. As we cover these topics, we will discuss findings probed at different biological levels of organization, which we call scales. Some scientists focus their questions at the micro-scale. Those questions focus on things like gene expression or epigenetic modifications (which are changes to DNA structure that can affect gene expression). Other scientists focus on the meso-scales, which is a scale that spans cells, tissues, and organs. Examples include the study of cellular migration during development or cell numbers. Yet, other scientists focus on macro-scales, and look at organs or whole organisms.

Here, we will discuss findings probed at different scales, including the genetic, molecular, anatomical, and behavioral scales. While insights in the field have traditionally been made from a specific scale of study, we encourage you to consider integrating these scales together to address problems of interest in neuroscience. Throughout this chapter, we have selected a handful of studies, which were chosen to represent advances made at different study scales (e.g., genetic, molecular, anatomical). As we go through the chapter, we will learn how methods used at different scales work, how they have contributed to the field of comparative neuroscience, and their potential to address general problems in neuroscience. We will first discuss how scientists choose a model system.

1.4.2: How Do We Choose A Model System?

Learning Objectives

By the end of this section, you should be able to

- 4.1.1 Explain how you would choose a model system.
- 4.1.2 Explain how to obtain institutional approvals to use an animal for study.

In this section, we will discuss how scientists select a model system to study, as well as some of the rules governing use of animals in research.

Selecting a model system

A model organism or model system is an animal that is studied to gain understanding about biological phenomena, with the expectation that what is learned will apply broadly across other species. The choice of model system depends on several key criteria. In behavioral neuroscience, it is primarily based on the behavior or dysfunction we aim to understand.

Scientists sometimes select closely related species with very different behaviors so that they may understand how differences in neural systems support differences in behaviors. For example, we will see in subsequent sections that several species of voles are conducive to studying social bonding because they are closely related to each other but show highly divergent social behaviors. These studies have helped researchers understand how neural organization of voles underlie social behaviors.

The selection of a model system can also be guided by its extraordinary ability. For example, bats use echolocation to navigate their environment. They send out sonic signals, which they then use to interpret the shape of their environment based on what sound bounces back. Bats integrate this information with visual information, making them good models to understand the neural basis of multi-sensory integration (Moss and Sinha, 2003).

Finally, phylogenetic proximity to humans is a key benefit when we want to use model organisms to understand human biology. For example, we will discuss how macaques have helped us understand human neurodevelopment because they are closely related to us. There are many other examples that illustrate the importance of letting behavior guide the choice of a model system. While researchers may each have a preferred model system for studying their question, the integration of information across model systems provides a comprehensive understanding of the neurobiological mechanisms of a behavior.

In addition to having the behavior drive model selection, there are practical concerns associated with the use of model species. In many cases, scientists are concerned about how easily the model organism can breed and be housed in a laboratory. While experiments in the wild can be informative, laboratory environments provide much greater control over what animals experience and how data are collected. Mice are by far the most used laboratory species in biomedical research because they are sufficiently similar to humans, and because they are readily (and cheaply) maintained in a controlled lab setting (de Sousa et al., 2023). They are also amenable to study because scientists can obtain many of them. Other model systems include rats, voles, hamsters, guinea pigs, naked-mole rats, rabbits, opossums, and cats (Clancy et al., 2001). Non-human primates are also used in research and include macaques and marmosets. Each of these organisms has practical drawbacks and benefits in their use.

History and regulation of animal research

Humans have been using animal models for centuries. For example, researchers in ancient Greece dissected animals with the goal of better understanding human anatomy. This is because there were taboos of studying human anatomy. Prominent physicians also performed surgeries on live animals called vivisections to learn about living anatomy in ways they could not in humans (Allen Shotwell, 2013). Today, we have different ethical standards than we did in the past, and scientists must follow a strict code of conduct when it comes to experimenting on animals or humans. That is, researchers must follow strict guidelines to perform research on animals.

Any research on animals must first be approved by an Institutional animal care and use committee (IACUC) at the researcher's

home institution. The IACUC is composed of scientists, as well as members of the general public. The first step in the process is for a researcher to write a proposal that articulates the necessity of using animals in research and explains the benefit to society. The IACUC reviews this proposal and evaluates whether the proposed study is sufficiently justified to warrant the use of animals in a research study (Prentice et al., 1992). A major focus for the IACUC is to ensure that measures are used to minimize pain. In addition, the IACUC considers how many animals the researcher proposes to use to make sure they are not proposing either more or less than are needed to yield reliable results. Therefore, IACUC plays a critical role in fostering ethical and responsible animal research, which benefits researchers as well as the community at large.

The use of animals in research has a proven track record of saving human lives. There are emerging alternatives that may reduce the need for animal models. Later in this chapter, we will discuss one exciting new frontier which has much potential to reduce the need for animals. We are making reference to organoids. Organoids are derived from stem cells and are grown into clumps that share many features with actual organs. Theoretically, these organoids can be grown from stem cells of any species. Organoids can be used to study biological processes in rare and endangered species, and to test possible treatments for disease. We can take skin cells, reprogram them to stem cells, grow organoids, and test possible treatments for disease (Quadrato et al., 2016). Testing treatments in organoids is a viable option, especially in cases where testing treatments directly in humans would be unethical. Therefore, these stem cell-based approaches open up new and exciting possibilities for research. They also provide insights about systems that would otherwise be unethical or impractical to study in a model system.

1.4.3: How Do We Compare Brains?

Learning Objectives

By the end of this section, you should be able to

- 4.2.1 Explain the concept of homology.
- 4.2.2 Articulate differences in structural organization of the telencephalon of birds and mammals.
- 4.2.3 Explain two opposing views to define homologies across the vertebrate telencephalon.

There are several challenges in comparing the nervous systems of different species. As is evident from Figure 4.2, brain structures are highly diverse.

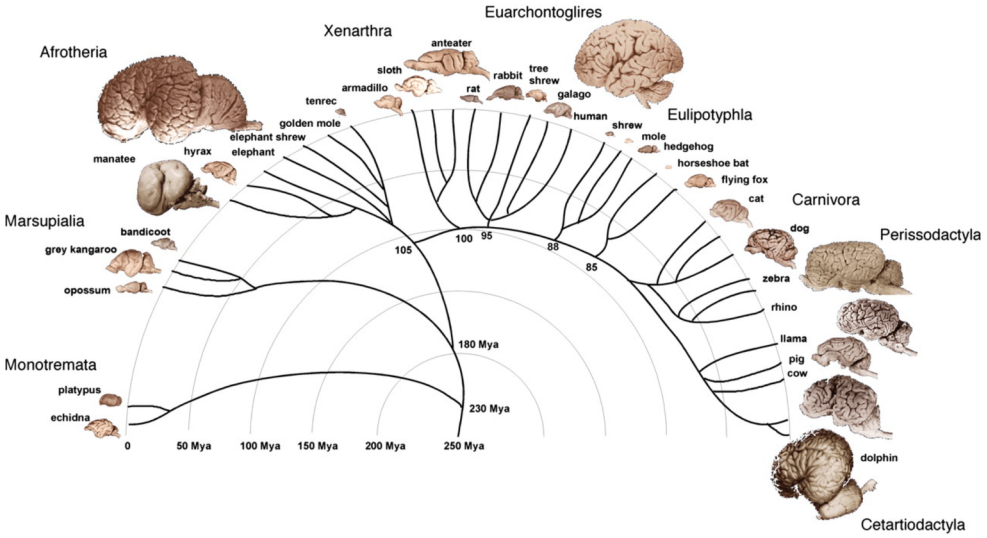

Figure 4.2 Diversity of brains Image credit: Herculano-Houzel, Suzana (2012). The remarkable, yet not extraordinary, human brain as a scaled-up primate brain and its associated cost. PNAS 109 (Supplement 1) 10661-10668. Reproduced with permission.

Comparative neuroscientists use the concept of homology to compare neural structures across species. Homology is a fundamental concept in comparative neuroscience and in biology generally. We will provide examples below. It is the term used to describe structures or organs that evolved from a shared ancestor. Identifying homologous structures may seem easy, especially when considering two closely related species where brain regions appear similar, as is the case in humans and chimpanzees. However, identifying equivalent brain regions becomes increasingly challenging in distantly related species because they share relatively few structural and genetic similarities. In those species that are distantly related, homologies can be controversial.

Comparing neural structures

In this section, we discuss homology and how it is used to compare neural structures in different species. As mentioned above, homologous structures share an evolutionary ancestry. Organ systems can be considered homologous regardless as to their function. One well known example concerns the mammalian forelimbs, which are homologous across mammals. These structures are considered homologous across species because they have similar patterns in bone structure, which reflect their shared ancestry. Yet, forelimbs take on many functions. For example, bats have evolved wings to fly, whales have evolved fins to swim, and horses have long hoofed legs to walk and gallop. Although forelimbs support different functions in different animals, forelimbs are homologous across mammals because the anatomical structures that make up forelimbs are recognizable across mammals and arise from a common ancestor.

Comparative neuroscience typically relies on identifying corresponding brain parts across species. Major anatomical divisions

and brain nuclei are considered homologous if these structures emerge from shared ancestry (i.e., homology). While this concept might appear relatively straightforward at first, identifying corresponding brain parts becomes a thorny problem when applied to distantly related species (Striedter, 2005). Scientists seeking to define homologous structures search for shared similarities in traits present in the last common ancestor. But which similarities they focus on can vary. Homologous characters may be neuroanatomical features (e.g., connectivity patterns) or genes expressed by different cell populations in adulthood, but they can also be based on developmental processes such as spatiotemporal patterns of gene expression. Importantly, focusing on developmental or adult phenotypes as a basis for homology can yield different conclusions (Medina and Reiner, 2000; Briscoe, 2019).

In the next section, we will discuss the issue of defining homologies across the brains of birds and mammals as one controversial example. We will discuss how the use of different characters to define homologous structures may lead to different conclusions. We will also discuss this challenging case because it is the investigation of challenging cases that deepens our understanding of homology.

Marked differences in anatomical organization between birds and mammals

As discussed previously, the brain is typically divided into three major regions that can be defined early in development. These are the forebrain, midbrain, and hindbrain. The forebrain is composed of the telencephalon and diencephalon. The telencephalon includes the cerebral cortex and several subcortical structures (e.g., basal ganglia, amygdala, hippocampus) (see Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy). In some species, the cerebral cortex makes up much of the telencephalon. We first discuss the basic features of the mammalian telencephalon before discussing how this basic organization of the mammalian telencephalon differs from that of birds.

The mammalian cerebral cortex consists of grey and white matter (see Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy). The grey matter largely contains cell bodies of neurons and glial cells. The white matter contains glial cells and axons coursing within and across cortical and subcortical structures. In the white matter, many of these axons are surrounded by a fatty sheath called myelin. It is myelin that gives the white matter its white color. In mammals, there is a clear distinction between the white and grey matter with cell bodies of neurons separated from the white matter, which consists of axons. The top half of Figure 4.3 show this segregated organization in a human and a mouse brain, on the left and right respectively.

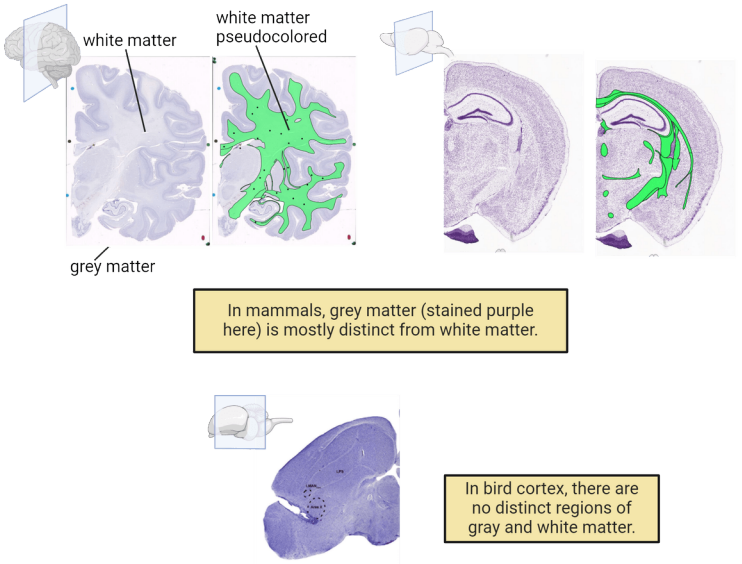

Figure 4.3 White and gray matter in birds and mammals Image credit: Mouse and human brain slices from Allen Brain Atlas. https://atlas.brain-map.org/. Front. Neurosci. 13:671. doi: 10.3389/fnins.2019.00671 CC BY 4.0

The grey matter also has a specific organization of interest. The mammalian cerebral cortex grey matter is typically organized into six layers (layers I-VI), shown in a mouse brain on the left side of Figure 4.4. Each cortical layer has a characteristic distribution of neuronal and glial populations with each layer possessing stereotypical patterns of efferent (outgoing) and afferent (incoming)

projections.

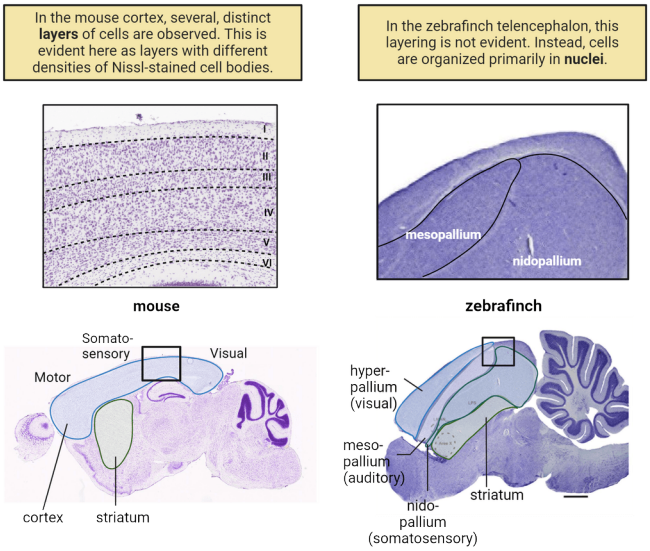

Figure 4.4 Cortical cell organization in birds vs mammals Image credit: Mouse brain images from Allen Brain Atlas. https://atlas.brain-map.org/ Zebrafinch brain image from Kumar S, Mohapatra AN, Sharma HP, Singh UA, Kambi NA, Velpandian T, Rajan R and Iyengar S (2019) Altering Opioid Neuromodulation in the Songbird Basal Ganglia Modulates Vocalizations. The basic organization of the mammalian cerebral cortex stands in sharp contrast to the structural organization of the avian telencephalon. At first glance, the telencephalon of birds appears drastically different from mammals. First, whereas the mammalian cerebral cortex consists of grey and white matter, there is no such distinction between grey versus white matter in the avian telencephalon, shown on the bottom of Figure 4.3. Rather, the axons of bird brains course through cell bodies with no segregation between cell bodies and axons. Second, whereas the mammalian cerebral cortex is organized into layers, neurons and glial cells in birds are primarily clustered into nuclei, shown on the right side of Figure 4.4.

The nomenclature to define regions of the avian telencephalon are also distinct from those used in mammals. The avian telencephalon is subdivided into the striatum, and the hyper, meso, and nidopallium. The meso- and nidopallium are organized into nuclei whereas the dorsal pallium has a layered organization, but only consists of at most three layers. These major differences in anatomical structures have contributed to challenges in defining homologies across the telencephalon of birds and mammals.

The differences in structural organization between birds and mammals are accompanied by differences in connectivity patterns, which further complicates the search for homologies. The hyper, meso, and nidopallium of the bird cortex receive input from the thalamus and process sensory information, including visual, somatosensory and auditory information. For example, the hyperpallium receives extensive visual input and the nidopallium processes somatosensory information. In mammals, in contrast, these kinds of sensory inputs project primarily to layer IV neurons spread along the cortical surface. The bottom of Figure 4.4 exemplifies these two organizations.

Some researchers have used connectivity patterns as a tool to define homologies, but others have used other criteria to define homologous structures across the telencephalon of birds and mammals. Depending on what criteria a researcher uses, they can come up with completely different ideas of which structures are homologous in birds and mammals. In the next section, we will learn more about one specific area of uncertainty in this field.

Definition and challenges: comparing bird brains to those of mammals

In this section, we detail conflicting definitions of homologous structures across the mammalian telencephalic structures in birds. Two opposing hypotheses in this debate are illustrated in Figure 4.5. As we will see below, some of the conflicting views here arise depending on which scale of investigation a researcher uses. Recall that scale refers to the biological level of organization. Here, we will see conflicting results between what the macro-scale (connectivity) suggests are homologous structures in birds and mammals and what the micro-scale (developmental gene expression) suggests are homologous structures.

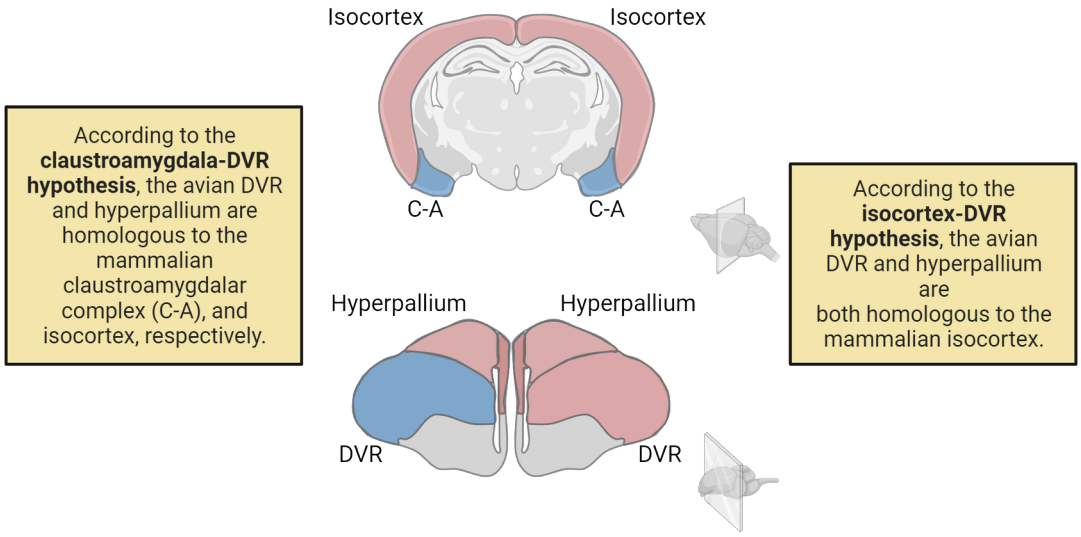

Figure 4.5 Bird vs mammalian telencephalon Image credit: Image and box text inspired by Faunes M, Francisco Botelho J, Ahumada Galleguillos P and Mpodozis J (2015) On the hodological criterion for homology. Front. Neurosci. 9:223. doi: 10.3389/fnins.2015.00223. CC BY.

Perspective from connections: Some researchers have focused especially on patterns of afferent and efferent projections in the avian pallium to define homologous structures between the avian and mammalian telencephalon (Karten, 1991). As we discussed above, in mammals, much of the cerebral cortex consists of primary cortical areas that receive extensive thalamic input and process sensory information. Those areas include the primary visual cortex, the primary somatosensory cortex, and the primary auditory cortex (see Chapter 9 Touch and Pain). The avian dorsal ventricular ridge (DVR) contains discrete nuclei (including those of the mesopallium and nidopallium) that receive extensive thalamic input (Butler, 1995; Butler et al., 2000). Researchers have used these insights to argue that the dorsal ventricular ridge of birds is homologous to the mammalian cerebral cortex. This is known as the isocortex-DVR hypothesis.

Perspective from development: Other researchers have reminded the community that homologous structures can take on different functions across species. That is, homology between structures arises from shared ancestry, which may or may not serve the same function across species. Think back to how bat wings fly, whale fins swim, etc. In this case, we are not looking at function. Rather, we are considering the evolutionary origins of populations of cells, an area called field homology. Field homology refers to populations of cells that derive from evolutionary conserved regions but may be populated across diverse morphological structures. Indeed, there are a number of cases where cells are generated in one location and migrate over long distances in the central nervous system (Corbin et al., 2001). Many researchers focus on developmental field homologies to define homologous cell populations. Typically, looking at developmental fields means that researchers focus on transcriptional (gene expression) landscapes in the embryo as a basis for defining homologies. These fields thus represent the basic units for comparisons.

To better understand what we mean when we say we are defining a developmental field, let's consider transcriptionally defined subdivisions as it applies to defining the homologous structure for the bird DVR in mammals. In this case, researchers have used a combination of genes to transcriptionally define fields (populations of cells that are similar to each other) and define comparable brain regions across species. For example, there are several genes, including Pax6, Tbr1, Nkx-2.1, and Dlx-2 that are expressed in specific locations during development. These genes are expressed in clusters of cells and can be used to define homologous areas because we know of their migratory patterns so we know where they will end up in adulthood. Evaluating spatiotemporal patterns of gene expression during development has been used to argue that the precursors in the DVR give rise to the amygdala in mammals and give rise to nido- and mesopallium in birds (Puelles et al., 2002). Therefore, large regions of the avian telencephalon that might be considered homologous to the cerebral cortex in mammals based on adult connectivity could be considered homologous to the mammalian amygdala when considered based on developmental fields (Striedter, 1994). In this case, consideration of homology based on developmental fields is called the claustroamygdala-DVR hypothesis, which stipulates that mammalian homologues of the DVR consist of the claustrum, endopiriform nuclei, and amygdala (Butler et al., 2012).

Defining homologous structures between species is a crucial effort, as this effort forms the foundation for any comparison between species. We have focused on developmental processes and connectivity patterns as two different ways to identify homologous structures. Researchers who focus on adult patterns of connectivity consider the lateral and ventral pallium to be homologous to the mammalian cortex because the lateral and ventral pallium of birds and the cortex of mammals both receive inputs from sensory thalamus. Researchers who focus on gene expression from a developmental perspective place an emphasis

on developmental patterns. In contrast, other researchers may support the notion that the meso and nidopallium in birds are homologous to the mammalian amygdala. This challenging case illustrates the difficulty in defining which features are relevant and should be used as a basis to compare highly divergent brains.

1.4.4: How Do Brains Vary in Size?

Learning Objectives

By the end of this section, you should be able to

- 4.3.1 Define allometry.
- 4.3.2 Describe how the size of the human cerebral cortex compares with other mammals.

While comparative neuroscience involves the study of many species, one species in particular has captured a disproportionate amount of attention: humans (de Sousa et al., 2023). A great deal of research has focused on what makes human brains special, such as why we can read, grow crops, and travel to outer space, while other species cannot. One of the most obvious features about the human brain is that it is large in absolute size compared with many (but not all) other mammals. Another notable feature about the human brain is that it is large relative to our body compared with other species. Accordingly, the field of comparative neuroscience began with an investigation of brain size, its parts, and how brain size correlates with sensory and cognitive capacities (Aboitiz, 1996; Hofman, 2014; de Sousa et al., 2023). Below, we evaluate the evidence supporting the notion that the expansion of brain regions is linked to specializations. We also discuss how some characteristic features of the human brain might appear to be unique to humans but may in fact be accounted for by total brain size (Finlay and Darlington, 1995; Reep et al., 2007; Yopak et al., 2010). The size of brain parts alone may be insufficient to explain human cognitive capacities. Additional changes at the molecular level likely have played an important role in human cognitive capacities.

The human brain is very big in comparison with many other species

One noticeable feature about humans is that our brains are large relative to many other mammals. However, the human brain is not the largest of mammals. For example, elephants and whales have larger brains than those of humans (Figure 4.2). Nevertheless, the observation that the human brain is approximately 3 times larger than that of great apes (i.e., chimpanzees, orangutans, gorillas) and any other nonhuman primates has led many researchers to suggest that it is the size of the human brain that confers humans with enhanced cognitive capacities. Indeed, there is a positive relationship between brain size and cognitive abilities across species. Yet, brain size accounts for only a small percentage of the variance in cognitive capacities across species. Importantly, these correlative analyses are unreliable indicators of causative relationships because correlations do not mean causation. It is therefore clear that size of the brain does not explain everything about human cognitive capacities, and that other factors must play a role in cognitive capacities.

Relative brain regions vary across species

One salient feature about the human brain is that the human cerebral cortex is very big, and that it occupies a large proportion of our brain, more so than in many other species. For example, the cerebral cortex occupies approximately 80% of the brain in humans but the cerebral cortex only occupies 20% of brain volume in mice. It might therefore seem reasonable to assume that our proportionally enlarged cerebral cortex sets humans apart from other mammals. But, it is well known that the size of brain parts, including the cerebral cortex, varies allometrically. Allometry means that proportions change with overall size (Dial et al., 2008). We will explain the concept of allometry in greater detail.

Brain region volumes vary across species. Figure 4.6 depicts brains of mice, rhesus macaques and humans.

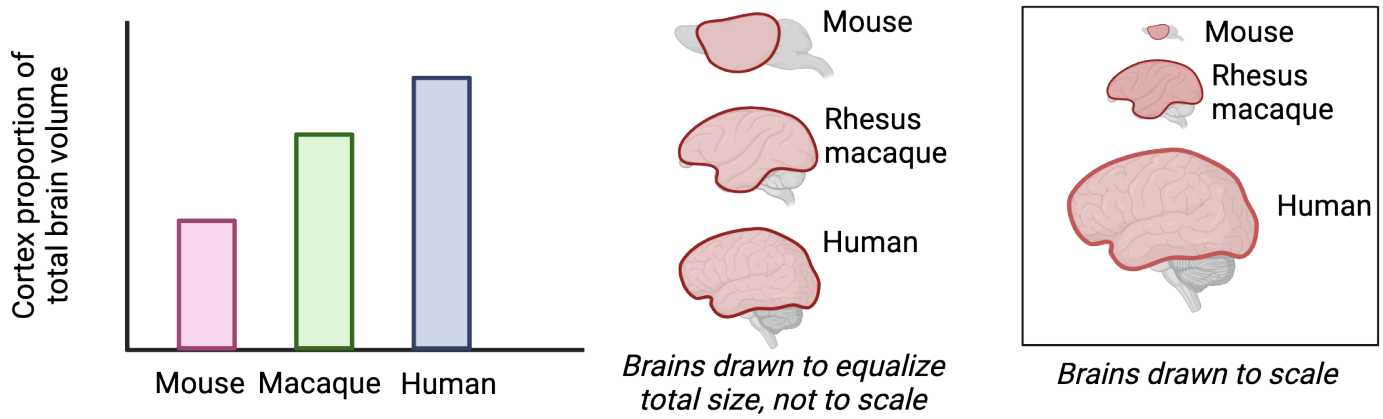

Figure 4.6 Brain regions vary allometrically A greater relative contribution of cortex to total brain mass is seen in monkeys and humans compared to mice, reflecting the positive allometry of the cortex.

As can be seen from the to-scale images in the far right, these brains have very different total sizes. One noticeable observation from Figure 4.6 is that larger brains are preferentially composed of the cerebral cortex. This observation is true when we consider these species, but it also holds when we consider other mammals. Brain allometry means that as overall brains vary in size, some brain regions come to occupy a relatively large proportion of the brain while other brain regions occupy a relatively small proportion of the brain.

A formal way to describe proportional changes in the relative size of brain parts is to say that brain regions vary allometrically (Stephan et al., 1981; Reep et al., 2007; Yopak et al., 2010; Bush and Allman, 2004). Saying that the cerebral cortex has a positive allometry means that the cerebral cortex becomes relatively enlarged in bigger brains. Species such as humans, whales, and elephants possess a big brain and a relatively enlarged cortex. In contrast, small-brained mammals such as mice, rats, hamsters, and mole rats have relatively small cerebral cortices by virtue of their small brain.

The human brain is by far the biggest of all primates and the human cortex occupies the largest proportion of the brain among primates. There are many debates as to whether the size of human brain regions, like the cortex, is unusually small, large or within the expected range considering the size of the human brain. It is possible our large cerebral cortex is exactly the size one would expect of a primate based on the total human brain size. The controversy as to whether human brain parts are small or large based on our brain size arises because we have no nonhuman primate brain of the same size for comparison, which fuels debate as to whether human cerebral cortices are unusual in size or the consequence of allometric changes. Given these debates, it is still a mystery as to whether the human cortex-to-brain ratio is large relative to other species.

Some brain regions vary across species as allometry would predict. That is, proportional differences in brain region volume are explained by changes in total brain volume. In other cases, we observe grade shifts. Grade shifts are relative changes in size of a brain region after controlling for brain size (Barton and Harvey, 2000; Charvet et al., 2012). In other words, brain regions may be larger or smaller than they should be based on what we would expect for a given brain size. What a grade shift means in terms of brain function, though, is still difficult to predict based on brain region size. We will discuss this topic below.

Grade shifts are evident in different groups of mammals (including primates), and they are observed in different regions. Some primate species, including great apes, and monkeys possess a disproportionately enlarged cerebral cortex relative to other mammals (Barton and Harvey, 2000, Finlay et al., 1998, Stephan et al., 1981). In the case of the cerebral cortex, the cerebral cortex is much bigger than that of other mammals of similar brain size. What is interesting is that we see grade shifts multiple times across different groups of mammals. For example, the cerebral cortex is bigger in monkey species relative to other rodents of similar brain size. For example, monkeys have relatively enlarged cortices even though these groups live in diverse environments each with species-specific life histories. The presence of these grade shifts shows that there is no clear one-to-one connection between the size of brain parts and behavior or environmental demands. Rather, changes in relative size of brain regions apply to whole groups of species.

Sensory and motor specializations across mammals

A standard approach to testing whether a brain region is unusually large or small is to ask whether a brain region is expanded or reduced after controlling for its overall brain size. Our example of the cerebral cortex in primates above suggests that just

seeing an enlarged brain region does not necessarily tell us its function. That is not to say that brain region sizes have no relationship to behavior. On the contrary, there are several prominent examples where brain region size tells us a lot about the behaviors of a species. The link between size and function is especially evident when considering animals with a loss of sensory capability or if they show a specialization. In those cases, there is generally an association between cortical area size and sensory ability after accounting for allometric variation in brain region size. For instance, the platypus detects vibrations in the water, and possesses an expanded primary somatosensory cortex, which is responsible for processing somatosensory information from the bill (Krubitzer, 1995; Krubitzer et al., 1995; Krubitzer and Prescott, 2018). The top of Figure 4.7 shows some representative brains from several species, which show how relative proportions of cortical areas vary across species.

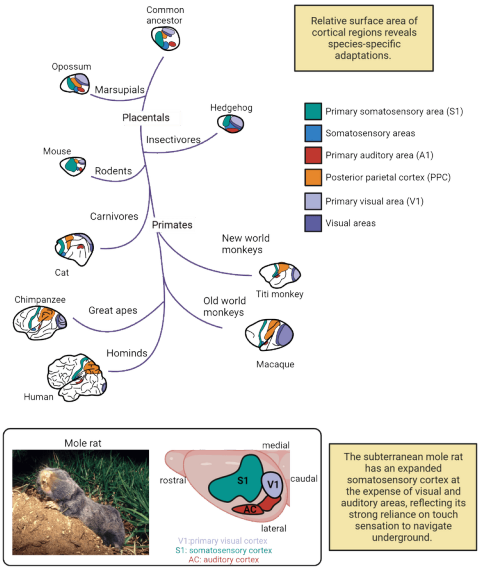

Figure 4.7 Evolution of cortical areas Image credit: Mole Image by Bassem18. "Palestine Mole-rat" (2007) CC BY SA 3.0 https://commons.wikimedia.org/wiki/F...Mole-rat_1.jpg

This variation is shaped by allometry as well as species-specific behavioral adaptations. If we compare the relative size of the rodent somatosensory area with that of primates, we see that rodents have expanded somatosensory cortex dedicated to input from their whiskers. This situation is similar to that observed in the platypus, which show an expanded somatosensory cortex linked to their bill (as described above). Primates, in contrast, rely far less on somatosensory input and have a much smaller relative somatosensory cortex. The expansion of somatosensory areas in rodents typically comes at a cost to visual and other sensory areas. Rodent species with reduced or no visual capabilities provide a particularly notable example of this kind of specialization. This is the case in blind mole rats, which are nearly blind (Figure 4.7). These blind mole rats have reduced cortical territory devoted to processing visual information and a massively expanded somatosensory cortex to process sensory information from the body.

A relevant question at this point is where these variations in cortical size come from? Are they “hard-wired” into each species or do they arise from experience and therefore can change? The answer is a bit of both. Much of the size differences in brain regions across species is encoded in the genome. That is, a human cannot increase their exposure to touch sensation and develop a somatosensory cortex to rival a platypus. Yet, experience can shape the size of brain regions to some extent. Indeed, a range of studies focused on the neural basis of experience-dependent plasticity and cross-species comparisons have systematically shown a link between experience and size in cortical territories. For example, musicians have an expanded auditory cortex, and this is thought to be because of their sustained attention to listening and playing music (described below; Strait et al., 2014; Moreno and Bidelman, 2014).

Studies from experimental models further demonstrate that cortical areas change with experience, and others show the importance of attention in mediating changes in cortical territory (Dooley et al., 2017; Ramamurthy and Krubitzer, 2018; Dooley and Krubitzer, 2019). Animals may be exposed to stimuli or be deprived from stimuli, and their cortices reorganize in response to this input. See Chapter 7 Hearing and Balance for an interesting example of how the auditory cortex reorganizes based on the frequencies of sound during development. Experimental results combined with cross-species analysis of sensory and motor specialization demonstrate that cortical plasticity is determined by the environment.

1.4.5: How Do Connections Differ Across Species?

Learning Objectives

By the end of this section, you should be able to

- 4.4.1 Describe what tract-tracers label in the brain.
- 4.4.2 Describe an advantage and a limitation in the use of tract-tracers.
- 4.4.3 Describe a major difference in organization between pathways.

The mammalian nervous system is made up of a network of interconnected cells. In this section, we will discuss the evolution of the cellular composition of brains with a specific focus on methods. We use these data to map the structural organization of pathways and connections in the human brain. This is a topic that shows the importance of using model systems to understand connections in humans. Much of our understanding of human brain pathways has been inferred from model systems.

Scientists have traditionally used information from rodents (e.g., mice, rats), carnivores (e.g., cats), marsupial mammals (e.g., opossum), and non-human primates (e.g., rhesus macaques) to make inferences about pathways and connectivity patterns in humans. The reason the human brain connectome is largely inferred from animals is because of the methods we use to study them. In general, methods available in model systems are invasive, and would be unethical to study in humans. These methods do have relatively fewer uncertainties in interpretation than those used to study humans. Methods available to model systems typically set gold standards whereas methods used to study humans are generally associated with uncertainties in their interpretation. Researchers typically integrate gold standards from model systems with non-invasive neuroimaging methods in humans to make inferences about connections in the human brain.

Below, we explore the different methods available in model systems and in humans, how they have moved us forward to understand brain organization, their limitations, as well as exciting topics for future research (Axer and Amunts, 2022). This section will show how we can use the principle of conservation to make inferences about connectivity patterns in humans.

Techniques to study the evolution of connections in model systems

The toolbox available in model systems typically relies on studying specific populations of neurons to identify afferent (incoming) and efferent (outgoing) connections. Methods available to trace pathways in model systems include tract-tracers and diffusible dyes (see Inorganic Dyes). We first discuss neural tract tracing techniques because these methods have been used for decades and are a major source of what we know about projection patterns.

Tract-tracers are injected in a region of interest and actively diffuse across neurons. Traditionally, tract-tracers are injected in the living brain, and post-mortem brains are cut into micron-thick sections to visualize labeled axons from histological material (Oh et al., 2014). There are various kinds of tract-tracers. Those include anterograde, retrograde, monosynaptic and trans-synaptic tracers (Figure 4.8). Anterograde tracers are taken up by neuronal cell bodies at the injection site and diffuse along the axon towards terminal processes. In contrast, retrograde tracers are taken up by a neuron's terminals and diffuse back towards (i.e., retrogradely) the soma. Mono-synaptic tract-tracers remain within the neuron they penetrated and do not diffuse to neighboring neurons. Other tract-tracers spread trans-synaptically (across synapses) to diffuse throughout the network. Therefore, there are many variant forms of tract-tracers that are available for study, though they only permit visualizing a few projections in the brain at a time.

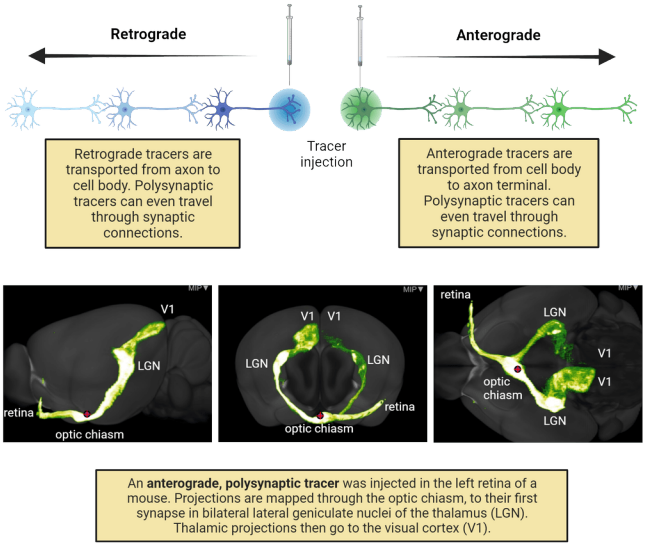

Figure 4.8 Retrograde and anterograde tracers Image credit: Mouse anterograde tracer image from Allen Brain Atlas: https://connectivity.brain-map.org/ Retina Kcng4-Cre image.

Tract-tracers have been used extensively to trace pathways across model systems and in different species. The bottom of Figure 4.8 shows three views of an example 3D reconstruction of tract-tracing performed using a trans-synaptic anterograde tracer injected in the left retina of a mouse. The tracer is seen extending from the eye, through the lateral geniculate nuclei of the thalamus, and on to the primary visual cortices (see Chapter 6 Vision). These methods enable the identification of anatomical pathways between brain regions.

Tract-tracers are invasive and permit only studying a few pathways at a given time. Combining the work of many researchers over many years has enhanced our understanding of how connections have evolved, and these methods have heavily influenced our understanding of vertebrate brain evolution. For example, researchers used this method to show connections from the thalamus to the DVR in birds, and these observations were used to support the notion that the DVR is homologous to the mammalian cortex (as discussed above).

As another example, this compendium of information on tract-tracers has yielded insights about pathway properties, and principles that explain how axons target other cells (Modha et al., 2010; Liu et al., 2020). One principle to emerge from these comprehensive analyses is that local projections are more common than long-range projections, and this is true whether we consider small or large brains. Brain networks follow a small-world organization, in that they are composed of highly connected cells coupled with sparse long-range projections (Liao et al., 2017). The example of connections from retina to the thalamus to the occipital cortex in Figure 4.8 makes striking 3D images, but these kinds of long-range connections are the minority of connections in the brain. Mostly, connections happen between neurons that are close neighbors.

As we will learn more in the next section, the direct study of human connections derives from non-invasive neuroimaging techniques, which are open to interpretation. We therefore use the principle of conservation to make inferences about connectivity patterns in the human brain.

Inorganic Dyes

Inorganic dyes can also be used to visualize pathways. Dyes move through brain cells via passive transport and are useful to identify projections in fixed tissue postmortem. This is a method that can be used on human tissues. Typically, dyes are applied to the surface of formalin-fixed tissue blocks, and these dyes diffuse in anterograde and retrograde directions via the lipid portion of neuronal membranes, resulting in complete labeling of the soma and dendritic tree. However, these dyes travel very short distances. As a result of their short travel distance, dyes have been used to primarily study developing pathways (i.e., relatively short axons) during fetal development in small model animals and in humans.

Techniques to study the evolution of connections in humans

Neuroimaging techniques are widely used in neuroscience to visualize neural activity and connections across the lifespan in humans. The non-invasive nature of neuroimaging has revolutionized the field of neuroscience. Here, we discuss a subset of neuroimaging techniques, which are used to make inferences about connectivity patterns from brain activity. Figure 4.9 provides an overview of several broad classes of neuroimaging techniques.

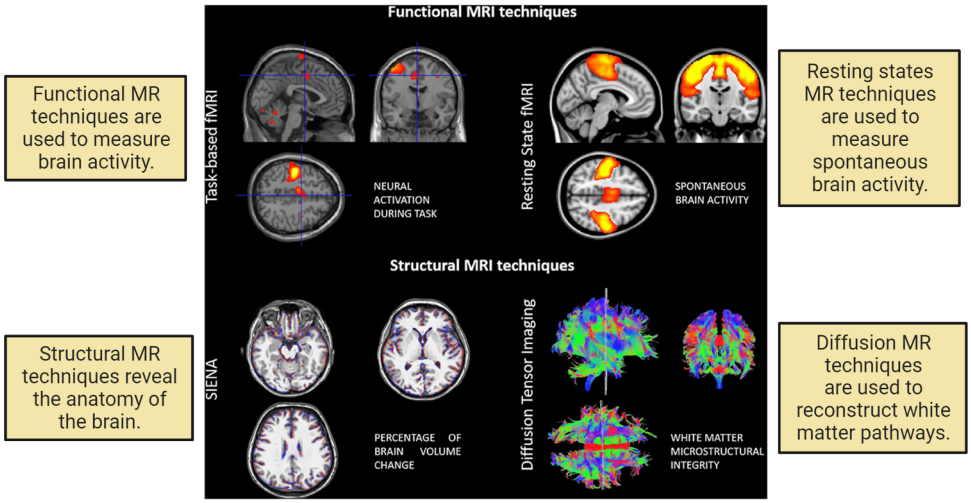

Figure 4.9 Imaging the live human brain Image credit: Tavazzi E, Cazzoli M, Pirastru A, Blasi V, Rovaris M, Bergsland N and Baglio F (2021) Neuroplasticity and Motor Rehabilitation in Multiple Sclerosis: A Systematic Review on MRI Markers of Functional and Structural Changes. Front. Neurosci. 15:707675. doi: 10.3389/fnins.2021.707675. CC BY 4.0.

We will cover structural and functional magnetic resonance imaging (MRI) (see Methods: fMRI). Structural MRI evaluates the tissue structure from the soft tissue structure of the brain. Functional magnetic resonance imaging relies on blood fluctuations (measured as BOLD or blood-oxygen-level-dependent signal) to infer neuronal activity levels. Two notable techniques used to study connectivity in the live human brain that rely on MRI imaging are resting states fMRI and diffusion MRI (right side of Figure 4.9). We will discuss how these methods work, how they have contributed to mapping pathways in humans, and what uncertainties they have. We will highlight the need for information from model systems to trace pathways in the human brain.

fMRI and Resting states: Many fMRI studies focus on BOLD signals that occur while the subject is performing certain tasks. Resting-state fMRI, in contrast, measures spontaneous low-frequency fluctuations in the BOLD signal at rest so that it can be used to investigate the functional architecture of the brain. Comparing the timing of BOLD activations at rest across regions can give clues about connections (Lee et al., 2013; Murphy et al., 2013). In this method, observations of covarying fluctuations in brain activity are used as an indirect means to infer connections between regions. Covariance of activity patterns (increases or decreases at the same time in two brain areas) suggests that the areas are in some way connected. A benefit of resting state fMRI is that it broadly surveys patterns of blood flow across the brain and can be studied in many individuals. This broad survey is in contrast with tract-tracers, which provide detailed but sparse information about projection patterns in model systems. One major limitation of resting states fMRI is that coordinated patterns of connectivity do not address the underlying pathways. A finding that regions co-activate doesn't necessarily mean that there are actual physical pathways that underlie the covariance in activity. That is, coordinated activity may arise without any direct connections (Murphy et al., 2013).

Diffusion MRI relies on the diffusion of water molecules to make inferences about the composition of neural structures. More specifically, diffusion MRI detects movement of water and relies on the principles that water diffuses preferentially along the axons. By measuring the direction of water diffusion, which correlates with the direction of axon fibers, we can reconstruct the location and orientation of fibers coursing through the adult and developing brain (Wedeen et al., 2005, 2008). Diffusion MRI tractography can be used to document similarities and differences in the projection patterns of different species.

There are certain limitations imposed by diffusion MRI tractography that have precluded its use at the level of detail needed to map some connections in the developing and adult brain. First, scans capture information at millimeters resolution (i.e., macroscale) and therefore can be used to average biological information that spans micro- and cellular scales. This limitation in

resolution means large amounts of critical biological information is lost. Another major issue is that the pathway reconstructions from diffusion MRI are not always accurate. In many cases, there is much uncertainty in what the correct pathway reconstructions are in the human brain. There is a lack of alternative methods to evaluate the accuracy of neuroimaging techniques in humans. Therefore, scientists use the principle of conservation from model systems to make inferences about human pathway reconstructions. There are a number of cases where reconstructed fibers from diffusion MRI tractography in the human brain appear very improbable (based on what we know about model systems). Overcoming these issues is an active area of research.

Despite these limitations, diffusion MRI tractography has yielded some interesting findings. For example, tractography studies have shown that some pathways connecting cortical areas are enlarged in humans relative to other species. For example, the arcuate fasciculus, which is a pathway that connects the lateral frontal and temporal lobe, is very large in humans compared to nonhuman primates. The arcuate fasciculus is of particular interest because it is a pathway thought to be associated with language comprehension (mediated by the parietal and temporal lobes) and production (mediated by lateral frontal cortical areas). Tractography studies have revealed a disproportionately expanded arcuate fasciculus in humans compared with both chimpanzees and macaques (Rilling et al., 2008). These observations have been used to argue that the expansion of the arcuate fasciculus may be linked to language in humans. While it is clear that the arcuate fasciculus is big in big-brained primates such as humans, it is still possible that the arcuate fasciculus has an allometry. That is, the arcuate fasciculus may have become disproportionately bigger in big brained species. The tractography has yet to be validated and we have very few tools available to ensure the accuracy of these projection reconstructions in humans versus great apes.

1.4.6: How Can Diverse Species Help Us Make Inferences about Human Neurobiology?

Learning Objectives

By the end of this section, you should be able to

- 4.5.1 Define major developmental processes in macaques.
- 4.5.2 Describe how social relationships vary between prairie and montane voles.
- 4.5.3 Describe how the neurobiology of prairie voles differs from that of montane voles.

Our discussion of connectivity in the human brain highlighted the need for model systems to understand human brains. This principle goes beyond just connectivity, though. Much of what we know about human neurobiology is inferred from model systems. The choice of the model system depends on the biological process we seek to understand. In this section, we will consider two cases where the use of model systems has been instrumental in understanding human neurobiology. Specifically, we will discuss how the timeline of brain development in monkeys has been studied to make inferences about human fetal development. We will also discuss how studying closely related species of voles has been used to make inferences about individual variation in the neurobiology of social bonds.

Monkeys as model systems to understand human fetal development

Much of what we know about development in humans, and especially human fetal brain development, is inferred from model systems. Human fetal development is an especially challenging phase to study because there are limited methods for study. Accordingly, there is only so much we can study in prenatal humans (Byrston et al., 2008). Macaque monkeys have been one important model system to understand human development. This monkey is a popular choice for this kind of research because of its close phylogenetic proximity to humans, and because monkeys share many similar features with humans (Passingham, 2009; Rakic, 2009). More recently, researchers are turning their attention to a small monkey called the marmoset because it is an easier animal to handle and breed than macaques. Macaques have been used for some time and they have yielded insights into human neurodevelopment (Mitchell and Leopold, 2015; Okano et al., 2012).

This section articulates the basic outline of fetal and early postnatal development in macaques and how it can be used to make inferences about human development. We discuss how the study of model systems can enhance our understanding of neurogenesis (the process of neuron production), and synaptogenesis (the process of generating synapses) in the human brain (Clancy et al., 2001). More detail on these and surrounding neurodevelopmental processes is in Chapter 5 Neurodevelopment.

Neurogenesis is the term used to describe this entire process of generating neurons. Early in development, the brain is composed of proliferating cells (i.e., cells that are in the process of multiplying), which have yet to adopt a final, functional form (such as being a neuron or glial cell). These early, undifferentiated cells are called neural stem cells, and they have a unique shape, with a long fiber or process extending from their cell body to the edge of the developing brain tissue (Figure 4.10). Neural stem cells divide to create daughter cells that turn on to mature, or differentiate, into neurons or glial cells (step 1 in Figure 4.10). The maturing cells wrap around elongated fibers and migrate radially towards the outer surface of the cortex (step 2 in Figure 4.10).

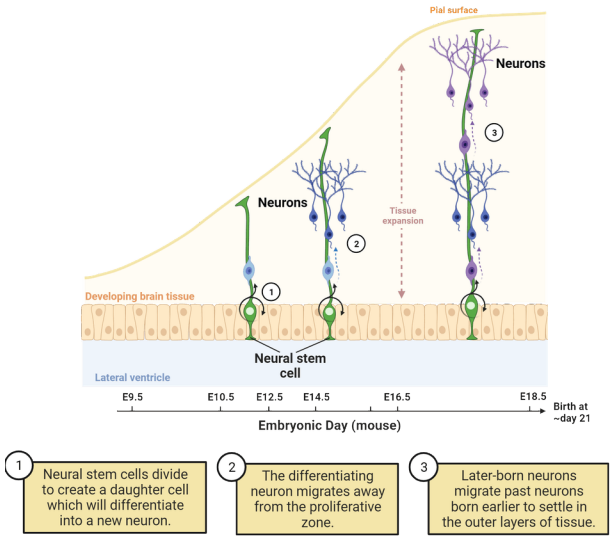

Figure 4.10 Neurogenesis in mammalian cortex

Neurogenesis largely occurs during prenatal development (Byrston et al., 2008), and extends to postnatal stages of development. In humans, we have limited tools available to visualize this process. We can make inferences about the process of neurogenesis from anatomy and histology (thin slices of post-mortem brains), from gene expression of individual cells or from tissue, but these methods are only indirect means to probe neurogenesis, and we have to map findings from model systems onto humans (Clancy et al., 2001; Charvet and Finlay, 2018; Boldrini et al., 2018; Kozareva et al., 2019).

The use of model systems, such as macaques, has enabled us to better understand the process of neurogenesis in humans (Rakic, 2002, 2009). For example, researchers have used cell birth-dating techniques to see where proliferative cells migrate to their final destination. Essentially, birth-dating involves the administration of a compound that gets taken into proliferating cells. The compound marks the cell, which enables researchers to visualize where the cell ends up at a later stage in development. Once the compound gets incorporated into the cell, we can track it over time. We can, for example, use this method to track migratory patterns of cells. These techniques obviously cannot be done in humans for ethical reasons, but they can be performed in macaques and other species.

Birth-dating methods in macaques have revealed basic patterns of migration from the proliferative pool to the cortical plate (upper edge of the tissue, where the neural stem cell fiber ends). For example, proliferative cells exit the cell cycle and migrate according to an inside-out fashion such that recently generated neurons migrate past older ones in the cortical plate (Rakic, 1974, 2002). Figure 4.11 shows how these birth-dating experiments trace the birth of different cell types. Here, we use mice as an example. Mother mice are injected with the tracer at different days of pregnancy and the compound is taken into only those cells that are in the process of proliferating at that particular time (step 1 in Figure 4.11). The brains of their offspring are then examined after birth (step 2 in Figure 4.11). Offspring exposed to the compound early in development show labeled cells in the inner layers of the cortex (step 3 in Figure 4.11). Offspring exposed to the compound later in development show cells in the outer layers of the cortex. Based on these observations, we can say the cortex forms inside-out, or the first-born cells form the inner layers with later born cells migrating past them to form the outer layers.

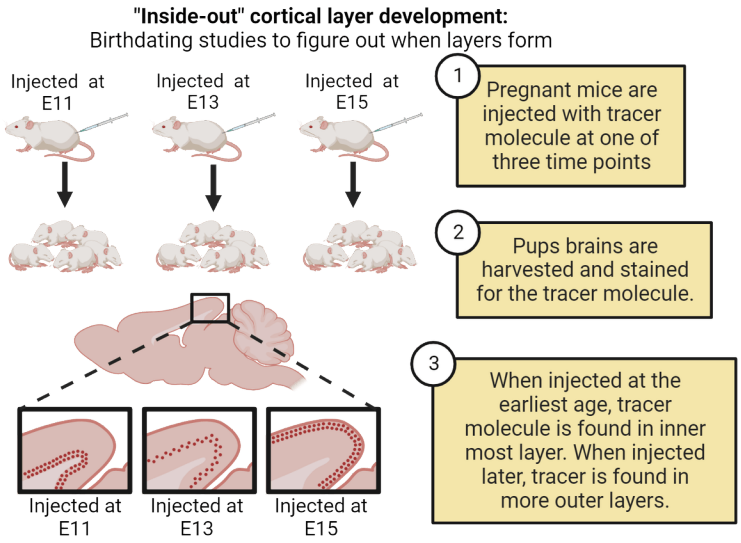

Figure 4.11 Cell birth dating and inside-out formation of the mammalian cortex

Similar experiments to the one diagrammed in mice have been performed in macaques and other primates. These experiments revealed wide conservation in the inside-out pattern of neurogenesis across mammals. Early in development, recently generated neurons preferentially populate lower/inner layers of the cortex. Later born neurons preferentially populate the outer layers. Conservation of this pattern goes beyond primates and rodents. The inside-out sequence of cell birth specification has been observed in every mammalian isocortex studied (primates, rodents, marsupial mammals; Clancy et al., 2001). Because we can't inject pregnant humans or their fetuses with tracers, we use observations such as these from model systems to make inferences about human brain development.

Synaptogenesis(i.e., the production of synapses) is yet another process that researchers have relied on model systems, particularly macaques and cats, to map the steps and the expected time course in humans. In macaques and cats, synaptogenesis occurs as neurogenesis wanes (Cragg, 1972; 1975; Bourgeois et al., 1994; Clancy et al., 2001). The number of synapses peaks in early infancy and subsequently declines in early adulthood. Many researchers believe that this surge in synapse numbers early in infancy provides an important critical period where young individuals can learn and adapt to their postnatal environment. Human synaptogenesis is to a large extent inferred from model systems.

In this section, we have considered how we make inferences about basic developmental processes from model systems, but not every developmental process is similar across humans and other species. For example, the overall duration of brain development is extended in humans compared with macaques (Clancy et al., 2001; Charvet and Finlay, 2018). The longer overall duration in neurogenesis, synapse development and myelination may be contributing factors to the evolution of the human brain structure and function. We can determine what is unique from a structural perspective in humans compared to other species, but we can't explain the reasons why those differences exist. For example, humans and other non-human primates may differ in their length of gestation, but we can't necessarily conclude that this is the reason why humans have some structural difference relative to non-human primates. We next discuss how we can use closely related species to learn basic concepts in neurobiology.

Visualizing synapses

Our understanding of the timing of synaptogenesis has been driven by electron microscopy (see Methods: Transmission Electron Microscopy). Synapses are tiny, far too small to see with conventional light-based microscopes. Electron microscopy, in contrast, has sufficient resolution to visualize individual synapses across different cells in post-mortem fixed tissue and has been used to quantify the number of synapses in a volume of tissue. Electron microscopy is well suited for model systems but less so for humans because of the way we need to preserve tissue. Our understanding of the timeline of synaptogenesis is therefore largely inferred from studies in macaques and cats (Huttenlocher et al., 1997; Finlay and Darlington, 1995; Clancy et al., 2001).

Studying closely related species to make inferences about the neural basis of social bonds

Thus far, we have focused on looking for *similarities* between species to allow us to investigate the neural bases of behavior and extrapolate to difficult-to-study species like humans. Investigating *differences* between closely related species is also a useful approach to understand the neural basis of behaviors. In species that are close in phylogenetic proximity, one would expect relatively few differences in brain and behavior. These relatively few differences across closely related species permit pinpointing what neural structures form the basis of select behaviors. We discuss an example where phylogenetic proximity has been used to make inferences about the neurobiological basis of social bonds.

Throughout their lives, humans form selective attachments to family, friends, and romantic partners, which are critical for both mental and physical well-being. The pair bonding of Microtine rodents such as prairie versus meadow or montane voles show variation that mirrors the variation in pair bonding in humans (see Chapter 11 Sexual Behavior and Development). Prairie voles are monogamous; they form stable pairs. Other vole species, such as montane voles, are polygamous with males and females forming multiple pairs. That is, individuals will copulate with multiple partners. In these studies, montane and meadow voles are used as the non-monogamous counterpart to the monogamous prairie vole. The affiliative behavior can be measured with a partner preference assay. In short, a male vole is given a choice of where to spend his time: with a female with whom he previously mated or with a new female. Pair-bonded prairie voles will spend the majority of their time with their partner when given the opportunity to do so, whereas meadow voles show no preference toward either an established partner or a novel opposite-sex partner. The diverse pair bonding behaviors across vole species mirrors the diverse behaviors we see among humans with some humans engaging in monogamous relationships whereas others form polygamous relationships.

These two vole species are closely related so that their brain structure and function is highly similar with only a few differences. Studies of the basis of social bonding using these species therefore started with the idea that there should be relatively few differences across species since they are closely related. Brain region differences, then, could be related to variation in pair-bonding between the two species (Winslow et al., 1993; Insel et al., 1994). Researchers compared the brains of these meadow and prairie voles, and they found interesting species differences in vasopressin receptors (i.e., vasopressin 1a receptors, V1aRs) in the basal ganglia. Specifically, expression of V1aR in a region called the ventral pallidum was higher in the pair-bonding voles than in the solitary voles. This difference is shown in the autoradiograms in the top two rows of Figure 4.12.

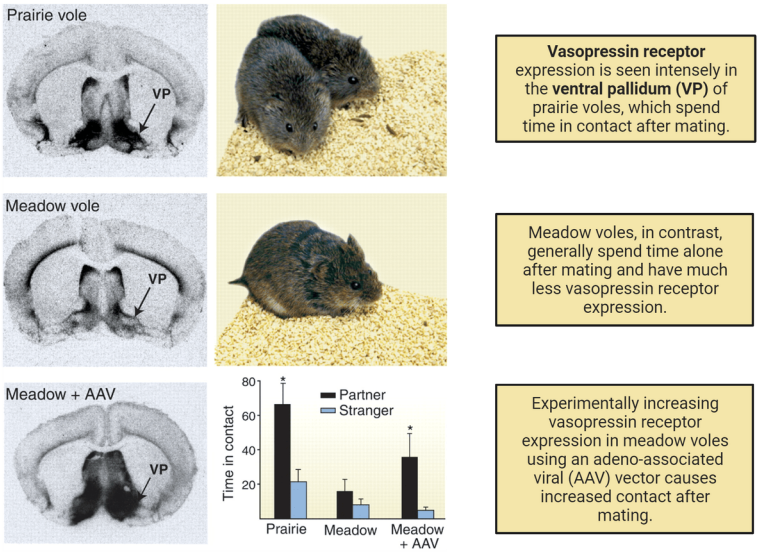

Figure 4.12 Pair-bonding in voles Image credit: From Donaldson, Zoe R., and Young, Larry J. "Oxytocin, Vasopressin, and the Neurogenetics of Sociality". Science, vol. 322, no. 5903, 2008, pp. 900-904. DOI: 10.1126/science.1158668. Reprinted with permission from AAAS.

While suggestive, these observed differences in V1aR expression do not by themselves demonstrate that the expression of vasopressin receptors is causally related to species differences in pair bonding. Researchers therefore went one step further with these cross-species investigations. Specifically, researchers experimentally increased the expression of vasopressin receptors in the normally non-pair bonding meadow voles to test whether the expression of vasopressin receptors is causally related to pair bonding. They then quantified partner preference as an index of pair bonding (Young et al., 1999). The bottom graph in Figure 4.12 shows the results of this experiment. First, untreated prairie voles showed a preference for their partner and untreated meadow

voles did not, as we would expect. Increasing vasopressin receptors in meadow voles changed this, though. Meadow voles with V1aR overexpressed behaved much more like the pair-bonding prairie voles, spending more time with a previous partner than with a stranger (Winslow et al., 1993; Insel et al., 1994).

These findings point to vasopressin receptor expression in the ventral pallidum area of the basal ganglia as a major player in specifying social bonds. Other molecules (e.g., oxytocin) are also important in dictating social bonds (Anacker and Beery AK, 2013; Romero et al., 2014; Ahern et al., 2021). While V1aR expression is clearly important for partner bonding in prairie voles, can we apply this knowledge to human behavior? Interestingly, the results of these vole studies motivated studies in humans, which have identified individual differences in vasopressin receptors, specifically finding genetic variants of this receptor that predict different partner bonding behaviors (Walum et al., 2018). That is, similar genetic variants account for behavioral variation amongst humans. Examples such as this one demonstrate that we can understand the neurobiology of social bonds in humans by focusing our efforts on comparing the neurobiological basis of social bonds.

1.4.7: How Can Brain Organoids Help Us Make Inferences about Brain Evolution?

Learning Objectives

By the end of this section, you should be able to

- 4.6.1 Explain how brain organoids are grown in the laboratory.
- 4.6.2 Explain how to measure RNA expression from sequencing.
- 4.6.3 Explain a major finding from studying brain organoids.

Certain ethics limit the use of experimentation on humans, and some alternate species are not readily available for study. For example, many great apes are endangered, and it is difficult to study how their brains compare with humans or other mammals. Brain organoids are emerging as interesting tools to study brains in groups that are otherwise difficult to study. Organoids are three-dimensional spheres grown in vitro from stem cells. Cells from any organism can be selected and grown to become different cell types, forming a variety of types of organoids including brain organoids. In this section, we discuss how brain organoids are generated in the laboratory, and we discuss recent findings that have emerged from their use in the laboratory.

How to grow stem cells into brain organoids

Organoids are generated from embryonic stem cells or induced pluripotent stem cells, which are a kind of stem cell made from a mature cell (like a skin cell) in the laboratory. As diagrammed in Figure 4.13, the stem cells are grown in a dish in the lab (step 1) and allowed to form small embryoid bodies (or collections of cells that stick to each other in a small ball) (step 2). Those balls of cells are then moved into a droplet of Matrigel, a substance filled with proteins that will support the further growth of the sphere and encourage the differentiation of cells into cell-specific fates such as the neuroectoderm lineage, which are developmental precursors of our nervous system (step 3 in Figure 4.13) (see Chapter 5 Neurodevelopment). Those bits of neuroectoderm are then spun at high speed (step 4 in Figure 4.13). The spinning forces make them stick to each other as cells grow. Remarkably, these cells self-assemble into a collection of progenitor cells (cells that can divide but are not as uncommitted as stem cells) that can give rise to neurons and glial cells that in many ways resemble pieces of a real brain.

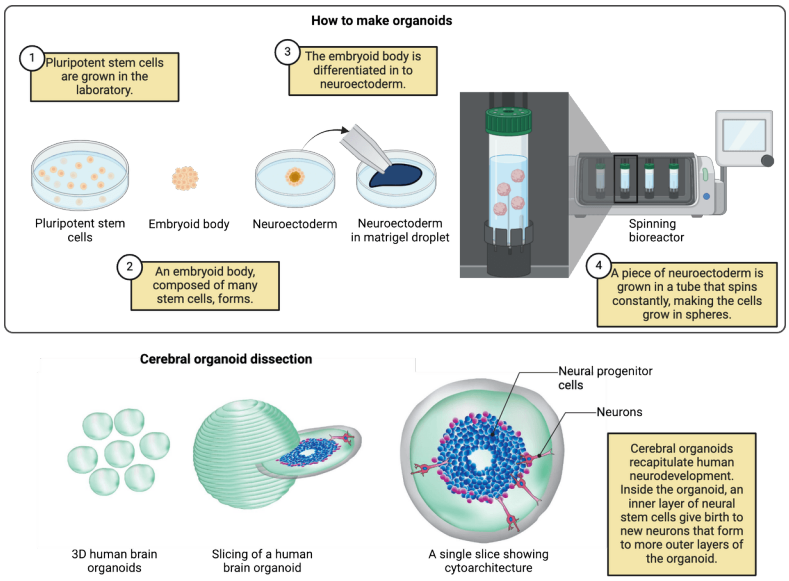

Figure 4.13 Organoids Image credit: 3D organoid image from: Gabriel at el., 2020. "Human brain organoids to decode mechanisms of microcephaly." Front. Cell. Neurosci., https://doi.org/10.3389/fncel.2020.00115. CC BY 4.0 International

Brain organoids express patterns of gene expression reminiscent of the developing nervous system, and form functional networks,

thus resembling miniature versions of brains. They also show cellular organization similar to developing brains. For example, the bottom of Figure 4.13 shows how the inside of a brain organoid has a ring of progenitor cells that give rise to neurons that migrate outwards. This arrangement strongly resembles the migration of developing neurons in the cortex that we discussed in 4.5 How Can Diverse Species Help Us Make Inferences about Human Neurobiology?.

Because of their similarity to real brain networks, brain organoids are providing exciting tools that can be geared for personalized medicine. For example, characterizing and testing therapies on organoids provides a new opportunity to define and evaluate the effectiveness of treatments to help individuals suffering from disorders (Schörnig et al., 2021). Mature cells from a given individual can be induced into pluripotency (i.e., a proliferative state), and grown into a brain organoid. In theory, this kind of model could allow screening of therapies for individual patients using tiny brains generated from their own cells.

Below, we will provide a few examples to show how brain organoids have provided new insights into the evolution of the brain. Many of these studies rely on gene expression to investigate species differences in organoids. We will therefore briefly describe how RNA is measured from sequencing methods in the brain before discussing how they are used to identify species differences from brain organoids.

Measuring RNA from sequencing technologies

The emergence of sequencing techniques has created many new and exciting opportunities to study transcriptional variation across species. Though there are multiple techniques to study gene expression, here we will focus on RNA sequencing, which is a method that probes gene expression very broadly in cells. RNA sequencing is a technique to measure the abundance of RNA transcripts. While many techniques for measuring RNA require that you pick which RNAs to measure ahead of time, RNA sequencing measures RNAs from many thousands of genes.

The basic process of RNA sequencing is shown in Figure 4.14.

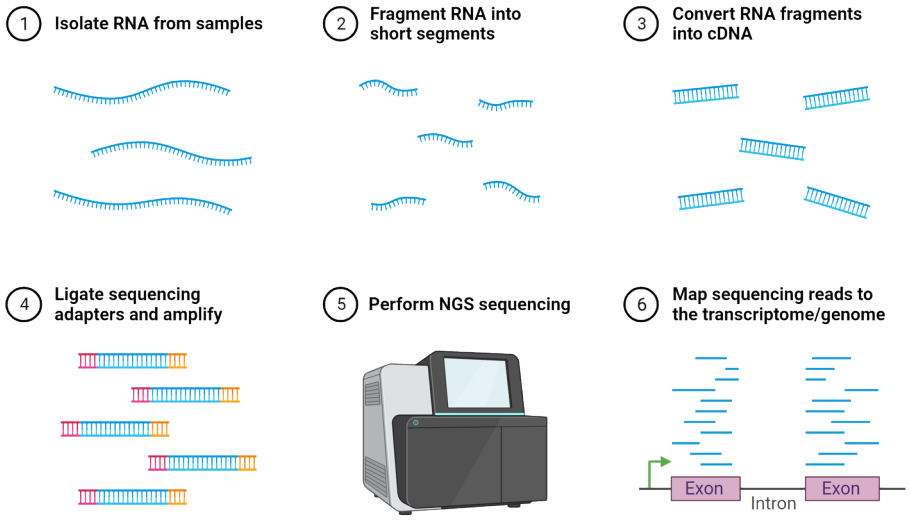

Figure 4.14 Sequencing technologies

Tissue is extracted and then RNA is isolated via a series of steps that capture and purify it (step 1 and 2 in Figure 4.14). Unlike DNA, which is double-stranded and stable, RNA is single stranded so that it easily degrades. Researchers turn their RNA into double stranded DNA to keep it stable (step 3 in Figure 4.14). The process of turning RNA back into DNA is called reverse transcription and we call the resulting DNA “cDNA” because it is copied (or complimentary) from the RNA it was made from. These cDNA fragments are sequenced (step 4 and 5 in Figure 4.14). This means that each nucleotide (adenine, uracil, guanine, cytosine) is read by a sequencing machine. Relatively short strings of nucleotides read at a time. The transcript reads are then aligned to the genome, which involves matching up sequences of nucleotides from the transcripts to the genome template (step 6 in Figure 4.14). This effectively aligns the transcripts to the corresponding gene. In a typical experiment, the process of generating read alignment will cause some genes to have many aligned transcripts. Whereas other genes will have very few or no aligned transcripts. The number of reads aligned to each gene is used as an index of gene expression (Finotello and Di Camillo, 2015; Van den Berge et al., 2019). Using these techniques, we can compare gene expression between a diseased state and a healthy

control, but we can also use these data to compare transcription across development and across the brains of different species. We can relate variation in gene expression with behavior in healthy and in diseased states.

Originally, researchers sequenced RNA from whole organs, or a piece of tissue, but this approach has limitations. Using whole pieces of tissue is a limitation because tissue is composed of a heterogeneous population of cells (e.g., neuron types, glial cells), and there is no way to tell which cells or cell populations express genes of interest. More recently, researchers developed novel methods to capture RNA sequencing from individual cells. We can now identify the transcriptional profiles from individual cells within a tissue rather than the whole piece of tissue as is the case with RNA sequencing from bulk samples. Various methods exist to measure gene expression from individual cells. Figure 4.15 shows one common way to approach single cell RNA sequencing.

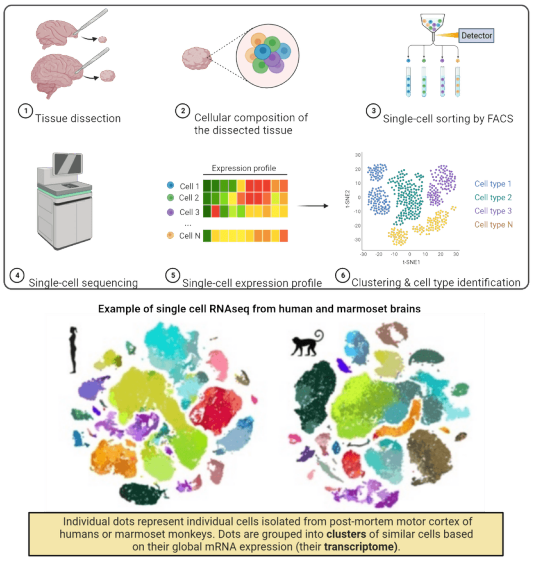

Figure 4.15 Single cell RNA sequencing of primate brain Image credit: Example single cell data from Bakken et al., Evolution of cellular diversity in primary motor cortex of human, marmoset monkey and mouse. biorXiv. https://www.biorxiv.org/content/10.1...03.31.016972v2 CC-BY-NC-ND 4.0

In this workflow, tissue is dissected (step 1 in Figure 4.15) and broken apart into a suspension where cells float separate from one another (step 2 in Figure 4.15). Sometimes, specific subpopulations of cells are selected using fluorescence activated cell sorting (FACS) (step 3 in Figure 4.15). FACS uses a machine to sort cells into separate tubes based on their fluorescence. We can make specific cells fluoresce using antibody labeling (see Methods: Immunohistochemistry) or by using transgenic model organisms that express fluorescent reporters in specific cell classes (see Methods: Transgenic Organisms). Once the cells of interest are collected, RNA sequencing is performed from individual cells, keeping transcripts from each cell separate (step 4 in Figure 4.15). This approach permits capturing transcriptional information from the individual cells that comprise a particular tissue. Researchers can now consider all of the transcriptional profiles from different cell populations (step 5 in Figure 4.15).

The data from single cell RNA sequencing can be visualized in several ways but one common way is in the kind of plots shown in the bottom of Figure 4.15 (also step 6 in Figure 4.15). On these plots, individual cells are represented as dots. Cells (dots) that are close to others are considered similar to each other. If cells are similar enough, they are considered a cluster. Clusters are shown as the color coding of the dots in Figure 4.15. These clusters are thought to represent different cell populations. For instance, glial cell subpopulations cluster together as do different neuronal populations. These methods have been used to investigate species differences in cell composition of different brain regions. Much of this work has been unfolding in the very recent years and we are in the early stages of using these techniques to learn about species differences in cellular composition. There are several interesting findings to emerge from this work already. For example, researchers have identified conservation but also modifications in cortical cell types across species (Bakken et al., 2021; Campagnola et al., 2022; Kim et al., 2023), and they have even identified novel cell types in the primate lineage (Krienen et al., 2020). Much work is ongoing to uncover species variations from single cell RNA sequencing. We now return to brain organoids and how these sequencing technologies have been used to assess species differences in brain organoids.

Species differences revealed from brain organoids

Comparative analyses of brain organoids at different stages of maturity have revealed interesting insights about the evolution

of brains. In these studies, researchers selected mature cells from humans and great apes, induced them into pluripotency, and grew them in the laboratory as brain organoids. They then sampled these brain organoids at different ages in different species and measured variables like gene expression and anatomy. For example, one study compared transcriptional profiles using RNA sequencing across the brain organoids of humans and chimpanzees (Pollen et al., 2019). They found that the maturation of brain organoids was similar in the early phases of organoid development, but later diverged between human and non-human primates. Another study relied on single cell RNA sequencing data in humans, chimpanzees, and macaques and found that the maturation of brain organoids in humans was slower than in other non-human primates (Kanton et al., 2019). Studies such as these have converged on the finding that the maturation of brain organoids is protracted in humans relative to other primates (Schörnig et al.. 2021). Yet, an unresolved question is how observations made from brain organoids translate to the full organism, and whether media used to grow these primate brain organoids are appropriate for other species.

1.4.8: Section Summary

4.1 How Do We Choose A Model System?

Access multimedia content

Interactive Content

This interactive element is not available in this format. Visit the link or scan the QR code to access it online.

View this Interactive Content online

Animal models are used to understand biological phenomena and behaviors that can be applied to a broad range of species. The choice of model organisms is based on behavioral characteristics, breeding, ease of handling and/or exceptional abilities. Animal research must follow strict guidelines and be approved by an ethics committee called IACUC. While animal models have a proven track record in saving human lives, there are emerging alternatives such as organoids that may reduce the need for animal testing.

4.2 How Do We Compare Brains?

To date, there is still no clear consensus as to what structures are homologous to the mammalian cortex and their equivalent in birds. We reviewed one unresolved case that highlights the challenges that arise from attempting to define homologous neural structures across distantly related lineages. This is not to say that neuroscientists simply argue about homologies. Rather, we selected this topic because unresolved cases demonstrate the many kinds of perspectives we might use to define homology. Some perspectives place an emphasis on adult structure whereas others place an emphasis on developmental processes that give rise to adult structures.

4.3 How Do Brains Vary in Size?

The size of the brain and parts are relatively large in humans compared with other species. Cross-species comparisons across diverse species show that brain regions sometimes vary allometrically (Finlay and Darlington, 1995; Finlay et al., 2011; Barton and Harvey, 2000), but grade shifts are also possible, which means that regions are larger or smaller than allometry would predict given their brain size. Sensory and motor specializations carve out cortical territories so that the relative size of brain parts is dictated by allometry, lifestyle, and environment.

4.4 How Do Connections Differ Across Species?

We discussed methods used to study brain pathways. It's a tricky subject and most of the pathways we study in human neuroscience are inferred from model systems. Some methods are only available in model systems (e.g., tracers) but others (e.g., diffusion imaging) are also available for use in humans. The map of human brain pathways remains a work-in-progress. Due to the inherent limitations of methods for studying human brain connectivity, many researchers use the principle of conservation to make inferences about connectivity profiles in humans. We rely on features that are constant across diverse mammalian species to extrapolate the map of human brain pathways. Yet, some pathways should be specific to humans, and we have yet to identify many of the pathway types that are unique to humans. Some researchers have turned to integration of large-scale maps from neuroimaging with genetics to identify how pathways have evolved across species (Charvet et al., 2022).

4.5 How Can Diverse Species Help Us Make Inferences about Human Neurobiology?

As is evident from our overview of the development and neural basis of social bonds, the selection of model systems depends on the biological program of interest. Groups of closely related species offer advantages in understanding human neurobiology as is the case of voles. Non-human primates also enable probing into our biological processes due to their phylogenetic proximity to humans. We discussed how we can use early postnatal development from macaques to study human fetal development.

4.6 How Can Brain Organoids Help Us Make Inferences about Brain Evolution?

The use of brain organoids coupled with RNA sequencing technology have provided new insights into the evolution of the human brain. Comparative analyses have converged on the finding that brain maturation in humans is extended relative to great apes. Questions remain as to how information gained from brain organoids relates to the individual. Nevertheless, these methods are exciting and open new avenues of research. Indeed, there is much left to learn about the evolution of the nervous systems. The field of comparative neuroscience is well positioned to make important contributions to many areas of biomedical sciences.

1.4.9: Key Terms

4.1 How Do We Choose A Model System?

Model system, IACUC

4.2 How Do We Compare Brains?

Homology, telencephalic/telencephalon, cerebral cortex, grey matter, white matter, layers, nuclei, field homology, isocortex-DVR hypothesis, claustroamygdala-DVR hypothesis

4.3 How Do Brains Vary in Size?

Allometry/allometric, grade shift

4.4 How Do Connections Differ Across Species?

Neuroimaging, tract-tracers, diffusible dyes, resting states fMRI, diffusion MR imaging

4.5 How Can Diverse Species Help Us Make Inferences about Human Neurobiology?

Synaptogenesis, neurogenesis, neural stem cell, birth-dating techniques, social bonds

4.6 How Can Brain Organoids Help Us Make Inferences about Brain Evolution?

Brain organoids, induced pluripotent stem cells, RNA sequencing

This page titled 1.4.9: Key Terms is shared under a CC BY-NC 4.0 license and was authored, remixed, and/or curated by Ivette Merced via source content that was edited to the style and standards of the LibreTexts platform.

1.4.11: Multiple Choice

4.1 How Do We Choose A Model System?

1.
We do we study model organisms?

a. Humans are not interesting to study.
b. They are computational approximations of real neural systems.
c. What we learn can apply across species.
d. We can conduct work in them without any regulatory approval.

2 .
IACUC review of proposed animal studies focuses on:

a. ensuring that the animals do not feel pain and/or that measures are taken to minimize pain.
b. keeping costs low for the researchers.
c. checking that the researchers have sufficient funding to perform the research.
d. All the above.

3.
To receive IACUC approval, an animal study must:

a. benefit the animal.
b. have potential value to society.
c. use a large number of animals.
d. use organoids.

4.2 How Do We Compare Brains?

4 .
Comparative neuroscience is typically studied at which scale?

a. Micro
b. Meso
c. Macro
d. All the above

5.
Organization of distinct grey and white matter:

a. is the same in bird and mammal telencephalon.
b. is found in bird but not in mammal telencephalon.
c. is found in mammal but not in bird telencephalon.
d. is not found in bird or mammal telencephalon.

6 .
Birds lack distinct grey and white matter in their telencephalon:

a. because they don’t have myelin.
b. because they don’t have neurons.
c. because their neurons are organized in nuclei instead of layers.
d. because the axons in birds are interspersed through among cell bodies and are not bundled together in large, distinct groups.

7.
In the isocortex-DVR hypothesis, what consideration drives how homologous regions of mammalian and avian brain are defined?

a. Field homology of the cells that populate brain regions
b. What cellular population from development eventually populates the area
c. How the areas connect to other brain regions
d. The physical shape of the brain regions

8 .
The bird DVR is homologous to what in mammalian brains?

a. It depends on how you define homology
b. The claustroamygdala complex
c. The neocortex
d. The hyperpallium

4.3 How Do Brains Vary in Size?

9.
Human brains have the most proportional brain volume dedicated to cortex among primates.

a. True
b. False

10 .
Differences in total brain size between species:

a. explain a large portion of differences in cognitive capacity.
b. explain only a tiny portion of differences in cognitive capacity.
c. reveal that humans have the largest brains of any known animals.
d. are overall small-that is, brains of most known species are around the same size.

11.
Imagine a species with a brain five times larger than a human's brain. Based on the allometry of the cortex, how large would you expect the cortex to be, relative to that of a human?

a. Also five times bigger
b. More than five times bigger
c. Less than five times bigger
d. None of the above

12 .
The "grade shift" in cortical volume proportion in the brain among primates means:

a. the primate cortex is larger than would be predicted just based on the primate's total brain size.
b. the primate cortex is smaller than would be predicted just based on the primate's total brain size.
c. the primate cortex is sized just as would be predicted just based on the primate's total brain size.
d. the primate cortex is homologous across species.

4.4 How Do Connections Differ Across Species?

13.
If you wanted to trace a neural pathway in mice, which technique would be best?

a. Inorganic dyes used on postmortem tissue
b. Tract-tracers injected in the brain region of interest
c. Structural MR imaging
d. Diffusion tensor imaging

14 .
Which kind of connection is most common in the brain?

a. Local connections
b. Long-range connections
c. We don't know
d. Local connections for smaller brains and long-range connections for larger brains

15.
Which imaging technique is used to measure spontaneous brain activity in humans?

a. Resting-state fMRI
b. Task-based fMRI
c. Structural MRI
d. Diffusion MRI

16 .
What does functional MR imaging measure most directly?

a. Blood fluctuations
b. Neuronal activity
c. Neuronal glucose uptake
d. Diffusion of water molecules along axonal pathways

17.
What is a limit to using tract-tracers to define neural circuits?

a. They cannot be ethically used in humans.
b. They are labor intensive and therefore studies using them take a long time to do.
c. They can only be used in live animals.
d. All of these are limits to tract-tracers.

18 .
Anterograde tracers move:

a. from cell body to the axon/axon terminals.
b. from axon/axon terminal to the cell body.
c. in both directions—to the axon and to the cell body.

19.
Connectivity in human brains is inferred from:

a. Resting-state fMRI.
b. Diffusion MRI.
c. Information from model systems.
d. All of these combined.

4.5 How Can Diverse Species Help Us Make Inferences about Human Neurobiology?

20 .
In the partner preference assay, a male vole spends more time near a female previously mated with than near a new female. What is most likely true about this male vole?

a. The male vole is a member of a monogamous pair-bonding species.
b. The male vole is a member of a polygamous species.
c. The male vole is an odd exception to the rule; rodents usually prefer novel partners.
d. It is a mystery what is going on here.

21.
Monogamous and polygamous voles are useful for studying pair-bonding because:

a. their brains are very similar, yet they show very different behaviors.
b. their brains are very different, yet they show very similar behaviors.
c. they are more closely related to humans than other primates.
d. they are the only species known to show monogamous pair bonding.

4.6 How Can Brain Organoids Help Us Make Inferences about Brain Evolution?

22 .
What are reason(s) we use organoids to study brain development?

a. We can make them from many species, including those that are hard to study, like humans.
b. They show many structural and gene expression similarities to the developing nervous system.
c. They can be derived from individual human patients.
d. All of these

23.
Brain organoids mimic many steps of neural development in real brains. If you gave a birth-date marker very early in organoid development then looked for that marker much later, where would you find it?

a. In the inner layers of the organoid
b. In the outer layers of the organoid
c. Spread throughout the organoid

24 .
Imagine you wanted to study when different cell populations (neurons, glia) emerge during development in humans and great apes. You are going to use organoids to model neurodevelopment in these two species. Which technique would best help you study your question?

a. Single cell RNAseq
b. Bulk RNAseq
c. MRI
d. FACS

1.4.12: Fill in the Blank

4.1 How Do We Choose A Model System?

1.
A _____ is an animal species that is studied to gain understanding about biological phenomena, with the expectation that what is learned will apply broadly across other species.

4.2 How Do We Compare Brains?

2 .
A researcher using connectivity patterns to define homology between bird and mammal telencephalon _____ (would/would not) define homologous regions similarly to someone using developmental origins of cells.

4.3 How Do Brains Vary in Size?

3.
The change in proportional contribution of different brain regions to total brain volume as total brain volume changes is called _____.

4.4 How Do Connections Differ Across Species?

4 .
_____ are compounds that diffuse passively along axons to allow tracing of neural pathways.

4.5 How Can Diverse Species Help Us Make Inferences about Human Neurobiology?

5.
Synapses are best visualized using _____.

4.6 How Can Brain Organoids Help Us Make Inferences about Brain Evolution?

6 .
Organoids are three-dimensional spheres grown in vitro from _____.

1.5: FUNCTIONAL ANATOMY- NERVOUS SYSTEM ANATOMY -FUNCTIONAL ANATOMY OF THE CEREBRAL CORTEX AND SPINAL CORD

Learning Objectives

At the end of this lab, you will be able to...

1. Correctly identify the structures of importance within cerebral cortex
2. Correctly identify the structures of importance within the spinal cord
3. Correctly name the cranial nerves and indicate general functions
4. Correctly and independently perform simple dissections
5. Use correct anatomical terminology when discussing structures of the nervous system

Pre-Lab Exercise:
After reading through the lab activities prior to lab, complete the following before you start your lab

1. The structures of the Central Nervous System include:
2. The connective tissues that surround the cerebral cortex and spinal cord are known as the and is made of three layers: that connect to the tissues, that connects to the bones and the that contains the cerebral spinal fluid.
3. You will make two incisions during the dissection of the brain (cerebral cortex) either along the fissure to separate the brain into a right and left hemisphere and along the fissure to separate the superior from the inferior.
4. Color the images for use as a reference for identifying the models and dissected specimens.

Materials:

- Brain Models
- Spinal Cord Model
- Sagittal Head Model
- Sheep's Brain and Dissection Tools
- Prosected Human Brain and Spinal Cord
- Stickers
- Felt Pens
- Colored Pencils

The central nervous system (CNS) is comprised of the neurons and glial cells that form the neural tissue of the cerebral cortex (including the lobes, limbic system, thalamus, hypothalamus, cerebellum, pons, and medulla oblongata), and spinal cord.

Activity 1: Cerebral Cortex:

The cerebral cortex is a gelatinous mass of cells, nothing like the fixed brains that we might think of, that is divided into distinct regions that perform functional tasks for maintaining homeostasis in the body. The neuron mass within the cerebral cortex is highly invaginated (folded) forming structures known as sulcus (fold) and gyrus (cell mass). This folding is generated by the synaptic connections occurring between cells that hold layers of cells together and move the layers based on movement of neurons in and around each other in order to maintain synaptic connections. The folding and invagination is the effect of having limited volume of the cranial vault for the mass of cells that are contained within the cerebral cortex.

Hindbrain

The Hindbrain is comprised on the pons, medulla oblongata and cerebellum. This is the most conserved region of the cerebral cortex. Within its many functions the hindbrain serves as a relay network that connects cerebral cortex to the spinal cord, forms projections that develop into the cranial nerves and the extra-pyramidal tracts of the spinal cord and serves as a region for regulation of autonomic functions.

Midbrain

The midbrain is the next most conserved region of the cerebral cortex. The structures of the midbrain, figure 14a-b and 15 c, are

involved with many of the regulatory functions of homeostasis along with establishing neural relays key to cognitive functions and learning. The midbrain establishes connections between forebrain and hindbrain structures along with direct paths to the spinal cord and is comprised of structures that are referred to as the Limbic cortex.

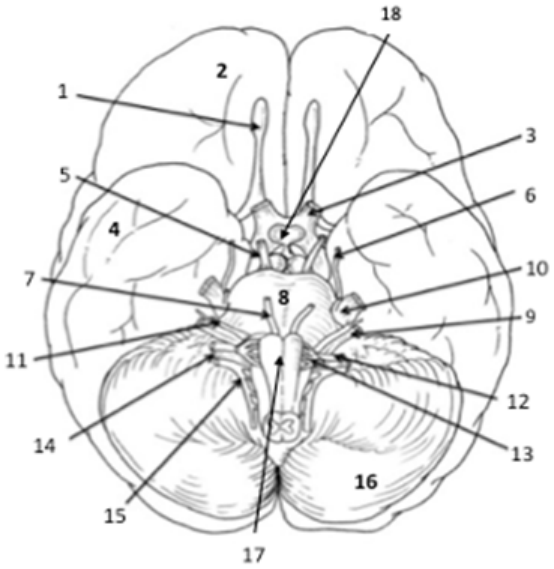
Limbic System

The Limbic structures are the midbrain structures involved with activities of memory integration and automatic/hormonal responses to somatic sensory (homeostatic) information or relays information for coding purposes to higher cortical regions or from higher cortical regions to periphery for response. These structures also include the Hypothalamus, Thalamus, Hippocampus, and various nuclei and ganglion within the central region of the brain.

Forebrain Lobes

The forebrain is comprised of the lobes and structures that are familiarly known and that is associated with controls and regulates complex activities within the body based on the individual lobe. These include the frontal, parietal, occipital and temporal lobes that are named based on the cranial bone that overlays the lobe of the cerebral cortex. The frontal lobe is associated with functions of conscious thought process, memory and emotional responses. The parietal lobe is associated with somatosensation and proprioception and interactions with the frontal lobe to allow for somatic motor control. The occipital lobe is associated with visual processing and spatial recognition. The temporal lobe is associated with auditory processing along with language and symbol recognition.

Cranial Nerves



The cranial nerves are specialized peripheral nerves that originate in the hindbrain and brainstem of the cerebral cortex that provides innervations to the cranium, internal organs of the torso and are involved with autonomic, somatic sensory, visceral sensory, somatic motor and special senses of the body. The naming and identification of the cranial nerves (CN) are done either by classical name, or numerically based on where the nerve exits the cerebral cortex. Where the order of numbering of the cranial nerve is established from the most anterior superior (rostral) being the first and the most posterior-inferior nerve (caudal) being the twelfth. Using the numerical orientation, the nerves are indicated as cranial nerve (CN) and then by Roman Numeral (I-XII) to indicate the order of exiting the cerebral cortex. The site of origin for the cranial nerve (CN) and location of specific nuclei of origination indicates how specific (or diffuse) of a role that nerve has on homeostatic functions for the body. CN I through CN II originate within the proencephalon, while CN III through CN XII originate within the mesencephalon and rhombencephalon from nuclei ganglion near to the Thalamus, Pons and Medulla.

Procedures:

1. Obtain models, stickers, felt pens
2. Write the names of the key anatomical structures of the cerebral cortex on to the stickers

    a. Frontal Lobe, Parietal Lobe, Occipital Lobe, Temporal Lobe, Cerebellum, Pons, Medulla Oblongata, Broca's Area, Wernicke's Area, Primary Motor Cortex, Primary Somatosensory Cortex
    b. Corpus Callosum, Thalamus, Hypothalamus, Fornix, Choroid Plexus, Lateral Ventricle, Fourth Ventricle, Cerebral Aqueduct

3. Select a "team leader" and using the colored images as reference have members of the group take turns labeling the brain model with the key anatomical structures.
4. Using a pen or pencil, take turns within your group identifying the cranial nerves on the model of the cerebral cortex.
5. With your instructor, observe the prosected human brain and spinal cord. Relate the structures that you have identified on the model and in the coloring images to what can be viewed on the human organs.
6. Have your instructor check your work and then move to the next activity.

Key Anatomical structures of the cerebral cortex:

1 Cranial Nerve I (Olfactory)

2 Frontal Lobe

3 Cranial Nerve II (Optic)

4 Temporal Lobe

5 Cranial Nerve III (Oculomotor)

6 Cranial Nerve IV (Trochlear)

7 Cranial Nerve VI (Abducens)

8 Pons

9 Cranial Nerve VIII (Cochleovestibular)

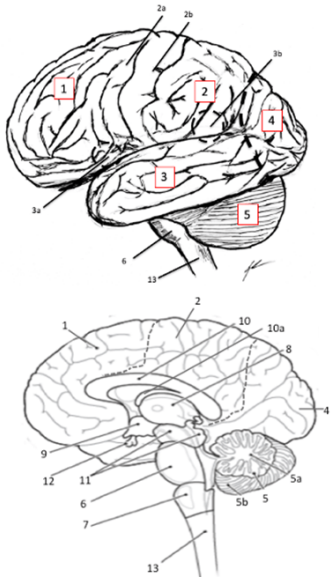
10 Cranial Nerve V (Trigeminal)

11 Cranial Nerve VII (Facial)

12 Cranial Nerve IX (Glossopharyngeal)

13 Cranial Nerve X (Vagus)

14 Cranial Nerve XI (Spinal Accessory)



15 Cranial nerve XII (Hypoglossal)

15 Cerebellum

17 Medulla Oblongata

18 Hypothalamus and Pituitary Gland

Color each structure a different color for use as a reference when identifying.

Key Anatomical structures of the cerebral cortex:

1 Frontal Lobe

2 Parietal Lobe

2a Primary Motor Cortex (Pre-Central Gyrus)

2b Primary Somatosensory Cortex (Post-Central Gyrus)

2c Central Sulcus

3 Temporal Lobe

3a Lateral Sulcus

3b Brocca's Area

3c Wernicke’s Area

4 Occipital Lobe

5 Cerebellum

5a Arbor Vitae of Cerebellum

5b Vermis of Cerebellum

6 Pons

7 Medulla Oblongata

8 Thalamus

9 Hypothalamus

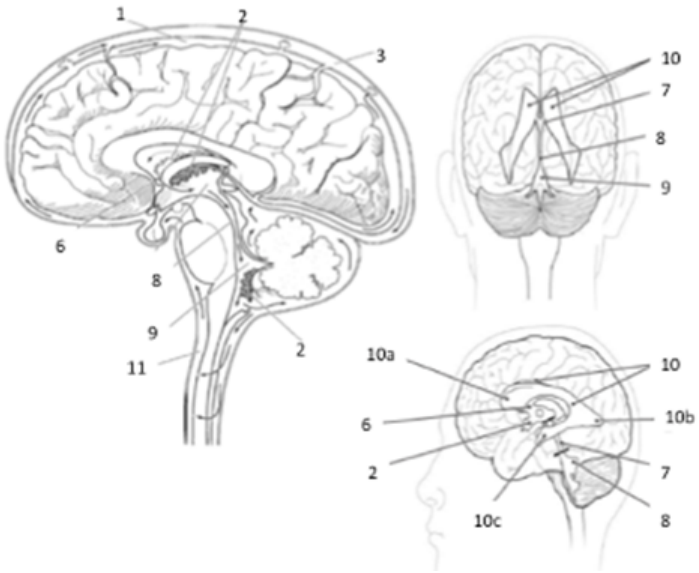
10 Corpus Callosum

10a Fornix

11 Tectum & Limbic System

12 Pituitary Glans

13 Spinal Cord



Color each structure a different color for use as a reference when identifying.

Activity 2: Connective Tissue and Ventricles:

The gelatinous mass that is the cerebral cortex is suspended in a viscous solution (cerebral spinal fluid, CSF) within the cranial vault between three fibrous membranes (mater layers) that connect it to the boney structures. The distinct type of mater layer is identified by what the connective tissue is connecting. The pia mater is dense regular connective tissue that connects to the neural tissues of the CNS. The arachnoid is loose areolar and reticular connective tissue that connects the dura mater to the pia mater. The arachnoid allows for the passage of blood and lymph vessels into the cerebral cortex tissues and structures of the CNS. The dura mater is dense regular connective tissue that connects to the bone tissues of the cranium and vertebrae. Within these layers of connective tissues, invaginations and folds develop. These folds are the ventricles of the maters within the cerebral cortex that allows for the movement of the cerebral spinal fluid within and throughout the tissues and connects the movement of CSF to the vascular flow to ensure that the tissues are perfused correctly and materials are flushed from the CNS on a regular basis.

Procedures:

1. Obtain models, stickers, felt pens
2. Write the names of the key anatomical structures of the meninges and ventricles on to the stickers
3. Select a “team leader” and using the colored images as reference have members of the group take turns labeling the sagittal head model with the key anatomical structures.
4. Have your instructor check your work and then move to the next activity.

Key Anatomical structures of the cerebral cortex:

1=Pia Mater

2=Choroid Plexus

3=Subdural Space

4=Arachnoid Matter

5=Dura Matter

6=Interventricular Foramen

7=Third Ventricle

8=Cerebral Aqueduct

9=Fourth Ventricle

10=Lateral Ventricle

10a=Anterior Horn of Lateral Ventricle

10b=Posterior Horn of Lateral Ventricle

10c=Lateral Horn of Lateral Ventricle

11=Central Canal

Color each structure a different color for use as a reference when identifying.

Activity 3: Spinal Cord:

The spinal cord is an elongation of axons and interneurons leaving the brain stem and hindbrain of the cerebral cortex and travelling the length the vertebral column. While we may discuss the spinal cord as being a solid bundle of tissues (axons) near

the inferior (caudal) aspects the spinal cord becomes slightly less bundled, forming the structure identified as the cauda equinae. This diffusion of axons typically occurs at the level of the second or third lumbar vertebrae. Within the organized axonal bundle region (from the foramen magnum through the initiation of the cauda equinae) there is a rigid structural orientation that the spinal cord possesses.
Within this rigid structure, there exists a general organization to the neural tissues within the spinal cord. The organization is such that we are able to divide the axonal and interneurons into tracts based on a dorsal (posterior) and ventral (anterior) orientation. Where the dorsal (posterior) will primarily have neural networks and tracts that are involved with sensory issues, while the ventral (anterior) will primarily have the neural networks and tracts involved with motor issues. Additionally, the tissue can be indicated based on staining as being “gray” or “white” tissue within the spinal cord. In which the gray is an indication of cell bodies and unmyelinated regions and the white is an indication of axons and myelinated regions.

Procedures:
1. Obtain models, stickers, felt pens
2. Write the names of the key anatomical structures of the spinal cord on to the stickers

    a. Dorsal Horn, Dorsal Nerve Root, Dorsal Root Ganglion, Dorsal Sensory Tracts, Commissure, Central Canal, Ventral Horn, Lateral Horn, Ventral Nerve Root, Spinal Nerve

3. Select a “team leader” and using the colored images as reference have members of the group take turns labeling the spinal cord model with the key anatomical structures.
4. Have your instructor check your work and then move to the next activity.

Key Anatomical structures of the cerebral cortex:

1a Cerebral Cortex

1b Thalamic Nuclei

1c Hind Brain

2 Spinal Cord

2a Cervical Nerve Roots

2b Thoracic Nerve Roots

2c Lumbar Nerve Roots

2d Sacral Nerve Roots

2e Coccygeal Nerve Roots

2f Cauda Equinae

3 Cervical Enlargement

3a Brachial Plexus

4 Spinal Nerves

4a Ventral Root

4b Dorsal Root

4c Dorsal Root Ganglion

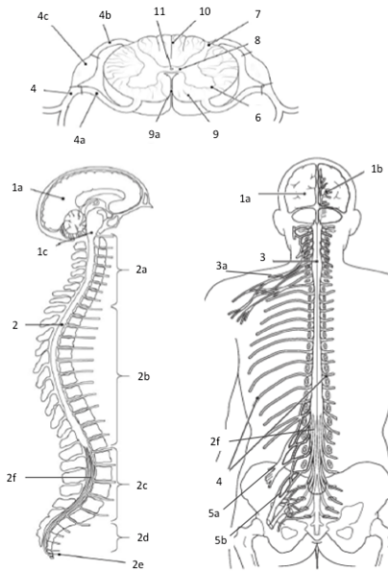
5a Lumbar Plexus

5b Sacral Plexus

6 Ventral Horn

7 Dorsal Horn

8 Gray Matter



9 White Matter

9a Ventral (Anterior) Median Sulcus

10 Dorsal (Posterior) Median Sulcus

11 Central Canal

Color each structure a different color for use as a reference when identifying.

Activity 4: Dissection:

1. Observe the external anatomy of the brain. Identify the meningeal layers covering the sheep's brain. Note the thickening of the meninges that forms between the cerebellum and the occipital lobe.
2. As you observe, turn the brain so that you are able to examine the exterior of the brain superiorly, inferiorly and laterally. In the inferior view, note the various cranial nerves that are visible, if the pituitary is still present, the pons and medulla oblongata
3. Using your dissecting shears, make a small hole near the most anterior part of the frontal lobe in the meninges
4. Take your blunt probe and insert it into the small hole that you just cut in the meninges and carefully lift the meninges to separate it from the brain tissue.
5. Using your dissection shears, scalpel and blunt probe, carefully remove the meninges from rest of the brain. Be careful as you remove meninges from the inferior part of the brain (if necessary, get assistance from your instructor).
6. After removing the meninges, repeat the examination of the external anatomy of the brain.
7. In the posterior examination, gently displace the cerebellum to reveal the Colliculi and Pineal Gland that is now visible between the cerebellum and rest of the brain.
8. After examining the external structure, place the brain on the dissection tray and locate the medulla oblongata.
9. Move the dissection tray to the dissecting scope and adjust the magnification until you are able to clearly see the edge of the medulla oblongata.

    a. Make a transverse cut across the medulla to separate the initial segment of the spinal cord from the rest of the brain
    b. Lay the spinal cord flat on the dissection tray and move the tray so that the spinal cord is seen in the dissection scope.
    c. Examine the spinal cord and note the organization of the horns, white matter, gray matter and commissure. Compare to the model that you have previously examined.

10. In your paired groupings: 1 group will perform the longitudinal dissection and 1 group will perform the superior transverse dissection.

    a. Longitudinal Dissection:

        i. Remove the dissection tray from the dissection scope and find the longitudinal fissure
        ii. Dissect the brain using a sagittal (longitudinal) cut through the longitudinal fissure and the medial structures
        iii. Continue the dissection until you have a right and left half of the brain to examine
        iv. Examine the anatomical structures of importance that are now visible to the internal medial surface

b. Superior Transverse Dissection:

i. Remove the dissection tray from the dissection scope and find the transverse fissure (“bump” that separates temporal lobe from frontal lobe
ii. Dissect the brain by making a circular incision around the right and left hemispheres to remove the “top” of the brain from the remainder of the sheep’s brain.
iii. The cut should reveal the opening to the lateral ventricles and the thalamus to the center and visible white matter (axonal pathways) through the remainder of the brain
iv. Examine the internal structures of importance that are now visible and then review the inferior aspects of the brain to identify structures of importance.

c. Combine the two groups and take turns within the groups to identify (using pins or probe) structures of importance.

1.5.1: Nervous System Tissue

Learning Objectives

1. Differentiate the central nervous system from the peripheral nervous system
2. Name the two types of cells found in nervous tissue
3. Explain the basic functions of neurons and glia
4. Describe the structures of a neuron
5. Give an example of a type of neuron that is classified by its structure, function, or other characteristic
6. Give an example of a glial cell and its function

Overview

This module presents a brief overview of the nervous system and goes into greater detail on nervous tissue cell types, including neurons (structure, types, and neurogenesis) and glia (types and functions).

In the Blink of an Eye

As you drive into a parking lot, a skateboarder suddenly flies in front of your car across your field of vision (Figure 1.5.1.1). You see the skateboarder in the nick of time and react immediately. You slam on the brakes and steer sharply to the right — all in the blink of an eye. You avoid a collision, but just barely. You're shaken up but thankful that no one was hurt. How did you respond so quickly? Such rapid responses are controlled by your nervous system.

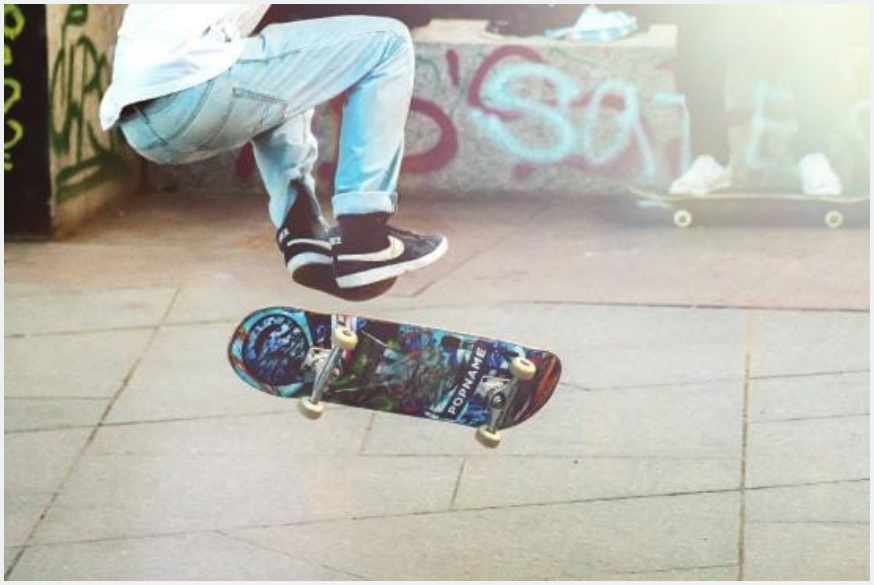

Figure 1.5.1.1: Skateboarder

Overview of the Nervous System

The **nervous system**, illustrated in Figure 1.5.1.2, is the human organ system that coordinates all of the body's voluntary and involuntary actions by transmitting electrical and chemical signals to and from different parts of the body. Specifically, the nervous system extracts information from the internal and external environments using sensory receptors. It then usually sends signals encoding this information to the brain, which processes the information to determine an appropriate response. Finally, the brain sends signals to muscles, organs, or glands to bring about the necessary response. The two main divisions of the nervous system are the central nervous system (CNS), consisting of the brain and the spinal cord, and the peripheral nervous system (PNS), which

includes all other nervous tissue, such as ganglia and nerves, outside the brain and spinal cord. The CNS and PNS are covered in greater detail in separate sections. In the example above, your eyes detected the skateboarder, the information traveled to your brain, and your brain instructed your body to act to avoid a collision.

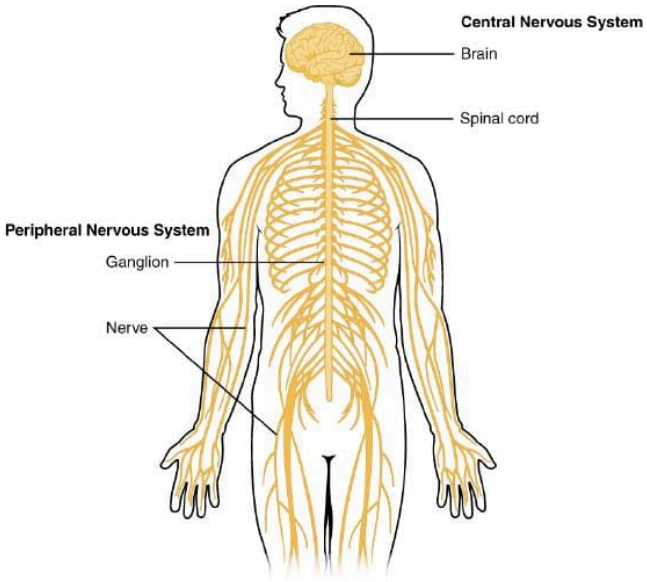

Figure 1.5.1.2: Overview of the Nervous System. The two main divisions of the nervous system are the central nervous system (the brain and the spinal cord) and the peripheral nerve system (which includes ganglia and nerves).

Nervous Tissue Cell Types

Nervous tissue is composed of two types of cells: neurons (also called nerve cells) and glia (also called glial cells or neuroglia), as shown in Figure 1.5.1.3. Neurons are responsible for the computation and communication that the nervous system provides. They are electrically active and release chemical signals to target cells. Glia are known to play a supporting role for nervous tissue. Ongoing research pursues an expanded role that glial cells might play in signaling, but neurons are still considered the basis of this function. Neurons are important, but without glial support they would not be able to perform their function.

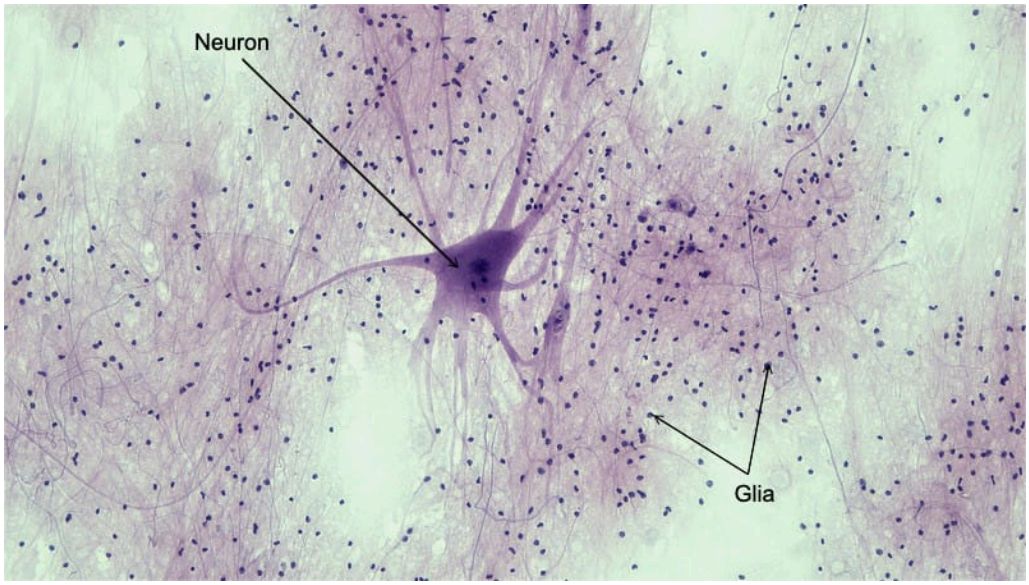

Figure 1.5.1.3: Labeled Nervous Tissue Smear. Nervous tissue from the spinal cord shows a neuron and glial cells. Glial cells are smaller and in larger quantities than neurons. The neuron shown is large and has multiple processes coming out of the soma (cell body). The magnification of the picture is 100X.

Neurons

Neurons, also called nerve cells, are electrically excitable cells that are the main functional units of the nervous system. Their function is to transmit nerve impulses. They are the only type of human cells that can carry out this function. Neurons are large cells with a high metabolic rate and they depend on a continuous and abundant supply of oxygen and glucose. Neurons are responsible for the electrical signals that communicate information about sensations, produce movements in response to those stimuli, and induce thought processes within the brain. An important part of the function of neurons is in their structure, or shape. The three-dimensional shape of these cells makes the immense numbers of connections within the nervous system possible. In the micrograph of human nervous tissue, Figure 1.5.1.4, the neon green structures in the forefront of the image are neurons.

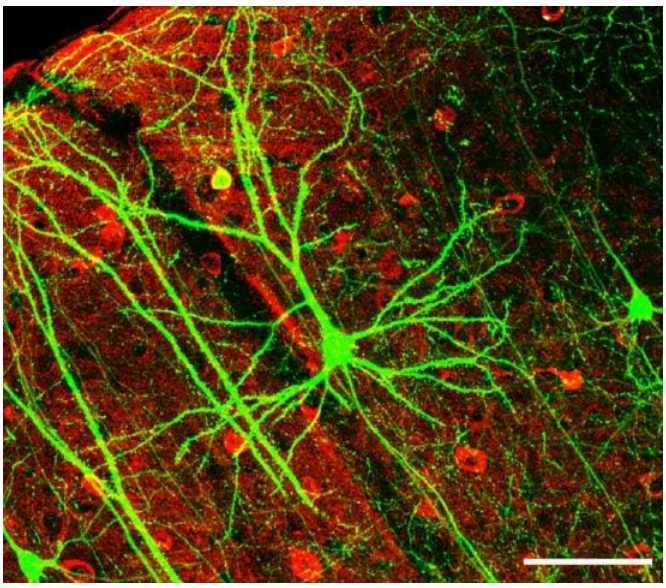

Figure 1.5.1.4: Interneurons of adult visual cortex.

Neuron Structure

The main thing that makes neurons special and differentiates them from other cells in the body is that they have many extensions of their cell membranes, generally referred to as processes. Neurons are usually described as having one, and only one, **axon**—a fiber that emerges from the cell body and projects to target cells. That single axon can branch repeatedly to communicate with many target cells. It is the axon that propagates the nerve impulse (also called an action potential), which is communicated to one or more cells. The other processes of the neuron are **dendrites**, which receive information from other neurons across specialized areas called **synapses**. The dendrites are usually highly branched processes, providing locations for other neurons to communicate with the cell body. Information flows through a neuron from the dendrites, across the cell body, and down the axon.

Figure 1.5.1.5 shows the structure of a typical neuron. The main parts of a neuron are labeled in the figure and described below.

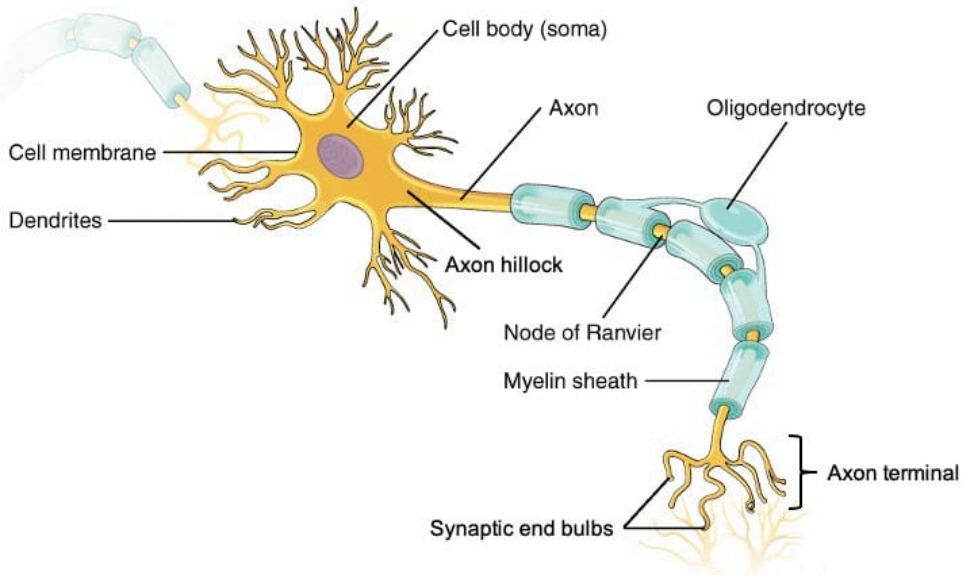

Figure 1.5.1.5: Neuron. A somatic motor neuron (in the CNS) with labeled structures: cell membrane, dendrites, cell body (soma), axon, axon hillock, node of Ranvier, myelin sheath, axon terminal, and synaptic end bulbs (also called axon terminal buttons). The oligodendrocyte shown to the side of the axon is a glial cell that forms the myelin sheath surrounding the axon.

- The **cell body** (or soma; soma = "body") is the part of a neuron that contains the nucleus (shown as an oval structure in the center of the cell body, but not labeled) and most of the major organelles. The cell body is usually quite compact, and may not be much wider than the nucleus. The **cell membrane** is the structure that surrounds all the surfaces of the cell (including the dendrites and axon) and separates the inside of the cell from the outside of the cell.
- **Dendrites** are thin structures that are extensions of the cell body. Their function is to receive messages (excitatory and inhibitory post-synaptic potentials, EPSPs/IPSPs- see the nervous system communication chapter) from other cells and carry them to the cell body. A neuron may have many dendrites, and each dendrite may branch repeatedly to form a dendrite "tree" with more than 1,000 **dendritic branches**. **Dendritic spines** (small extensions on the surface of the dendritic branches) further increase surface area for receiving messages, allowing a given neuron to communicate with thousands of other cells.
- The **axon** is a long, thin extension of the cell body. It transmits nerve impulses away from the cell body and toward other cells. The **axon hillock** is a small bulge found at the base of motor neuron axons. The nerve impulse (or action potential) starts from the axon hillock.
- The axon branches at the end, forming the **axon terminal**. Branches of the axon terminal end in **axon terminal buttons** (also called axon endings, synaptic end bulbs, synaptic buttons/boutons, bouton terminaux, etc.) These are the points where the message is transmitted to other cells (via the release of chemicals called neurotransmitters), often to the dendrites of other neurons. A small gap called a **synapse** (also called a synaptic gap or synaptic cleft) is located between the end of the axon terminal and the surface of the receiving cell. An axon may branch hundreds of times, but there is never more than one axon per neuron.
- Many axons (especially the long axons of nerves in the peripheral nervous system) are covered by sections of myelin (also called the **myelin sheath**). The myelin sheath is composed of lipid layers that surround the axon. Myelin is a very good electrical insulator, like the plastic or rubber that encases an electrical cord. Axons that are covered by sections of myelin are called **myelinated**, whereas axons without myelin sheaths are called **unmyelinated**.
- Regularly spaced gaps between sections of myelin occur along the axon. (The gaps are actually much further apart than is shown in the figure- it is necessary to shrink the distance to fit all the structures in a diagram!) These gaps are called **nodes of Ranvier**, and they allow the transmission of nerve impulses along the axon. Nerve impulses jump from node to node in a process called **saltatory conduction**, allowing nerve impulses to travel along the axon very rapidly.
- The **oligodendrocyte** shown in the figure is a glial cell that produces myelin sheaths in the central nervous system (brain and spinal cord)- see the Glia section below.

Classification of Neurons

There are many neurons in the nervous system- an estimated 86 billion in the brain alone (Lent et al., 2012). And there are many different types of neurons, exhibiting a variety of structures and functions. Neurons can be classified depending on their structure, function, or other characteristics.

Structural Classification

One type of structural classification depends on the number of processes attached to the cell body: one, two or multiple (Figure 1.5.1.6). The structures of these three different types of vertebrate neurons support their unique functions, as described below.

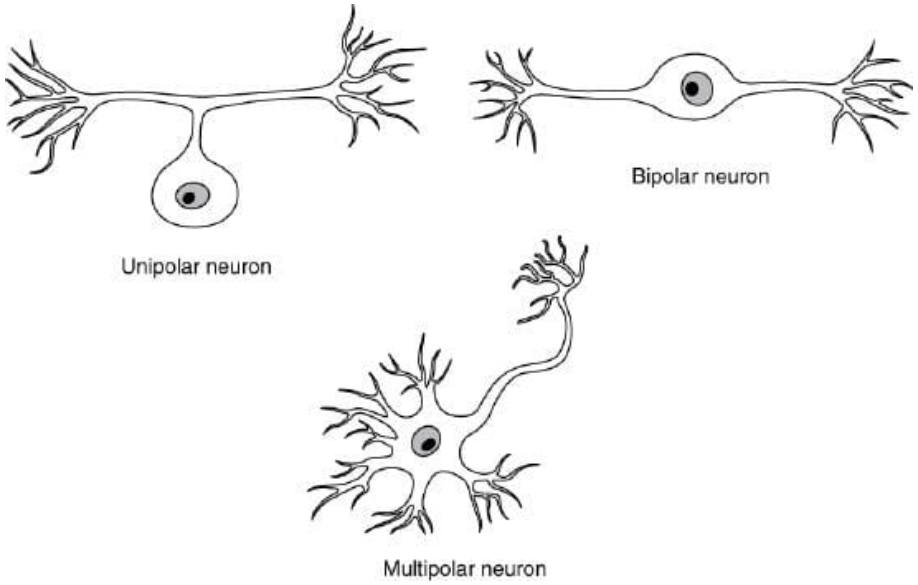

Figure 1.5.1.6: Neuron Classification by Structure. Unipolar neurons have one process emerging from the soma which contains both the axon and the dendrite. Bipolar neurons have two processes emerging from the soma: one is an axon and the other is a dendrite. Multipolar neurons have more than two processes emerging from the soma: one is an axon and two or more others are dendrites. (Note: True unipolar neurons are only found in invertebrates. The unipolar neuron pictured is technically a pseudo-unipolar neuron.)

Unipolar neurons have only one process emerging from the cell. True unipolar cells are only found in invertebrate animals, so the unipolar cells in humans are more appropriately called “pseudo-unipolar” cells. (Invertebrate unipolar cells do not have dendrites.) Human unipolar cells have an axon that emerges from the cell body, but it splits so that the axon can extend along a very long distance. At one end of the axon are dendrites, and at the other end, the axon forms synaptic connections with a target. Unipolar neurons are structured in a way that is ideal for relaying information forward. Unipolar cells are exclusively **sensory neurons** (see functional classification below), involved in processes like transmission of physiological information from the body’s periphery (such as communicating body temperature through the spinal cord up to the brain).

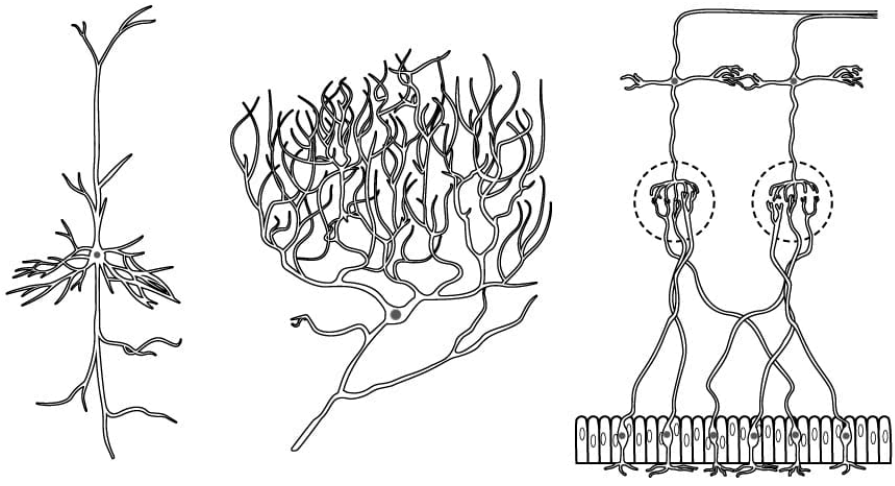
Bipolar neurons have two processes which extend from each end of the cell body opposite to each other. One is the axon and the other is the dendrite. Bipolar neurons help acquire and pass sensory information to various centers in the brain, and are not very common. Bipolar cells are are involved in sensory perception such as smell (from the olfactory epithelium), and light (in the retina of the eye). The bipolar cells of the retina are an intermediate layer of neurons between the deepest layer, the visual receptors (photoreceptors, comprised of the rods and cones), and the retinal ganglion cells, the most superficial layer of retinal neurons, whose axons bundle together to form the optic nerve (see the chapter on sensory systems for more information).

Multipolar neurons are all of the neurons that are not unipolar or bipolar, and are also the most common. They have one axon (which can branch forming multiple endings) and two or more dendrites (usually many more), which allows them to communicate with many other neurons. Multipolar neurons convey sensory and motor information in the brain, spinal cord, and throughout the body. With the exception of the unipolar sensory ganglion cells, and the two specific bipolar cells mentioned above, all other neurons are multipolar. Multipolar neurons can have multiple functions and include **motor neurons** (see functional classification below), which carry commands from the brain and spinal cord to muscles and glands, and **interneurons** (see functional classification below), which constitute the majority of neurons. One of the most prominent neuron types is a pyramidal neuron, which falls under the multipolar category. As mentioned below, it gets its name from the triangular or pyramidal shape of its soma (for examples see, Furtak, Moyer, & Brown, 2007).

Functional Classification

The main functional classification depends on which function the neuron is carrying out: sensation, integration or motor. A mnemonic to remember the functional classification and which direction the nerve impulses travel (towards the CNS= afferent;

away from the CNS= efferent) is "***SAME***" (***S***ensory -- ***A***fferent and ***M***otor -- ***E***fferent).



Sensory (also called afferent) **neurons** carry nerve impulses from sensory receptors in tissues and organs to the central nervous system. They convert physical stimuli such as touch, light, and sound into nerve impulses.

Motor (also called efferent) **neurons**, like the one in Figure 1.5.1.5, carry nerve impulses from the central nervous system to muscles and glands. These signals then stimulate or inhibit the activity of these structures.

Interneurons carry out integrative functions (such as retrieving, processing, and storing information) and facilitate communication between sensory and motor neurons (inter = "between"). Interneurons are found in the brain and spinal cord, and their processes do not extend outside of the structure they occupy. In other words, a given interneuron will have its dendrites, cell body, and axon all contained within the brain region or spinal cord segment where it is located.

Other Classifications

Neurons can also be classified on the basis of what they look like, where they are found, who found them, what they do, or even what chemicals (neurotransmitters) they use to communicate with each other. Some of these classifications will be discussed in greater detail in the communication in the nervous system chapter. As a b

(a) Pyramidal cell of the cerebral cortex

(b) Purkinje cell of the cerebellar cortex

(c) Olfactory cells in the olfactory epithelium and olfactory bulbs

Figure 1.5.1.7: Other Neuron Classifications. Three examples of neurons that are named on the basis of other criteria. (a) The pyramidal cell is a multipolar cell with a cell body that is shaped something like a pyramid. (b) The Purkinje cell in the cerebellum was named after the scientist who originally described it. (c) Olfactory cells (located in the olfactory epithelium and olfactory bulbs) are named for the functional group to which they belong.

Gray Matter and White Matter

The nervous tissue in the brain and spinal cord consists of **gray matter** and **white matter**. Gray matter contains mainly the cell bodies and dendrites of neurons. It is gray only in cadavers; living gray matter is actually more pink than gray (Figure 1.5.1.8). White matter consists mainly of myelinated axons, giving it a white color. In the brain, the gray matter is on the outside surface (the **cortex**) and the white matter is on the interior; in the spinal cord it is reversed- the gray matter is inside and the white matter surrounds it.

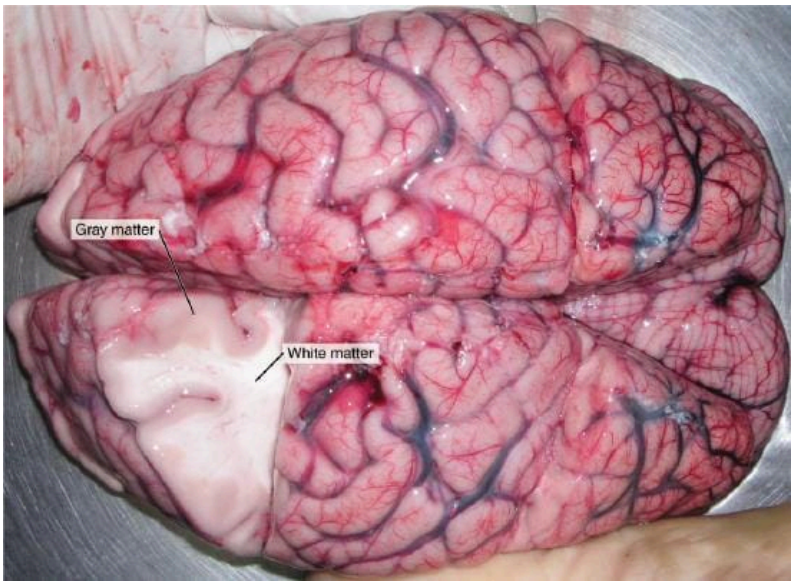


Figure 1.5.1.8: White and gray matter. You can see the layers of (pinkish) gray matter and white matter in this photo of a brain from a recently deceased human patient.

Nerves in the peripheral nervous system are also white matter. Nerves consist of long bundles of myelinated axons that extend to muscles, organs, or glands throughout the body. The axons in each nerve are bundled together like wires in a cable. Axons in nerves may be more than a meter long in an adult. The longest nerve runs from the base of the spine to the toes.

Neurogenesis

Fully differentiated neurons, with all their special structures, cannot divide and form new daughter neurons. Until recently, scientists thought that new neurons could no longer be formed after the brain developed prenatally (see the section on nervous system development). In other words, they thought that people were born with all the brain neurons they would ever have, and as neurons died, they would not be replaced. However, new evidence shows that additional neurons can form in certain areas of the brain, even in adults, from the division of undifferentiated neural stem cells that are found throughout the brain. The production of new neurons is called **neurogenesis.** The extent to which it can occur in adult humans is not known, but it is not likely to be very great.

Recent research indicated that new neurons formed in the amygdala of adult mice (Jhaveri at al., 2018). As the amygdala is important for emotional memory, particularly related to fearful experiences, future research may suggest new treatments for disorders such as post-traumatic stress disorder (PTSD) and depression.

If research on rats is found to apply also to humans, then sustained aerobic exercise such as running can increase neurogenesis in the adult brain, specifically in the hippocampus, a brain structure important for memory as well as learning temporally and/or spatially complex tasks. Although the research is still in the beginning stages, it suggests that exercise may actually lead to a "smarter" brain. Exercise is certainly beneficial for your body, even if it ends up not being confirmed to result in neurogenesis in humans, so it can't hurt to get more aerobic exercise!

Glia

Glia (also called neuroglia or glial cells), are the other type of cell found in nervous tissue. They are considered to be vital supporting cells, and many functions are directed at helping neurons complete their function for communication. Although they do not participate in the communication between cells in the same fashion that neurons do, some researchers have found evidence that suggests that some glia may participate in information processing activities along with neurons (Fields & Stevens-Graham, 2002; Perea, et al., 2014). Some glial functions include digesting debris from dead neurons, carrying nutritional support from blood vessels to the neurons, and helping to regulate the ionic composition of the extracellular fluid.

The name glia comes from the Greek word that means "glue," and was coined by the German pathologist Rudolph Virchow, who wrote in 1856: "This connective substance, which is in the brain, the spinal cord, and the special sense nerves, is a kind of glue (neuroglia) in which the nervous elements are planted." Modern research into nervous tissue has shown that there are many

deeper roles that these cells play. After his death in 1955, Albert Einstein's brain was studied by scientists worldwide—all wanting to gain insight into the anatomy of a genius. But it wasn't until the 1980s when Marian Diamond reported that Einstein had more glial cells than the average male brain (Diamond et al., 1985). Now it is clear that glia may play a more active role in brain activity, and research may reveal much more about them in the future.

One type of glial cell, radial glia, exist only during prenatal development, guiding migrating neurons to their final destinations. After this task is complete, most of these cells become neurons, but some become astrocytes or oligodendrocytes (Kalat, 2019), described below. There are six types of glial cells in the adult nervous system. Four of them are found in the CNS- astrocytes, oligodendrocytes, microglia and ependymal cells, and two are found in the PNS- satellite cells and Schwann cells. Table 1.5.1.1 outlines some common characteristics and functions of these glia.

Table 1.5.1.1: Glial Cell Types by Location and Basic Function.

CNS glia	PNS glia	Basic function
Astrocyte	Satellite cell	Support of the nervous tissue, form the blood-brain barrier (BBB)
Oligodendrocyte	Schwann cell	Insulation, myelination
Microglia	-	Immune surveillance and phagocytosis
Ependymal cell	-	Creating cerebrospinal fluid (CSF)

Important Functions of Some Glia

Astrocytes, named for their star-shaped appearance under the microscope (astro = “star”), have many processes extending from their main cell body (not axons or dendrites like neurons, just cell extensions). Those processes interact with neurons, blood vessels, or the connective tissue covering the CNS known as the pia mater. One important role of astrocytes is their contribution to the **blood-brain barrier**. The brain and spinal cord are isolated from the circulation — and most toxins or pathogens in the blood — by the blood-brain barrier, a highly selective membrane that separates the circulating blood from the extracellular fluid in the CNS. The barrier allows water, certain gases, glucose, and some other molecules needed by the brain and spinal cord to cross from the blood into the CNS while keeping out potentially harmful substances. Very little can pass through by diffusion. Most substances that cross the wall of a blood vessel into the CNS must do so through an active transport process. While this barrier protects the CNS from exposure to toxic or pathogenic substances and makes the CNS less susceptible to injury, it also keeps out the cells that could protect the brain and spinal cord from disease and damage (such as white blood cells, one of the body’s main lines of defense). Damage to the CNS is thus likely to have more serious consequences. The blood-brain barrier also causes problems with drug delivery to the CNS. Pharmaceutical companies are challenged to design drugs that can cross the blood-brain barrier as well as have an effect on the nervous system. Aside from finding efficacious substances, the means of delivery is also crucial.

Schwann cells and **oligodendrocytes** are the glia that produce the myelin sheath insulating axons. A single entire Schwann cell wraps around and surrounds a portion of only one axon segment in the peripheral nervous system, whereas oligodendrocytes have processes that reach out to multiple axon segments in the central nervous system. Oligodendrocyte (sometimes called just “oligo”), means “cell of a few branches” (oligo = “few”; dendro = “branches”; cyte = “cell”). Each dendritic process extends from the cell body and wraps around an axon many times to insulate it in myelin. One oligodendrocyte will provide the myelin for many axon segments- 30 to 50 (Kalat, 2019), either along the same axon or by branching out to separate axons.

The diagram (Figure 1.5.1.9) shows several types of central nervous system cells associated with two multipolar neurons. Astrocytes are star-shaped cells with many dendrite-like projections but no axon. They are connected with the multipolar neurons and other cells in the diagram through their dendrite-like projections. Ependymal cells have a teardrop shaped cell body and a long tail that branches several times before connecting with astrocytes and the multipolar neuron. Microglial cells are small cells with rectangular bodies and many dendrite-like projections stemming from their shorter sides. The projections are so extensive that they give the microglial cell a fuzzy appearance. The oligodendrocytes have circular cell bodies with dendrite-like projections. Each projection is connected to a segment of myelin sheath on the axons of the multipolar neurons. In the diagram, the oligodendrocytes are the same color as the myelin sheath segment and are adding layers to the sheath using their projections.

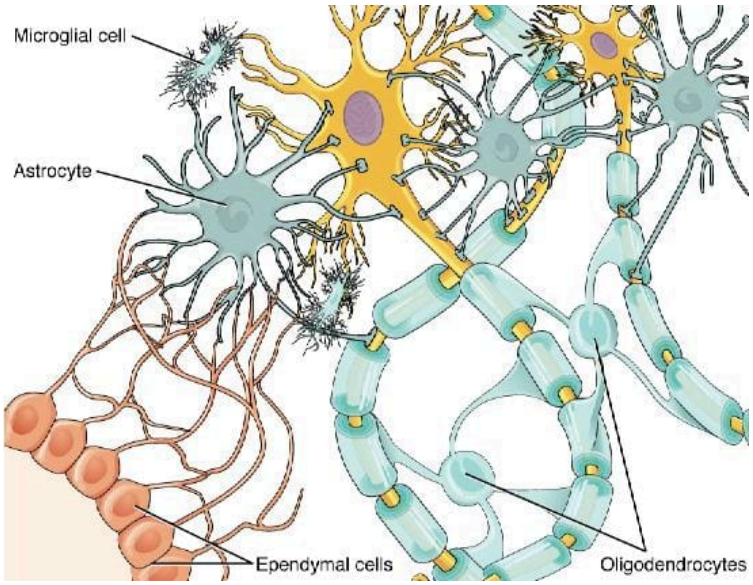

Figure 1.5.1.9: Glial Cells of the CNS. This diagram shows several types of central nervous system cells (astrocytes, oligodendrocytes, microglia, and ependymal cells) associated with two multipolar neurons.

Summary

The nervous system coordinates all of the body's voluntary and involuntary actions by transmitting electrical and chemical signals to and from different parts of the body. The two main divisions of the nervous system are the central nervous system (CNS, the brain and the spinal cord), and the peripheral nervous system (PNS, all other nervous tissue in the body).

Nervous tissue contains two major cell types, neurons and glial cells. Neurons are the cells responsible for communication through electrical signals. Glial cells are supporting cells, maintaining the environment around the neurons.

The structures that differentiate neurons from other body cells are the extensions of their cell membranes, namely one axon that projects to target cells, and one or more dendrites, which receive information from other neurons across specialized areas called synapses. The axon propagates nerve impulses (action potentials), which are communicated to one or more cells.

Neurons can be classified depending on their structure, function, or other characteristics. One structural classification is based on the number of processes the neuron has- one (unipolar), two (bipolar) or many (multipolar). One functional classification groups neurons into those that participate in sensation (sensory neurons), integration (interneurons) or motor (motor neurons) functions. Some other ways of classifying neurons include what they look like, where they are found, who found them, what they do, or what neurotransmitters they use.

The nervous tissue in the brain and spinal cord consists of gray matter and white matter. Gray matter contains the cell bodies and dendrites of neurons and white matter contains myelinated axons. Typically, neurons cannot divide to form new neurons. Recent animal research indicates that some limited neurogenesis is possible, but the extent to which this applies to adult humans is unknown.

Several types of glial cells are found in the nervous system, including astrocytes, oligodendrocytes, microglia, and ependymal cells in the CNS, and satellite cells and Schwann cells in the PNS. Astrocytes contribute to the blood-brain barrier that protects the brain. Oligodendrocytes and Schwann cells create the myelin that insulates many axons, allowing nerve impulses to travel along the axon very rapidly.

1.5.2: Nervous System Structure and Terminology

Learning Objectives

1. Describe anatomical position and describe the location of at least two structures using anatomical direction terms
2. Explain the difference between frontal (/coronal), transverse (/horizontal), and sagittal sectional planes
3. Understand the six common divisions of the nervous system
4. List the four major regions of the central nervous system
5. Explain the structures that protect the brain and spinal cord
6. Describe the components of the ventricular system in the brain and spinal cord

Overview

This module starts with anatomical position, sectional planes and directional terms and continues with the divisions of the nervous system. Some areas and structures of the central nervous system (brain and spinal cord) are then discussed, including the four major regions, the protective coverings, and the ventricular system.

Anatomical Orientation and Directions

Anatomical Position

When anatomists or health professionals identify the location of a structure in the human body, they do so in reference to a body in anatomical position. That is, they figure out the location based on the assumption that the body is starting out in anatomical position. Anatomical position for a human is when the human is standing up, facing forward, with arms extended to the sides, and palms facing out, as illustrated by two human models in Figure 1.5.2.1.

Figure 1.5.2.1:

Female (left) and male (right) human body in anatomical position seen from anterior (upper) and posterior (lower) views.

When referencing a structure that is on one side of the body or the other, we use the terms “anatomical right” and “anatomical left.” Anatomical right means that the structure is on the side that a person in anatomical position would consider their right-hand side (not necessarily on the right of the viewer) and anatomical left means that the structure is the side that a person in

anatomical position would consider their left-hand side (which likewise is not necessarily the left side of the viewer.)

Anatomical Planes

To view the interior of a body, we expose the organs and structures that are visible when that body is cut open along one of three commonly used sectional planes. These planes are the different directions a body is cut to reveal different views of its internal structures.

- **Frontal** (or **coronal**) **plane—**A vertical cut that separates the front from the back of the individual/structure.
- **Transverse** (or **horizontal**) **plane—**A horizontal cut that separates the top from the bottom of the individual/structure. (May also be called cross-sections.)
- **Sagittal plane—**A vertical cut that separates the left half from the right half of the individual/structure.
  - **Midsagittal** (or **median**) **plane—**A vertical cut down the exact center line of the individual/structure that separates the left half from the right half.
  - **Parasagittal plane—**A vertical cut that is off-center that separates the left of the individual/structure from the right in unequal portions. It does not matter whether it is the left side or the right side that is larger, as long as they are not equal.

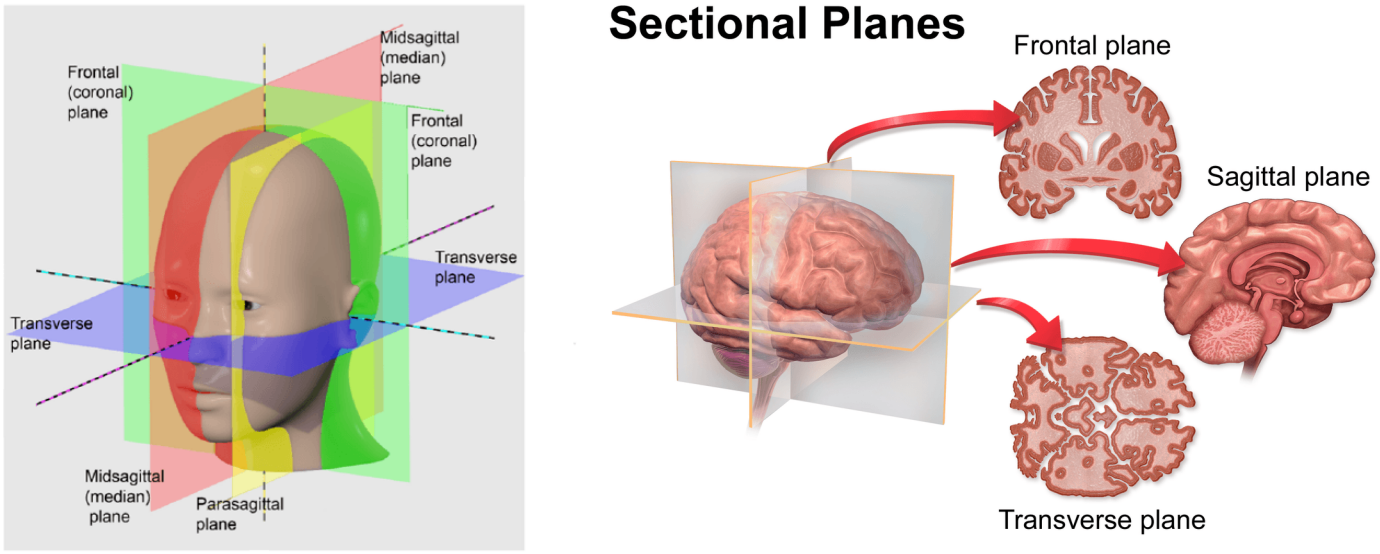

Figure 1.5.2.2: The different sectional planes used to expose internal structures, and examples of these planes through the human brain.

Anatomical Directional Terms

To be able to direct others to specific anatomical structures, or to find structures based on someone else's directions, it is useful to have specific pairs of terms that allow you to orient your search with respect to the location of another known structure. The following pairs of terms are used to make comparisons. Each term is used to orient a first structure or feature with respect to the position of a second structure or feature. All of these terms refer to the body in anatomical position, and are illustrated in Figure 1.5.2.3.

- **Superior/Inferior**–Equivalent to above (superior) versus below (inferior) when moving along the long axis of the body. A structure that is superior to another is above the second structure. A feature that is inferior to another is below the second feature.
- **Proximal/Distal**–Equivalent to near (proximal) versus far (distal). Usually used to orient the positions of structures and features along the limbs with respect to the trunk of the body. A feature that is proximal to something else is closer to the limb's point of attachment to the trunk. A structure that is distal to something else is farther away from the limb's point of attachment. Although less precise, these terms are occasionally used in the trunk of the body itself to indicate whether something is closer to (proximal) or farther away from (distal) something else.
- **Medial/Lateral**–Equivalent to towards the middle (medial) versus towards the edge (lateral). These terms are used with respect to the midline of the trunk of the body. A structure that is medial to another is closer to the midline of the body's

trunk. A feature that is lateral to another is farther away from the midline of the trunk.

- **Anterior/Posterior**–Equivalent to the front (anterior) versus the back (posterior) of the body. A structure that is anterior to another is closer to the front of the body. A feature that is posterior to another is closer to the back of the body.
- **Ventral/Dorsal**–Equivalent to belly-side (ventral) versus back-side (dorsal) of the body. For a human in anatomical position, this pair of terms is largely equivalent to anterior versus posterior. However, for the head and brain, dorsal is on the top (superior) and ventral is on the bottom (inferior), whereas the front of the face would be anterior and the back of the head would be posterior. These terms match four-legged animals in what is considered their anatomical position, where the belly-side is not equivalent to the front of the animal. A structure below the human head that is ventral to another is closer to the belly-side of the body, whereas a feature that is dorsal to another is closer to the back of the body.
- **Superficial/Deep**–Equivalent to closer to the surface (superficial) versus farther from the surface (deep). A structure that is superficial to another is closer to the surface of the body. A feature that is deep to another is farther from the surface of the body.
- (**Cephalic/Caudal**–Equivalent to closer to the head (cephalic) versus closer to the tail (caudal). These terms are more useful for four-legged animals with tails than for upright humans with only a few vestigial tail bones and no visible tail- an area which is also not at the end of the body like the tail is in four-legged animals.)

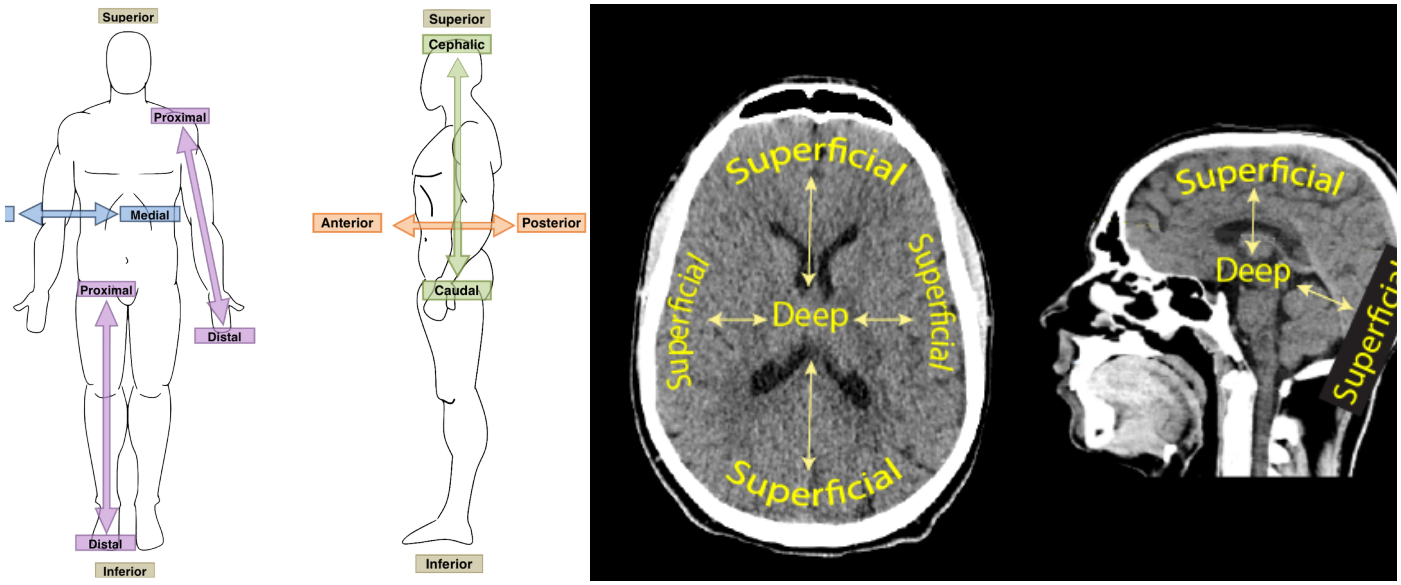

Figure 1.5.2.3: Pairs of terms providing anatomical direction or orientation, shown on body outlines in the first image, and in a cross-section (left) and sagittal section (right) of the brain in the second image.

Organization of the Nervous System

As you might predict, the human nervous system is very complex. It has multiple divisions, beginning with its two main parts, the **central nervous system** (CNS) and the **peripheral nervous system** (PNS), as shown in Figure 1.5.2.4. The CNS includes the brain and spinal cord, and the PNS consists of all other nervous tissue in the body- mainly nerves, which are bundles of axons from sensory and motor neurons. The nerves of the PNS connect the CNS to the rest of the body.

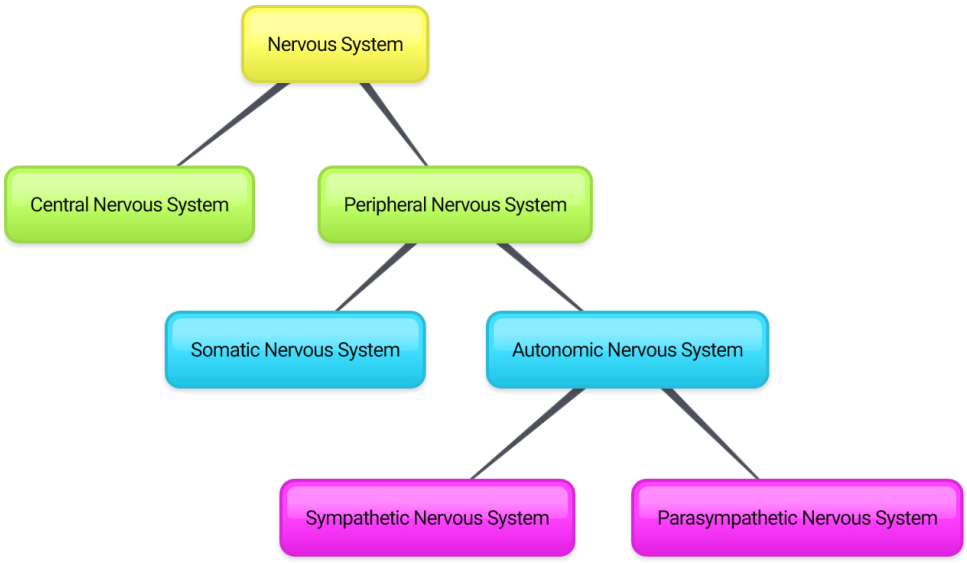

Figure 1.5.2.4: This concept map illustrates that the nervous system is divided into the central and peripheral systems. The peripheral nervous system is further divided into the somatic and autonomic systems. The autonomic nervous system is further divided into the sympathetic and parasympathetic systems.

The PNS is divided into two major parts, called the autonomic and somatic nervous systems. The **somatic nervous system** (SNS) is responsible for activities that are under voluntary control and awareness, such as turning a steering wheel or feeling water splashing on your hands. The **autonomic nervous system** (ANS) controls involuntary activities, such as digesting a meal or regulating your heartbeat. The autonomic nervous system also has two divisions: the sympathetic and parasympathetic nervous systems. The **sympathetic nervous system** controls the "fight-or-flight" response during emergencies, and the **parasympathetic nervous system** controls the routine “housekeeping” functions of the body (sometimes referred to as the "rest and digest" division). Generally speaking, your body is usually activating a balance of sympathetic and parasympathetic functions.

The CNS and the sympathetic and parasympathetic branches of the ANS (itself a division of the PNS) are described in greater detail in other modules of this chapter. The other division of the PNS, the SNS, is composed largely of sensory receptors and their connections (covered in the sensory system chapter) and structures related to voluntary motor control (addressed in the movement chapter).

Central Nervous System Regions

Some commonly used terms referring to regions in the central nervous system (such as forebrain, midbrain, and hindbrain) derive from embryonic development and are discussed separately (see the module on development of the nervous system).

In its fully formed state, the CNS may be described in terms of four major regions: the cerebrum, the brainstem (comprised of the diencephalon, the midbrain, the pons, and the medulla- note that some definitions separate the diencephalon out as an additional separate region- Basinger and Hogg, 2021), the cerebellum, and the spinal cord. These regions are colored in on an MRI of an adult in Figure 1.5.2.5.

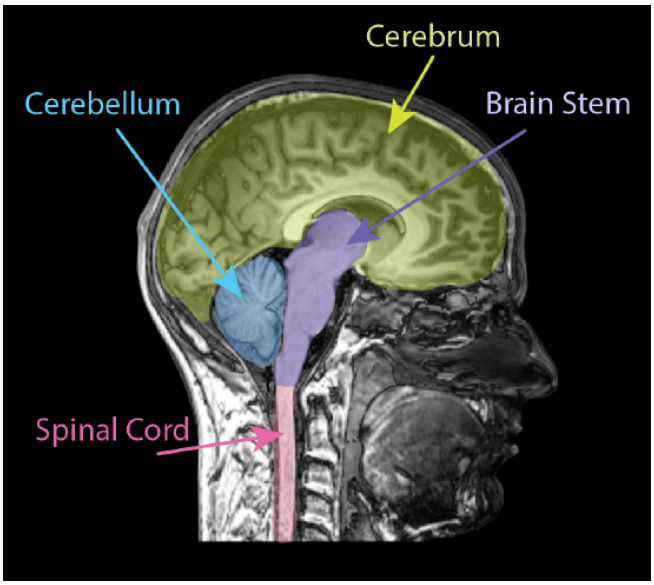

Figure 1.5.2.5: Regions of the adult central nervous system: The cerebrum, cerebellum, brainstem (including the diencephalon) and spinal cord.

Protective Coverings of the Central Nervous System

The central nervous system (CNS) is crucial to the operation of the body and any compromise of function in the brain and spinal cord can lead to severe difficulties. Both the brain and spinal cord are protected by multiple structures. First, the bones of the skull enclose and house the brain, and the bones of the vertebral column enclose and protect the spinal cord. Figure 1.5.2.6 shows a segment of the spinal cord within its protective vertebra.

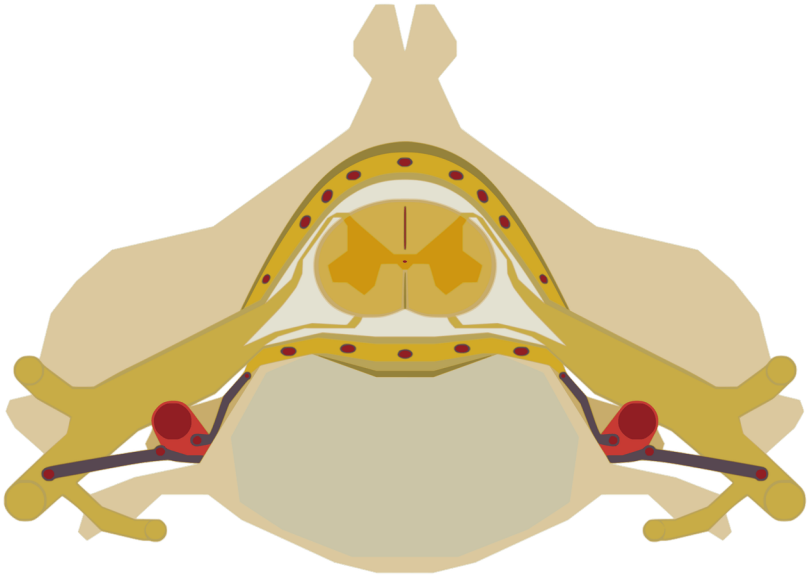

Figure 1.5.2.6: Cross-section of a spinal cord segment shown encased in its vertebra. The back of the person is at the top of the image.

Underneath the skeletal structures, the brain and spinal cord are surrounded and protected by tough **meninges**, a three-layer protective sheath made of connective tissue that surrounds, supports, stabilizes and partitions the nervous tissue. The meninges also contain cushioning **cerebrospinal fluid** (CSF). The three meningeal layers are the **dura mater**, the **arachnoid mater**, and the **pia mater**. Figure 1.5.2.7 shows the three layers of meninges covering the spinal cord and Figure 1.5.2.8 shows all the protective structures of the brain. The subdural cavity of the spinal cord and the subdural space of the brain lie between the dura mater and the arachnoid mater, whereas the subarachnoid cavity of the spinal cord and the subarachnoid space of the brain lie between the arachnoid mater and the pia mater. The **superior sagittal sinus** is a space between layers of dura mater immediately superior to the **longitudinal fissure** (the separation between the left and right hemispheres) of the brain.

In the spinal cord, the posterior (/dorsal) and anterior (/ventral) roots converge to form the **spinal nerve**. The **spinal ganglion** (also known as the **dorsal root ganglion**), an enlargement of the posterior (/dorsal) root, encases sensory neuron cell bodies.

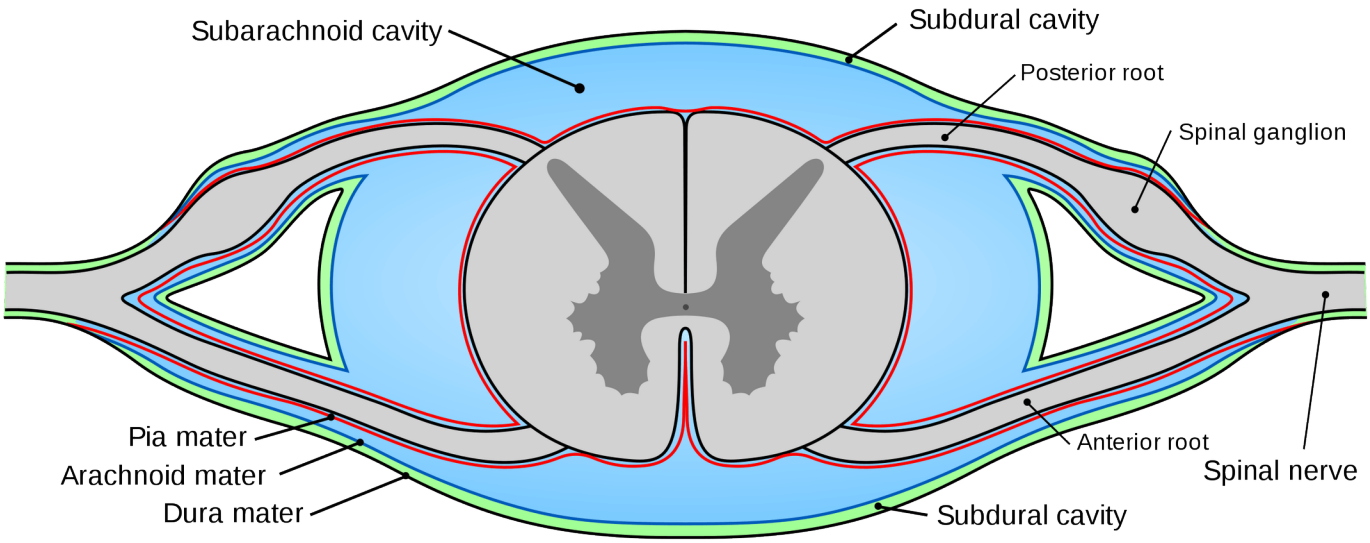

Figure 1.5.2.7: Cross-section of a spinal cord segment with the meninges and other structures labeled.

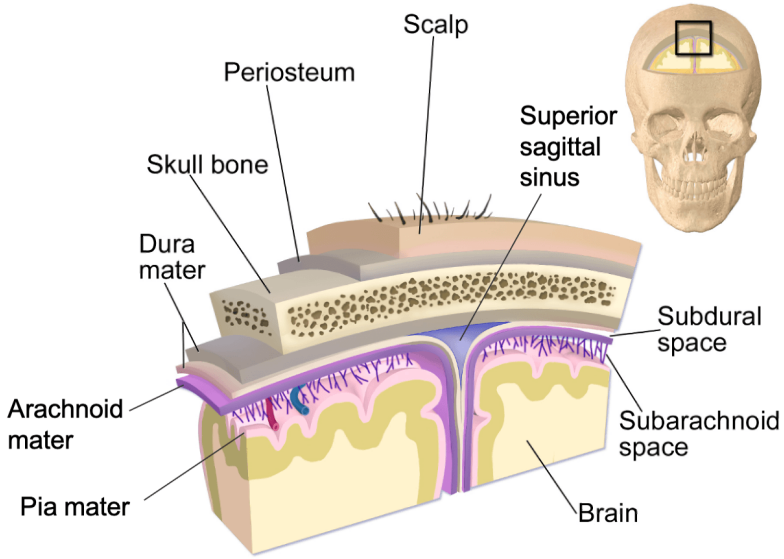

Figure 1.5.2.8: Protective structures of the brain. Superficially, the skin of the scalp and components of the skull bone create the first layer of protection. Deep to these layers, the meninges (the dura mater, arachnoid mater and pia mater) cover and partition the brain.

Ventricular System

There are four **ventricles** within the brain, all of which developed from the original hollow space within the neural tube, the **central canal**. The ventricles are lined with **ependymal cells** (a type of glia) that produce cerebrospinal fluid (CSF). The first two ventricles are named the **lateral ventricles** and are deep within the brain. The two lateral ventricles are shaped like a letter "C" and are located in the left and right hemispheres. (They were originally referred to as the first and second ventricles.) These ventricles are connected to the **third ventricle** by two openings called the **interventricular foramina** (plural; "foramen" is the singular term). The third ventricle opens into a canal called the **cerebral aqueduct** that passes through the midbrain and connects the third ventricle to the **fourth ventricle**. The fourth ventricle is the space between the cerebellum and the pons and upper medulla. From the fourth ventricle, CSF continues down the central canal of the spinal cord. Figure 1.5.2.9 illustrates the ventricles, from both a lateral and anterior viewpoint. CSF circulates through the brain and the spinal cord within these structures.

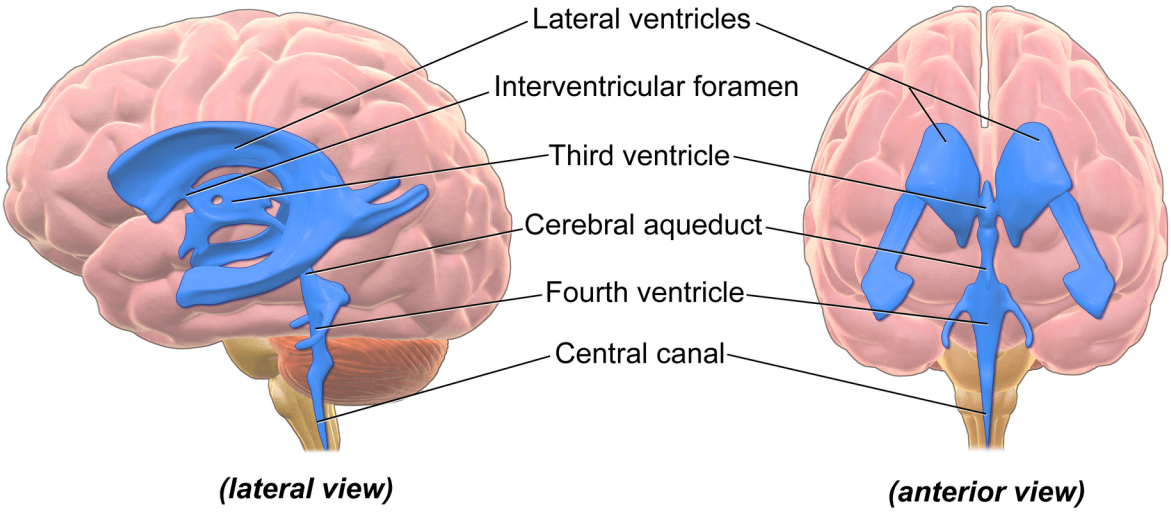

Figure 1.5.2.9: Ventricles. Deep within the brain are the lateral ventricles, which are connected to the third ventricle by two openings called interventricular foramina. The third ventricle opens into a canal called the cerebral aqueduct which connects to the fourth ventricle. The fourth ventricle is connected to the central canal of the spinal cord.

Summary

Anatomical position for humans is standing up, facing forward, with arms extended to the sides, and palms facing out. Anatomical planes are the different directions a body is cut to reveal different views of its internal structures, which include frontal (coronal) planes, separating the front from the back, transverse (horizontal) planes, separating the top from the bottom, and sagittal planes, separating the left and right halves. A midsagittal (or median) plane is exactly on the center line and a parasagittal plane divides the left and right halves unevenly. Pairs of anatomical directional terms are used to make comparisons between one structure with respect to the position of a second structure. These include superior (above) versus inferior(below), proximal (near) versus distal (far), medial (towards the middle) versus lateral (towards the edge, anterior (front) versus posterior (back), ventral (belly-side) versus dorsal (back-side), and superficial (closer to the surface) versus deep (farther from the surface).

The organization of the nervous system includes six divisions. The CNS includes the brain and spinal cord, and the PNS consists of all other nervous tissue in the body. The nerves of the PNS connect the CNS to the rest of the body. The PNS is further divided into the autonomic and somatic nervous systems. The somatic nervous system (SNS) is responsible for activities that are under voluntary control and awareness. The autonomic nervous system (ANS) controls involuntary activities. The autonomic nervous system also has two divisions: the sympathetic and parasympathetic nervous systems. The sympathetic nervous system controls response during emergencies, and the parasympathetic nervous system controls the routine functions of the body.

The adult CNS is separated into four major regions: the cerebrum, the brainstem, the cerebellum, and the spinal cord. Anatomical structures help to protect and isolate the CNS, including the skull (surrounding the brain) and the vertebral column (surrounding the spinal cord). Layers of connective tissue called meninges support and stabilize the brain and spinal cord, as well as partition the brain into specific regions. The outer layer is the dura mater, the middle layer is the arachnoid mater and the inner layer is the pia mater.

The ventricular system is composed of four fluid-filled ventricles in the brain (two lateral ventricles, the third ventricle and the fourth ventricle) which connect to each other (via the interventricular foramina and the cerebral aqueduct) and the central canal of the spinal cord. Cerebrospinal fluid (CSF) circulates through the brain and the spinal cord within these structures.

1.5.3: Nervous System Development

Learning Objectives

1. Explain how the neural tube forms
2. Describe the growth and differentiation of the anterior neural tube into primary and secondary vesicles
3. Understand the mechanisms of postnatal brain development
4. Describe the development of the posterior neural tube into the adult spinal cord
5. Identify at least four stages of neuron development

Overview

This module starts with the value of an embryologic perspective, and then discusses the formation of the neural tube, embryonic brain development (the process of the anterior neural tube differentiates into primary and secondary vesicles), postnatal brain development, spinal cord development, and neuron development.

An Embryologic Perspective

The brain is a complex organ composed of gray and white matter, which can be hard to distinguish. Starting from an embryologic perspective allows you to understand more easily how the parts relate to each other. The embryonic nervous system begins as a very simple structure—essentially a plate of tissue, which then gets increasingly complex. Looking at the development of the nervous system through a few early snapshots makes it easier to understand the whole complex system. Many structures that appear to be adjacent in the adult brain are not connected, and the connections that exist may seem arbitrary. But there is an underlying order to the system that comes from how different parts develop. By following the developmental pattern, it is possible to distinguish the major regions of the nervous system.

Neural Tube

To begin, a sperm cell and an egg cell fuse to become a fertilized egg. The fertilized egg cell, or zygote, starts dividing to generate the cells that make up an entire organism. Sixteen days after fertilization, the developing embryo's cells belong to one of three germ layers that give rise to the different tissues in the body (Figure 1.5.3.1). The endoderm, or inner tissue, is responsible for generating the lining tissues of various spaces within the body, such as the mucosae of the digestive and respiratory systems. The mesoderm, or middle tissue, gives rise to most of the muscle and connective tissues. Finally the ectoderm, or outer tissue, develops into the integumentary system (the skin) and the nervous system. It is probably not difficult to see that the outer tissue of the embryo becomes the outer covering of the body. But how is it responsible for the nervous system?

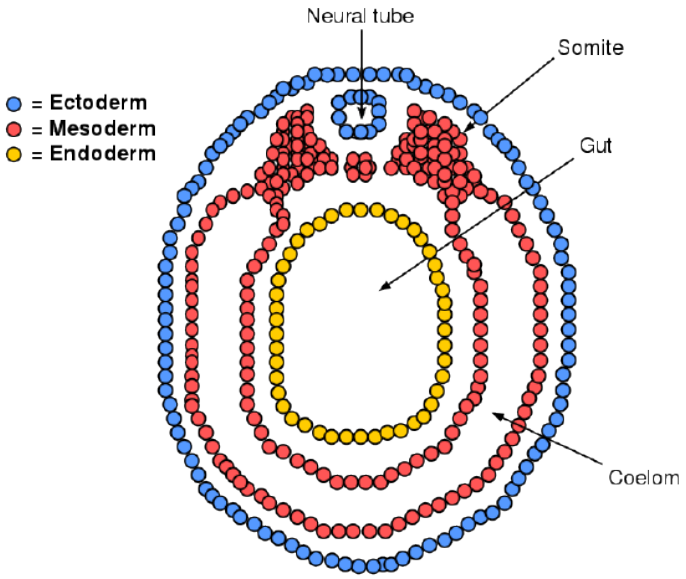

Figure 1.5.3.1: Cross section of a vertebrate embryo in the neurula stage. This stage is characterized by development of the nervous system through the formation of the neural tube, shown as a small circle of ectoderm tissue at the top of the image, just inside the large outer circle of ectoderm tissue. The neural tube later develops into the brain and the spinal cord. The middle horseshoe-shaped loop of two layers of mesoderm tissue has clumps of cells at the upper closed ends representing somites. The somites become the vertebral column and the skeletal muscles. The coelom is the open space inside the two layers of mesoderm forming the loop- internal organs develop here. The innermost circle is endoderm tissue; the gut is enclosed in the center.

As the embryo develops, a portion of the ectoderm differentiates into tissue that will become the nervous system. Molecular signals induce cells in this region to form a **neural plate**. The cells then begin to change shape, causing the tissue to buckle and fold inward (Figure 1.5.3.2). A **neural groove** forms, visible as a line along the dorsal surface of the embryo. The ridge-like edge on either side of the neural groove is referred to as the **neural fold**. As the neural folds come together and converge, the underlying structure forms into a tube called the **neural tube,** located just beneath the remaining ectoderm (which will form the epidermis).

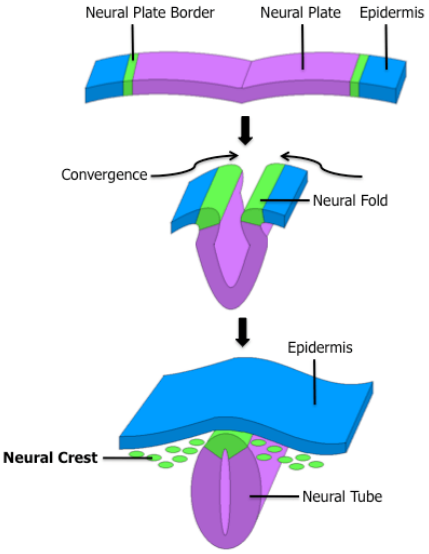

Figure 1.5.3.2: Formation of the Neural Tube. The ectoderm layer forms the epidermis and the nervous system. The neural plate (with a border on either side separating that tissue from tissue that forms the epidermis) begins to fold inward to form the neural groove (visible in the middle drawing but not labeled), with the neural plate borders becoming the neural folds on either side. As the two sides of the neural groove converge, the neural folds fuse together and form the neural tube, which lies beneath the epidermis tissue (similarly merged to form a continuous outer plate). The anterior end of the neural tube will develop into the brain, and the posterior portion will become the spinal cord. The neural crest (formed from part of the neural folds) sits laterally to the neural tube and develops into structures in the peripheral nervous system.

At this point, the early nervous system is a simple, hollow tube. It runs from the anterior end of the embryo to the posterior end.

Beginning at 25 days, the anterior end develops into the brain, and the posterior portion becomes the spinal cord. This is the most basic arrangement of tissue in the nervous system, and by the fourth week of development it gives rise to the more complex structures.

Brain Development

Embryonic Brain Development

Overview

The vertebrate brain has three major regions based on embryonic development: the forebrain (including the cerebrum, thalamus, hypothalamus, and limbic system structures), the midbrain, and the hindbrain (including the medulla, pons, and cerebellum). Figure 1.5.3.3 shows the embryologic vesicles (originating from bulges in the neural tube, explained in greater detail below) that contribute to these regions. The prosencephalon (forebrain) is composed of the telencephalon and the diencephalon, the mesencephalon is the midbrain, and the rhombencephalon (hindbrain) is composed of the metencephalon and the myelencephalon. The spinal cord extends below the hindbrain.

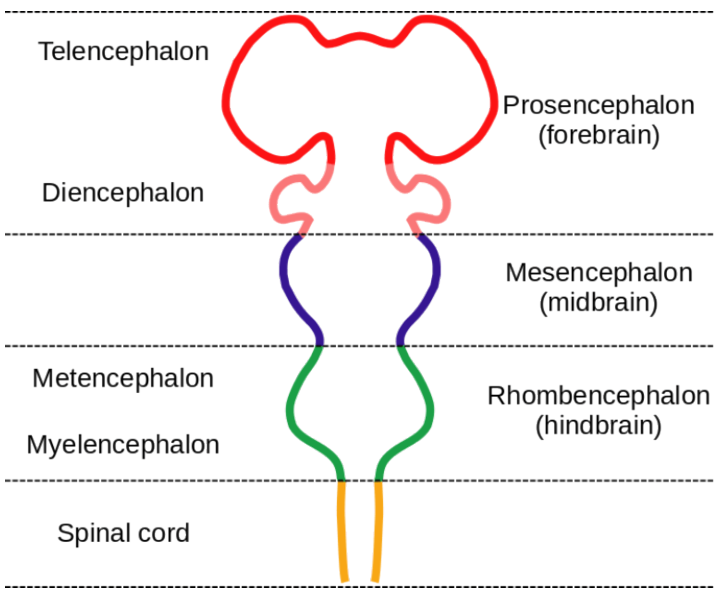

Figure 1.5.3.3: Terms for the regions of the central nervous system during embryonic development. The anterior end of the neural tube forms vesicles that become the brain. The left side of the figure lists the five secondary vesicles, which differentiate from the three primary vesicles listed on the right side. The telencephalon and diencephalon differentiate from the prosencephalon (forebrain), The mesencephalon (midbrain) is fully differentiated at the primary vesicle stage (and thus does not form any additional secondary vesicle divisions). The metencephalon and myelencephalon differentiate from the rhombencephalon (hindbrain). The posterior end of the neural tube forms the spinal cord.

The diencephalon is the one region of the adult brain that retains its (Greek) embryonic name in common usage. This is because there is no better term for it (dia = “through”). The diencephalon is between the cerebrum and the rest of the nervous system and can be described as the region through which all projections have to pass. All vertebrate brains have these regions, but in humans the anterior forebrain is enlarged to the extent that the diencephalon (posterior forebrain), the midbrain, and even part of the hindbrain is hidden from view by the cerebrum.

Another aspect of the adult CNS structures that relates to embryonic development is the cerebral ventricles—open spaces within the CNS where cerebrospinal fluid circulates. They are the remnant of the hollow center of the neural tube. The four ventricles and the tubular spaces associated with them can be linked back to the hollow center of the embryonic brain.

Primary Vesicles

When the embryo is three to four weeks of age, the anterior end of the neural tube starts to develop into the brain. It undergoes a couple of enlargements; the result is the production of sac-like vesicles. Similar to a child’s balloon animal, the long, straight

neural tube begins to take on a new shape. Three vesicles form at the first stage, which are called **primary vesicles**. These vesicles are given names that are based on Greek words, the main root word being *enkephalon*, which means “brain” (en- = “inside”; kephalon = “head”). The prefix to each generally corresponds to its position along the length of the developing nervous system.

The **prosencephalon** (pros- = “in front”) is the forward-most vesicle, and the term can be loosely translated to mean **forebrain**. The **mesencephalon** (mes- = “middle”) is the next vesicle, which can be called the **midbrain**. The third vesicle at this stage is the **rhombencephalon**. The first part of this word is also the root of the word rhombus, which is a geometrical figure with four sides of equal length (a square is a rhombus with 90° angles). Whereas prosencephalon and mesencephalon translate into the English words forebrain and midbrain, there is not a word for “four-sided-figure-brain.” Instead, the third vesicle is called the **hindbrain**. One way of thinking about how the brain is arranged is to use these three regions—forebrain, midbrain, and hindbrain—which are based on the primary vesicle stage of development (Figure 1.5.3.4a).

Secondary Vesicles

The brain continues to develop in a five-week old embryo, and the vesicles differentiate further (Figure 1.5.3.4b). The three primary vesicles become five **secondary vesicles**. The prosencephalon enlarges into two new vesicles called the **telencephalon** and the **diencephalon**. The telecephalon will become the cerebrum. The diencephalon gives rise to several adult structures; two that will be important are the thalamus and the hypothalamus.

The mesencephalon does not differentiate any further, but remains an established region of the brain. The rest of the brain develops around it and constitutes a large percentage of the mass of the brain. Dividing the brain into forebrain, midbrain, and hindbrain is useful in considering its developmental pattern, but the midbrain is a relatively small proportion of the entire brain.

The rhombencephalon develops into the **metencephalon** and **myelencephalon**. The metencephalon corresponds to the adult structure known as the pons and also gives rise to the cerebellum. The cerebellum (from the Latin meaning “little brain”) accounts for about 10 percent of the mass of the brain and is an important structure in itself. The most significant connection between the cerebellum and the rest of the brain is at the pons, because the pons and cerebellum develop out of the same vesicle. The myelencephalon corresponds to the adult structure known as the medulla (or medulla oblongata).

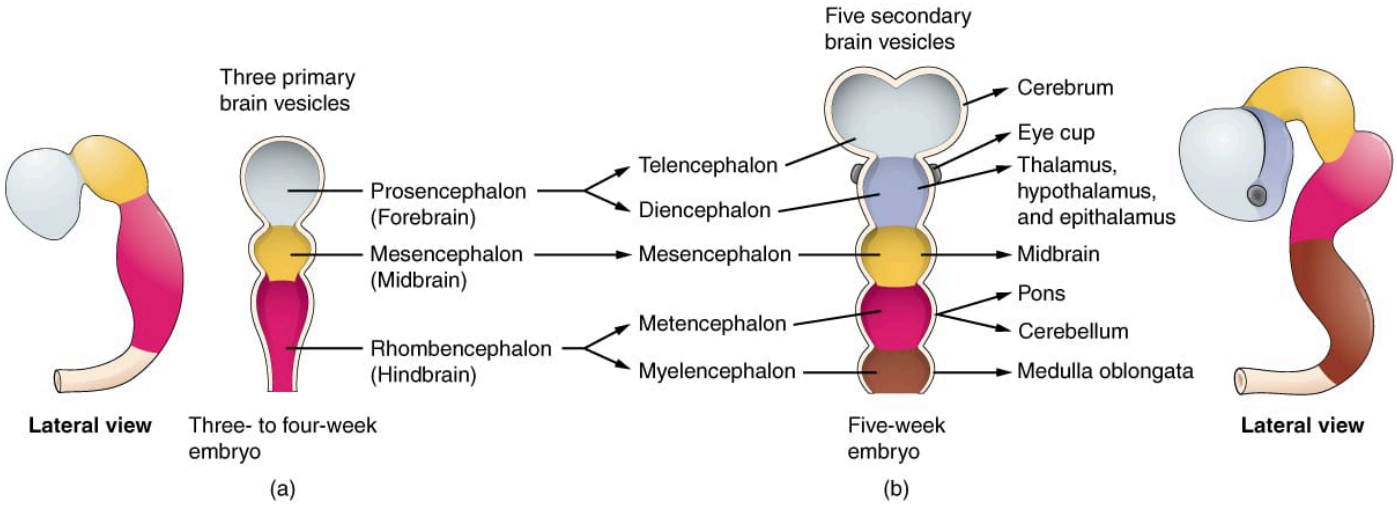

Figure 1.5.3.4: Primary and Secondary Vesicle Stages of Development. The embryonic brain develops complexity through enlargements of the neural tube called vesicles. In part a, the primary vesicle stage which happens around 3 to 4 weeks of embryonic development shows three vesicles: the prosencephalon (forebrain) is superior and anterior; the mesencephalon (midbrain) is inferior to the prosencephalon; and the rhombencephalon (hindbrain) is the most inferior vesicle. In part b, the secondary vesicle stage which happens at 5 weeks of embryonic development shows five regions. From anterior and superior to posterior and inferior, these regions (and structures that form from them) are: telencephalon (cerebrum), diencephalon (eye cup; thalamus, hypothalamus and epithalamus), mesencephalon (midbrain), metencephalon (pons; cerebellum), and myelencephalon (medulla oblongata). Lateral views of each stage are also depicted.

Postnatal Brain Development

As summarized by Stiles & Jernigan (2010, p. 328), "Human brain development is a protracted process that begins in the third gestational week … and extends at least through late adolescence, arguably throughout the lifespan". During the preschool years

(roughly age three to five years), the brain quadruples in size, attaining about 90% of adult volume by age six (Stiles & Jernigan, 2010). Figure 1.5.3.5 illustrates the growth between a one-month old baby and a six-year-old child, in both brain size and neuron complexity.

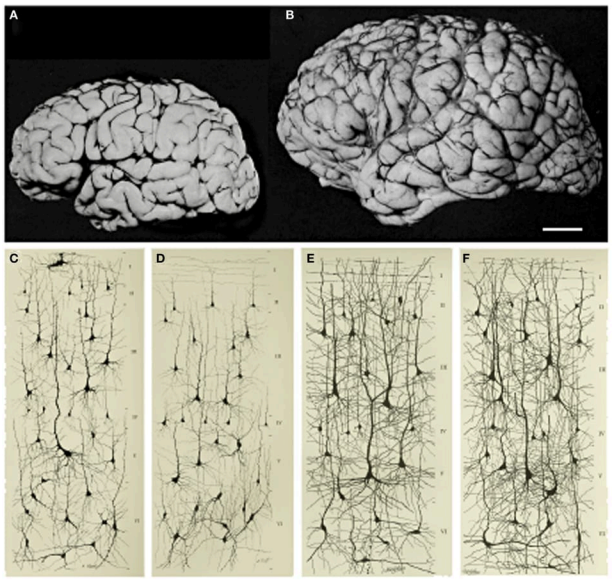

Figure 1.5.3.5: Increase in brain size and the maturation of cortical circuits. The maturation of mental processes and motor skills is associated with an approximately four-fold enlargement in brain size. Photographs of the brains of a A. 1-month and B. 6-year-old child. This size increase is accompanied by a dramatic development in the complexity of the neuronal processes, which in turn is influenced by the genetic background and the surroundings. This increase in the complexity is clearly evident in the drawings of Golgi-stained cortical neurons from the cerebral cortex of a 1-month-old child (C. showing the cortical area known as “pars triangularis of gyrus frontalis inferior”; D. showing “orbital gyrus”) and a 6-year-old child (E. “pars triangularis of gyrus frontalis inferior”; F. “orbital gyrus”). Scale bar for A and B: 2 cm.

Changes in the structure of both gray matter and white matter components of the brain continue through childhood and adolescence, accompanied by changes in both functional organization and behavior. Young children, particularly infants, have much higher connectivity between neurons in the brain than adults. As development continues, these connections become more specialized (through pruning of less efficient pathways, as determined by experience- see neuron development below). Correspondingly, "plasticity and capacity for adaptation ... is the hallmark of early brain development" (Stiles & Jernigan, 2010, p. 328). Plasticity (the ability of the brain to change based on experience) continues throughout life, but slows down with age. It is still possible to "teach an old dog new tricks"- it just takes longer!

Although the human brain increases five-fold in volume between infancy and adulthood, there is little change in the number of neurons present. Brain growth occurs as a result of axon myelination and increased connections between neurons (Budday et al., 2015).

Spinal Cord Development

While the brain is developing from the anterior neural tube, the spinal cord is developing from the posterior neural tube. However, its structure does not differ from the basic layout of the neural tube. It is a long, straight cord with a small, hollow space down the center. The neural tube is defined in terms of its anterior versus posterior portions, but it also has a dorsal–ventral dimension. As the neural tube separates from the rest of the ectoderm, the side closest to the surface is dorsal (toward the back), and the deeper side is ventral (toward the belly).

As the spinal cord develops, the cells making up the wall of the neural tube proliferate and differentiate into the neurons and glia of the spinal cord. The dorsal tissues will be associated with sensory functions, and the ventral tissues will be associated with motor functions

DISORDERS OF THE...

Development of the Nervous System: Spina Bifida

Early formation of the nervous system depends on the formation of the neural tube. A groove forms along the dorsal surface of the embryo, which becomes deeper until its edges meet and close off to form the tube. If this fails to happen in the posterior region where the spinal cord forms, a developmental defect called spina bifida occurs. The closing of the neural tube is important for more than just the proper formation of the nervous system. The surrounding tissues are dependent on the correct development of the tube. The connective tissues surrounding the CNS can be involved as well.

There are three classes of this disorder: occulta, meningocele, and myelomeningocele (Figure 1.5.3.6). The first type, spina bifida occulta, is the mildest because the vertebral bones do not fully surround the spinal cord, but the spinal cord itself is not affected. No functional differences may be noticed, which is what the word occulta means; it is hidden spina bifida. The other two types both involve the formation of a cyst—a fluid-filled sac of the connective tissues that cover the spinal cord called the meninges. “Meningocele” means that the meninges protrude through the spinal column but nerves may not be involved and few symptoms are present, though complications may arise later in life. “Myelomeningocele” means that the meninges protrude and spinal nerves are involved, and therefore severe neurological symptoms can be present.

Often surgery to close the opening or to remove the cyst is necessary. The earlier that surgery can be performed, the better the chances of controlling or limiting further damage or infection at the opening. For many children with meningocele, surgery will alleviate the pain, although they may experience some functional loss. Because the myelomeningocele form of spina bifida involves more extensive damage to the nervous tissue, neurological damage may persist, but symptoms can often be handled. Complications of the spinal cord may present later in life, but overall life expectancy is not reduced.

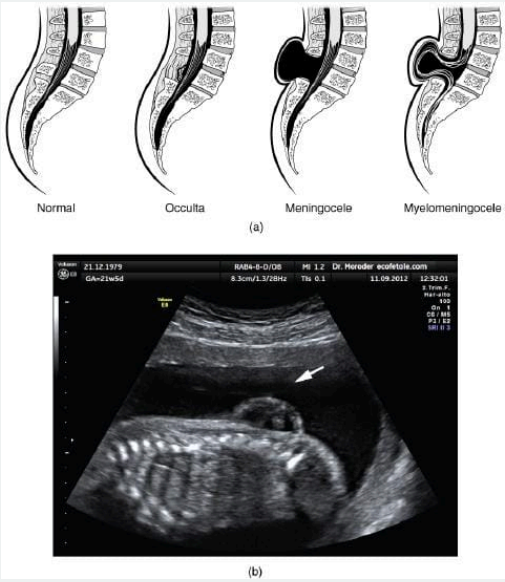

Figure 1.5.3.6: Spina Bifida. Spina bifida is a birth defect of the spinal cord caused when the neural tube does not completely close, but the rest of development continues. The result is the emergence of meninges and neural tissue through the vertebral column. Part (a) shows the difference between a normal spinal cord, and the three types of spina bifida: occulta, meningocele and myelomeningocele. In part (b), an ultrasound taken at 21 weeks shows a fetal myelomeningocele.

Neuron Development

Neuron development is typically divided into several stages, although the names of the stages may vary somewhat from one source to another. **Neuron production** (also called proliferation) is the first stage, when **neurogenesis**, the production of new neurons from stem cells, occurs (Kalat, 2019). In humans, this begins around the fifth week of gestation (Budday et al., 2015), or on the 42nd day after conception (Stiles & Jernigan, 2010). It is mostly finished by 28 weeks gestational age, and if premature birth occurs before 28 weeks, further neurogenesis is inhibited (Kalat, 2019). Figure 1.5.3.7 shows a photograph of neurons developing in an embryo.

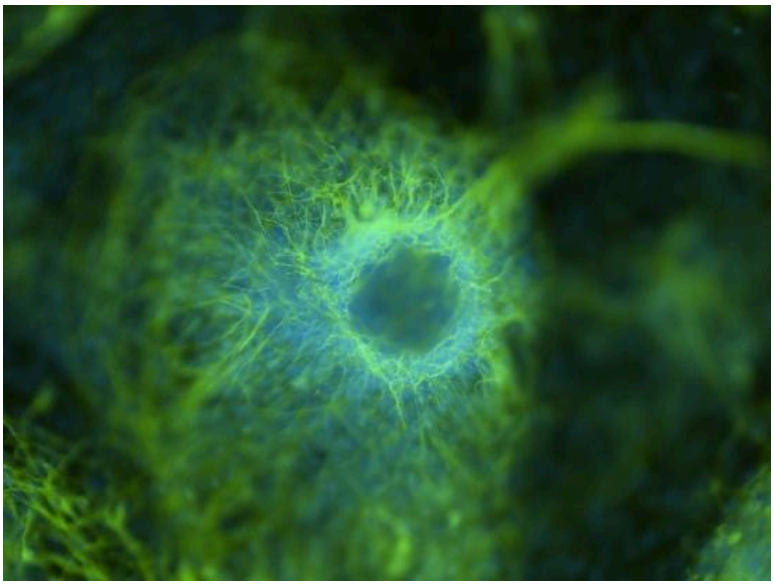

Figure 1.5.3.7: Neuron cluster. Human embryonic tissue can be differentiated into many different cell types, including neurons. BIII-tubulin (green) is used as a marker for immature neurons. DAPI (blue) staining identifies the cells' nuclei.

As the neurons are forming, **migration** (movement to their final destinations) starts, following chemical signals (Kalat, 2019). The six-layered mature structure of the cerebral cortex is formed via the orderly migration of neurons (Stiles & Jernigan, 2010). **Differentiation** is the process of a neuron achieving the features that make it distinct from other body cells- forming an axon and one or more dendrites (Kalat, 2019). The term differentiation also encompasses the formation of different types of neurons (Stiles & Jernigan, 2010), or gaining the features that distinguish one type of neuron from another.

Synaptogenesis is the creation of connections between neurons by forming synapses (Kalat, 2019). It begins mid-gestation, and as connectivity progresses, axons form and reach out to numerous targets "until each neuron connects with thousands of other neurons" by birth (Budday et al., 2015, p. 5). Synaptogenesis "continues throughout life, as neurons form new synapses and discard old ones" (Kalat, 2019, p. 118).

Myelination is the process of axons becoming insulated with a layer of myelin, which speeds up the transmission of nerve impulses. Myelination starts in the spinal cord and then progresses from the hindbrain to the midbrain and finally the forebrain. This occurs gradually over decades and may also be implicated in learning new motor skills (Kalay, 2019).

Synaptic **pruning** is the process of removing synapses that are not useful or efficient, based on the specific experiences of the individual. Pruning starts around birth and is completed during adolescence, by the time sexual maturity is attained. It is thought that learning corresponds with pruning (Budday et al., 2015).

An estimated timeline for these stages of neuron development is shown in Figure 1.5.3.8.

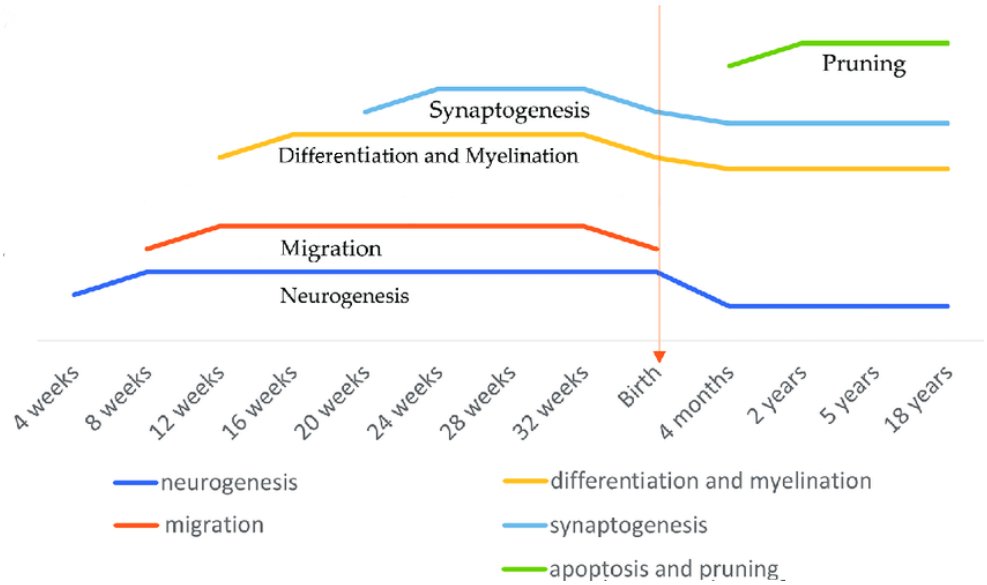

Figure 1.5.3.8: Timeline for stages of neuron development. GA= gestational age. The timeline ends with age 18 years, but some of these processes may continue throughout life. Neurogenesis starts at four weeks GA and decreases sharply after birth, to almost nothing by four months of age and beyond. Migration starts at eight weeks GA, increases through 12 weeks GA, stays steady through 32 weeks GA, and then decreases, ending at birth. Differentiation and Myelination start at 12 weeks GA, increase through 16 weeks GA, stay steady through 32 weeks GA, decrease through four months of age, and then stay steady through 18 years of age. Synaptogenesis starts at 20 weeks GA, increases through 24 weeks GA, stays steady through 32 weeks GA, decreases through four months of age, and then stays steady through 18 years of age. Pruning starts at four months of age, increases through two years of age, and then stays steady through 18 years of age.

Summary

The development of the nervous system starts early in embryonic development. The outer layer of the embryo, the ectoderm, gives rise to the skin and the nervous system. A specialized region of this layer becomes a groove that folds in and becomes the neural tube beneath the dorsal surface of the embryo. The anterior end of the neural tube develops into the brain, and the posterior region becomes the spinal cord.

The brain develops from this early tube structure and gives rise to specific regions of the adult brain. As the neural tube grows and differentiates, it enlarges into three vesicles that correspond to the forebrain, midbrain, and hindbrain regions of the adult brain. Later in development, two of these three vesicles differentiate further, resulting in five vesicles. Those five vesicles can be aligned with the four major regions of the adult brain. The cerebrum is formed directly from the telencephalon. The diencephalon is the only region that keeps its embryonic name, and includes the thalamus and the hypothalamus. The mesencephalon becomes the midbrain, the metencephalon forms the pons and the cerebellum, and the myelencephalon becomes the medulla.

Brain development is a lifelong process, and the brain retains plasticity (the ability to change based on experience) throughout life. The increase in brain size during postnatal brain development occurs largely due to the myelination of axons and increased connections between neurons.

The spinal cord develops from the remainder of the neural tube and retains the tube structure, with the nervous tissue thickening and the hollow center becoming a very small central canal through the cord. The rest of the hollow center of the neural tube corresponds to open spaces within the brain called the ventricles, where cerebrospinal fluid is found.

Several stages of neuron development have been identified- neuron production (or proliferation), migration, differentiation, synaptogenesis (increased connectivity), myelination, and synaptic pruning.

1.5.4: The Central Nervous System

Learning Objectives

1. Name the structures that comprise the central nervous system
2. Identify the three main parts of the brain
3. Describe the lobes of the cerebrum and their locations
4. Identify the components of the diencephalon and describe their functions
5. Identify the regions of the brainstem and describe their functions
6. Identify the major structures of the limbic system and describe their functions
7. Describe the structure and function of the cerebellum
8. Describe the structure and function of the spinal cord

Overview

This module defines the central nervous system (the brain and spinal cord) and goes into detail on its components. Structures and functions of the brain are discussed, including the cerebrum: hemispheres and lateralization, the cerebral cortex, the frontal, parietal, temporal and occipital lobes; the brainstem: diencephalon, midbrain, pons and medulla; the limbic system; and the cerebellum; as well as structures, function and injury of the spinal cord.

Homunculus

Figure 1.5.4.1: Front and rear views of a sensory homunculus model.

Figure 1.5.4.1 is a very odd-looking model called a homunculus. This model shows the relative representation of different parts of the body in the primary sensory cortex, an area in the parietal lobe of the brain. As you can see, larger areas of the brain in this region are associated with the hands, face, and tongue than the arms, torso, legs and feet. Larger areas of representation in the brain result in greater sensitivity in those body areas. Given the importance of speech, manual dexterity, and face-to-face social interactions in human beings, it is not surprising that relatively large areas of the brain are needed to relay sensation from these body parts. (There is a similarly odd-looking representation of voluntary motor functions called the motor homunculus that is located in the primary motor cortex, an area in the frontal lobe of the brain.) The brain is the most complex organ in the human body and is part of the central nervous system.

What Is the Central Nervous System?

The central nervous system (CNS) is the part of the nervous system that includes the brain and spinal cord. Figure 1.5.4.2 shows the central nervous system both as it appears in the body dissected from the backside and also completely removed from the body. The central nervous sytem and the peripheral nervous system (PNS, the other main division, which is addressed in a separate module), work together to control virtually all body functions.

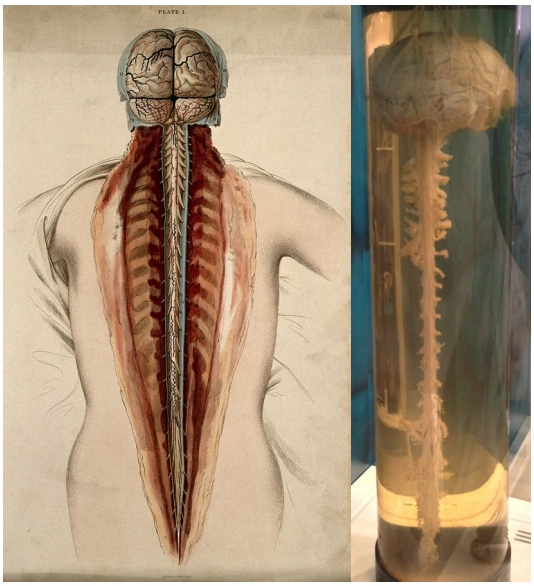

Figure 1.5.4.2: The human central nervous system. A back view dissection of the brain and spinal cord (colored line engraving by W.H. Lizars, circa 1827) and a preserved brain and spinal cord.

The Brain

The **brain** is the control center not only of the rest of the nervous system but of the entire organism. The adult brain makes up only about two percent of the body's weight, but it uses about 20 percent of the body's total energy. The brain contains an estimated 86 billion neurons (Lent et al., 2012), and each neuron has thousands of synaptic connections to other neurons. It is estimated that the brain also has about the same number of glial cells as neurons. No wonder the brain uses so much energy! In addition, the brain uses mostly glucose for energy. As a result, if the brain is deprived of glucose, it can lead to unconsciousness.

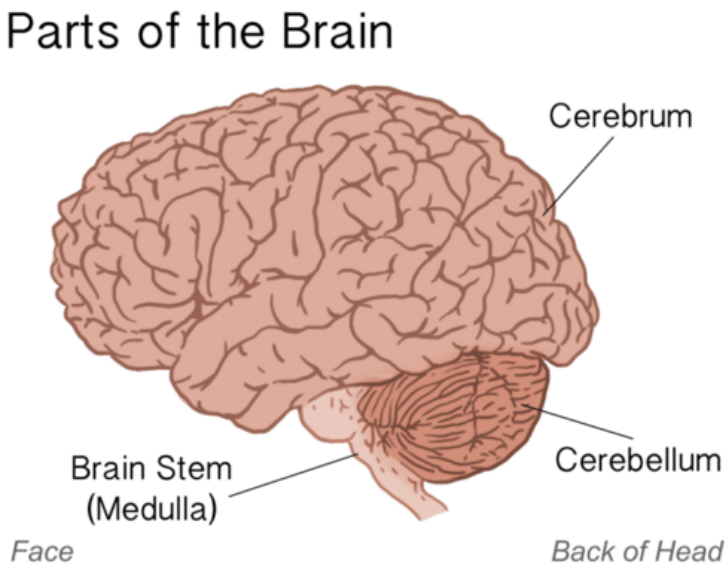

Figure 1.5.4.3: The major parts of the brain are the cerebrum, cerebellum, and brainstem. The medulla is part of the brainstem.

The brain controls such mental processes as reasoning, imagination, memory, and language. It also interprets information from the senses and commands the body's responses. It controls basic physiological processes such as breathing and heartbeat as well as voluntary activities such as walking and writing. The brain has three major parts: the cerebrum, cerebellum, and brainstem (Figure 1.5.4.3). The figure shows the brain from the left side of the head. It shows how the brain would appear if the skull and meninges were removed. The brainstem links to the spinal cord via the medulla. The cerebellum is a small structure at the back of the brain. The largest part of the brain is the cerebrum.

Cerebrum

The iconic gray mantle of the human brain, which appears to make up most of the mass of the brain, is the **cerebrum**. It controls conscious, intellectual functions, such as reasoning, language, memory, sight, touch, and hearing. When you read a book, play a video game, or recognize a classmate, you are using your cerebrum. The wrinkled portion is the **cerebral cortex** (see below), and the rest of the structure is deep to that outer covering.

Hemispheres and Lateralization of the Cerebrum

There is a large separation between the two sides of the cerebrum called the **longitudinal fissure**. It separates the cerebrum into two distinct halves, the right and left **cerebral hemispheres**. The two hemispheres are connected by a thick bundle of axons, known as the **corpus callosum**, which lies deep within the cerebrum. The corpus callosum is the major pathway for communication between the two hemispheres, connecting each point in the cerebral cortex to the mirror-image point in the opposite hemisphere. The location of the corpus callosum is shown with a dotted outline in Figure 1.5.4.4, as though you are looking through the outside and deep inside the brain. Figure 1.5.4.5 shows a three-dimensional image of the corpus callosum in relation to other deep brain structures and surrounded by the cerebrum.

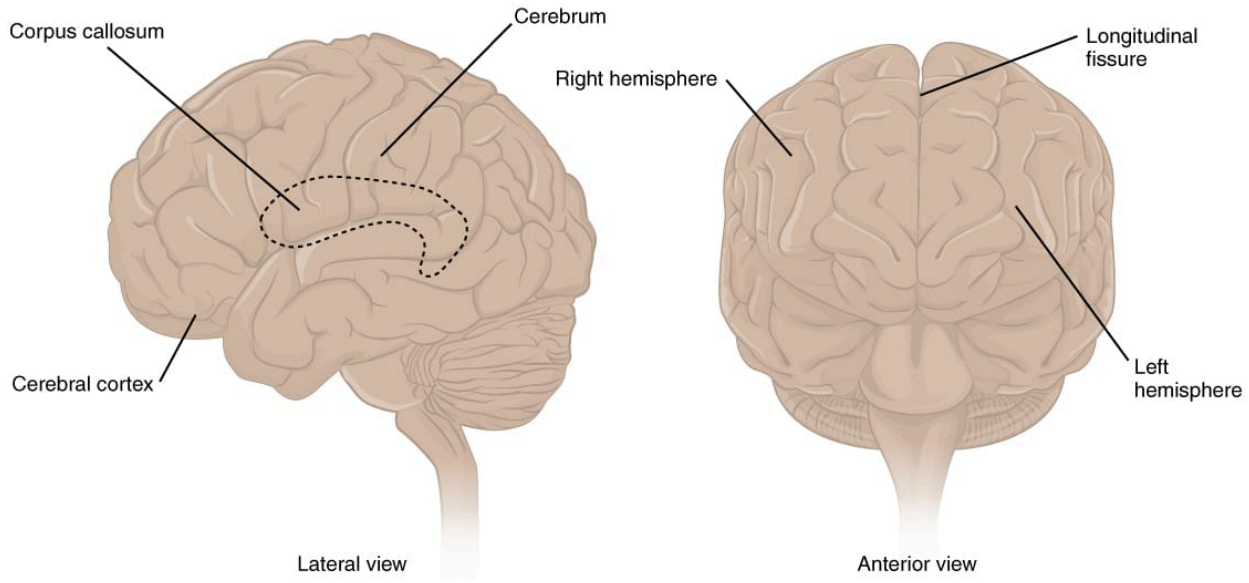

Figure 1.5.4.4: The cerebrum is a large component of the CNS in humans, and the most obvious aspect of it is the folded surface called the cerebral cortex.

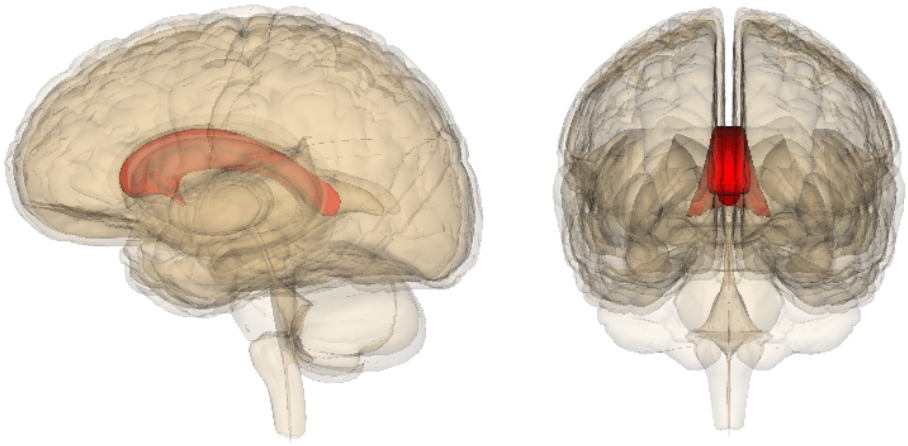

Figure 1.5.4.5: The corpus callosum (shown in red) is a thick bundle of axons connecting the left and right hemispheres of the brain. It is located deep within the cerebrum.

The right and left hemispheres of the cerebrum are similar in shape, and most areas of the cerebrum are found in both hemispheres. Some areas, however, show **lateralization,** or a concentration in one hemisphere or the other. For example, in most people, language functions are more concentrated in the left hemisphere, whereas abstract reasoning and visual-spatial abilities are more concentrated in the right hemisphere.

For reasons that are not yet clear, each hemisphere of the brain interacts primarily with the **contralateral** (opposite) side of the body. The left side of the brain receives messages from and sends commands to the right side of the body, and the right side of the brain receives messages from and sends commands to the left side of the body. Sensory nerves from the spinal cord to the brain and motor nerves from the brain to the spinal cord both cross to the other side of the body.

Cerebral Cortex

The cerebrum is covered by a continuous layer of gray matter that wraps around either side of the forebrain—the **cerebral cortex**. This thin (just a few millimeters thick), extensive region of wrinkled gray matter is responsible for most of the information processing and higher functions of the nervous system. The cerebral cortex has many folds in it that greatly increase the surface area of the brain. A **gyrus** (plural = gyri) is the ridge of one of those wrinkles, and a **sulcus** (plural = sulci) is the groove between two gyri. The pattern of these folds of tissue indicates specific regions of the cerebral cortex. At birth, the head of the newborn is limited by the size of the birth canal, and the brain must fit inside the cranial cavity of the skull. Extensive folding in the cerebral cortex enables more gray matter to fit into this limited space. If the gray matter of the cerebral cortex in an adult were peeled off of the cerebrum and laid out flat, its surface area would be about 2,500 cm^2 (2.5 ft^2), or about the size of the top of a card table.

Lobes of the Cerebral Cortex

The surface of the brain can be mapped on the basis of the locations of large gyri and sulci. Using these landmarks, the cortex can be separated into four major regions, or lobes (Figure 1.5.4.6). The **lateral sulcus** that separates the **temporal lobe** from the other regions is one such landmark.

Superior to the lateral sulcus are the **frontal lobe** and **parietal lobe**, which are separated from each other by the **central sulcus**. The most posterior gyrus of the frontal lobe is the **precentral gyrus**, which is where the primary motor cortex is located, while the most anterior gyrus of the parietal lobe is the **postcentral gyrus**, which is where the primary somatosensory cortex is located. (The primary somatosensory cortex is the area that the homonculus in Figure 1.5.4.1 represents.)

The posterior region of the cortex is the **occipital lobe**, which has no obvious anatomical border between it and the parietal or temporal lobes on the lateral surface of the brain. From the medial surface, the **parieto-occipital sulcus** separates the parietal and occipital lobes.

Figure 1.5.4.7 has only the four lobes labeled for quicker reference. The lobes are associated with multiple functions. The image shows one function of each lobe: frontal is associated with reasoning, parietal with touch, occipital with sight, and temporal with hearing. The lobes (found on each hemisphere of the cerebrum) are described in greater detail below.

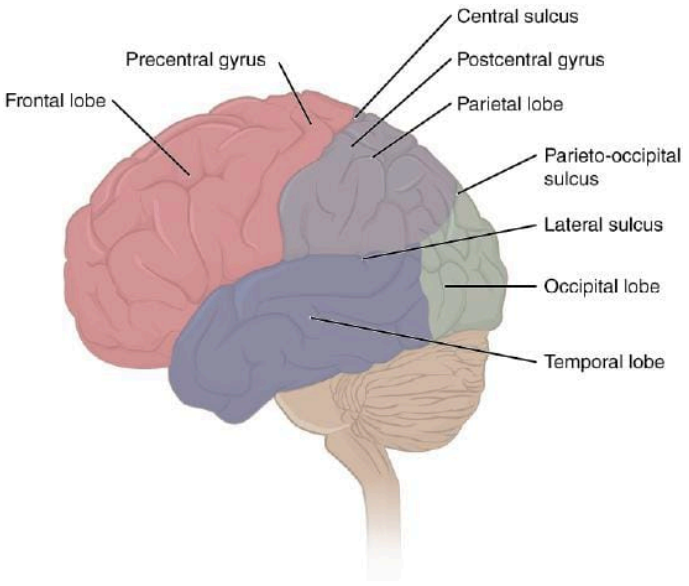

Figure 1.5.4.6: Major gyri, sulci and lobes of the cerebral cortex.

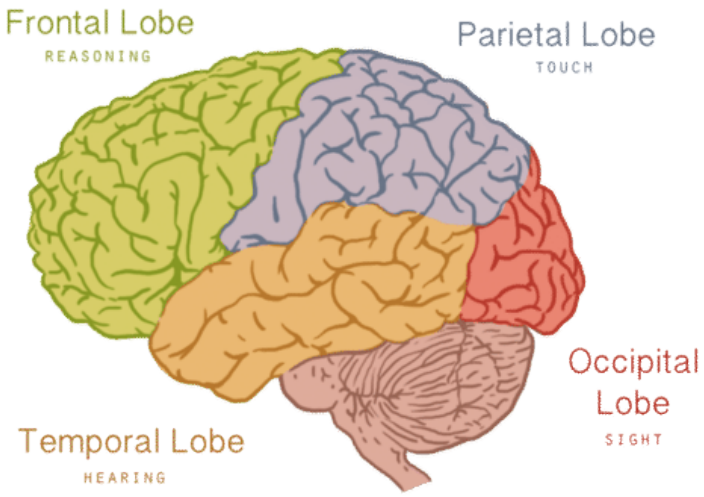

Figure 1.5.4.7: The four major lobes of the brain.

Frontal Lobe

The **frontal lobes** are located at the front of the brain behind the forehead. The frontal lobes are associated with executive functions such as attention, self-control, planning, problem-solving, reasoning, abstract thought, language, and personality. Another important function of the frontal lobes is movement- as mentioned above, the precentral gyrus (indicated on Figure 1.5.4.6) contains the primary motor cortex. Like the sensory homunculus pictured in the beginning of this section (Figure 1.5.4.1), there is a similarly disproportionate representation of voluntary motor control (the motor homunculus) located in the precentral gyrus. Figure 1.5.4.8 shows the areas of the primary motor cortex dedicated to movement of various body areas. Notice that like the sensory homunculus, the hands, fingers, thumb, and facial areas have a greater share of the cortex than areas with less fine-tuned movement (like the shoulders, trunk, and hips, for example).

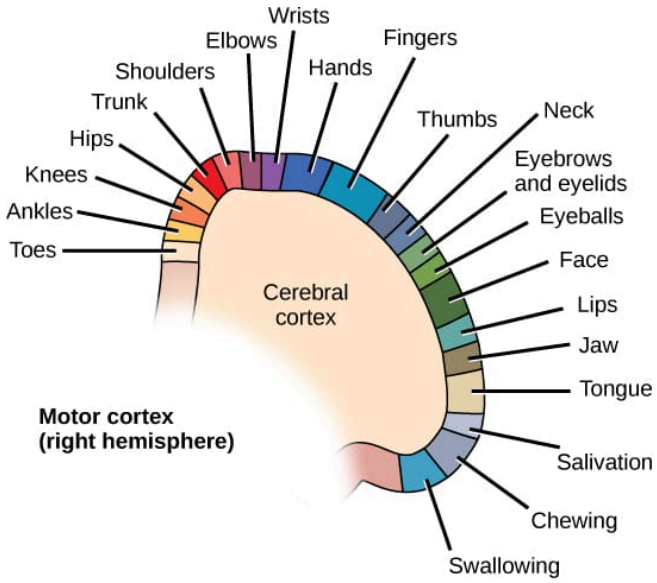

Figure 1.5.4.8: Different regions of the motor cortex control different muscle groups and their neighboring regions control neighboring muscle groups. Although the right hemisphere is shown, a mirror-image exists in the left hemisphere as well. Note that all areas of the body that have voluntary motor control are represented on the primary motor cortex.

Parietal Lobe

The **parietal lobes** are located posterior to the frontal lobes at the top of the head. The parietal lobes are involved in body sensations, including temperature, touch, and pain. As mentioned above, the postcentral gyrus (indicated on Figure 1.5.4.6) contains the primary somatosensory cortex. The sensory homunculus model pictured in the beginning of this section (Figure 1.5.4.1) shows the strange character that results from making the body areas proportional to their representation in the brain. The drawing in Figure 1.5.4.9 shows the sensory homunculus stretched out along the postcentral gyrus of the parietal lobe. Notice that areas that have sensation but no voluntary motor control (like the genitals and the intra-abdominal organs) are present on the primary somatosensory cortex but not on the primary motor cortex (Figure 1.5.4.8). Reading and arithmetic are also functions of the parietal lobes.

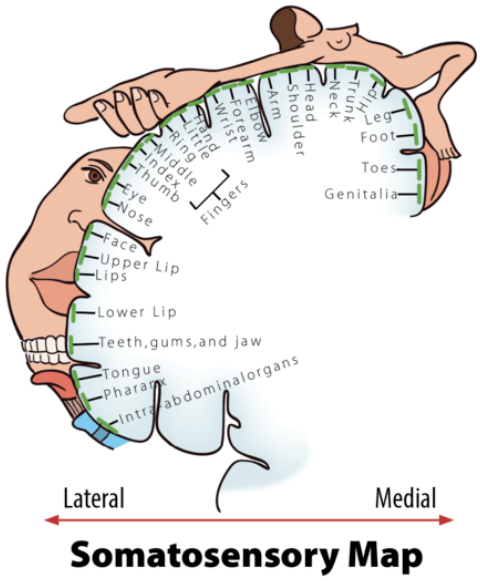

Figure 1.5.4.9: Somatosensory Map. The sensory map of your body represented on the primary somatosensory cortex in your brain is not proportional to the actual size of your body parts. Sensitive areas like your face (particularly your lips) and hands (particularly your fingers) occupy a larger section of cortex than less sensitive areas like your limbs (arms and legs) or trunk. Although the left hemisphere is shown, a mirror-image exists in the right hemisphere as well. Note that all areas of the body that register touch sensations are represented on the primary somatosensory cortex.

Temporal Lobe

The **temporal lobes** are located at the sides of the head below the frontal and parietal lobes. The temporal lobes enable the formation and retrieval of memories, the integration of memories and sensations, and perception of the senses of hearing (audition), and smell (olfaction)- primary auditory cortex and primary olfactory cortex are both located in the temporal lobes.

Occipital Lobe

The **occipital lobes** are located at the back of the head below the parietal lobes. The occipital lobes are the smallest of the four pairs of lobes. Primary visual cortex is located in the occipital lobes, and they are dedicated almost solely to vision.

Brainstem

As noted separately (see the nervous system structure module), sometimes the diencephalon is considered as a separate additional region, and sometimes it is included as the uppermost part of the brainstem (Basinger and Hogg, 2021), as it is here. The **brainstem** is the central region of the brain that connects the cerebrum (on the superior end) to the diencephalon, midbrain, pons, medulla, and ultimately joins the spinal cord (on the inferior end). The **cerebellum** is attached to the brainstem, but is considered a separate region of the adult brain.

One of the brainstem's most important roles is that of an "information highway." That is, all of the information coming from the body to the brain and the information from the cerebrum to the body go through the brainstem. Sensory pathways for such things as pain, temperature, touch, and pressure sensation go upward to the cerebrum, and motor pathways for movement and other body processes go downward to the spinal cord. Most of the axons in the motor pathways cross from one side of the CNS to the other as they pass through the medulla. As a result, the right side of the brain controls much of the movement on the left side of the body, and the left side of the brain controls much of the movement on the right side of the body. Similarly, axons in sensory pathways cross from one side of the CNS to the other either in the spinal cord or in the medulla (depending on the specific sensory information carried, such as pain versus localized touch), such that the right side of the brain receives sensation primarily from the left side of the body and vice versa.

Diencephalon

The diencephalon ("through brain") is the one region of the adult brain that retains its name from embryonic development. It connects the cerebrum and the rest of the nervous system, with one exception. The brainstem, the spinal cord, and the PNS all send information to the cerebrum through the diencephalon, and output from the cerebrum then passes back through the diencephalon. The single exception to this pattern is the sense of smell (olfaction), which connects directly to the cerebrum first. The diencephalon comprises the ventral surface of the forebrain (and connects to the tapering cone of the midbrain, pons, and medulla, the remaining structures in the brainstem).

The diencephalon is located deep within the cerebrum and constitutes the walls of the third ventricle. The diencephalon can be described as any region of the brain with "thalamus" in its name. The two major regions of the diencephalon are the thalamus itself and the hypothalamus (Figure 1.5.4.10). There are other structures as well, such as the epithalamus, which contains the pineal gland.

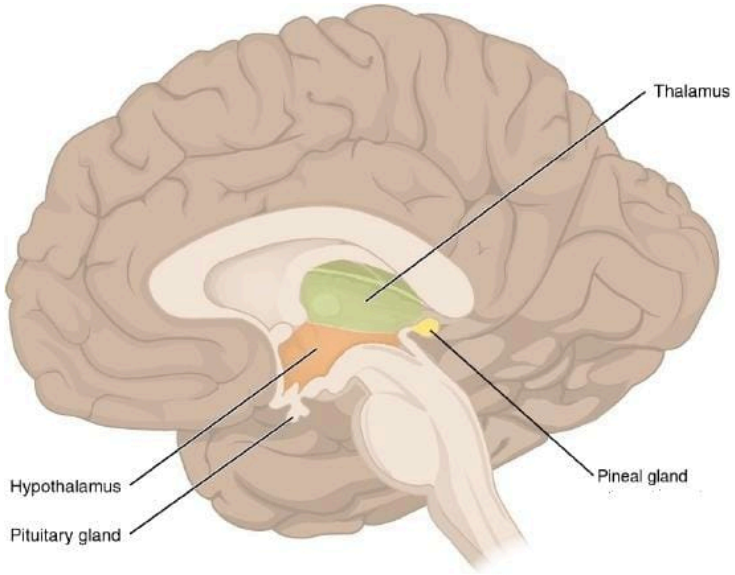

Figure 1.5.4.10: The diencephalon.

Thalamus

The **thalamus,** which is located above the hypothalamus (Figure 1.5.4.10 and Figure 1.5.4.11), is a major hub for information traveling back and forth between the spinal cord, brainstem, and cerebrum. It filters sensory information traveling to the cerebrum. It relays sensory signals to the cerebral cortex and motor signals to the spinal cord. It is also involved in the regulation of consciousness, sleep, and alertness. As noted above, olfaction (smell) is the only sense that travels directly to the cortex and does not travel through the thalamus (as part of the diencephalon) first. However, olfactory messages do travel from the cortex back to the thalamus, so smell is still a participant in the "sensory relay" functions of the thalamus.

Hypothalamus

The **hypothalamus** ("below thalamus") is about the size of an almond and is responsible for certain metabolic processes and other activities of the autonomic nervous system, including body temperature, heart rate, hunger, thirst, fatigue, sleep, wakefulness, and circadian (24-hour) rhythms. The hypothalamus is also an important emotional center of the brain. The hypothalamus can regulate so many body functions because it responds to many different internal and external signals, including messages from the brain, light, steroid hormones, stress, and invading pathogens, among others.

One way the hypothalamus influences body functions is by synthesizing hormones that directly influence body processes. For example, it synthesizes the hormone oxytocin, which stimulates penile and vaginal contractions during orgasm, uterine contractions during childbirth, and the letdown of milk during lactation. It also synthesizes the hormone vasopressin (also called antidiuretic hormone), which stimulates the kidneys to reabsorb more water and excrete more concentrated urine. These two hormones are sent from the hypothalamus via a stalk-like structure called the **infundibulum** ("pituitary stalk", see Figure 1.5.4.11) directly to the posterior (back) portion of the **pituitary gland**, which secretes them into the blood.

The main way the hypothalamus influences body functions is by controlling the pituitary gland, known as the "master gland" of the **endocrine system**. (The endocrine system is considered separately in the communication and the endocrine system module.) The hypothalamus synthesizes neurohormones called releasing factors that travel through the infundibulum directly to the anterior (front) part of the pituitary gland. The releasing factors generally either stimulate or inhibit the secretion of anterior pituitary hormones, most of which control other glands of the endocrine system.

Figure 1.5.4.11 shows where the thalamus, hypothalamus, and pituitary gland (typically considered an extension of the hypothalamus) are located in the brain. The cerebrum, hypothalamus, and thalamus exist in two halves, one in each hemisphere. The pituitary gland is a single structure in the center, connected to the hypothalamus by the infundibulum (or "pituitary stalk").

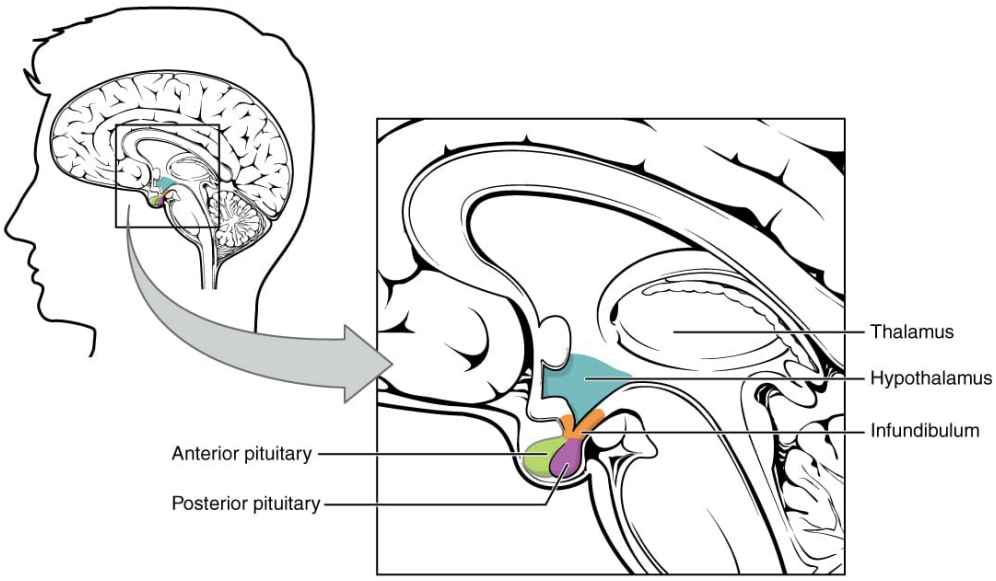

Figure 1.5.4.11: Just inferior (and deep) to the cerebrum is the thalamus. The hypothalamus is located a little bit anterior and inferior to the thalamus. The pituitary gland is attached to the hypothalamus via a stalk called the infundibulum.

The remaining parts to the brainstem are the midbrain, the pons, and the medulla, which are shown in Figure 1.5.4.12 below. These structures are primarily involved in the unconscious functions of the autonomic nervous system as well as several types of sensory information. They also help coordinate large body movements such as walking and running.

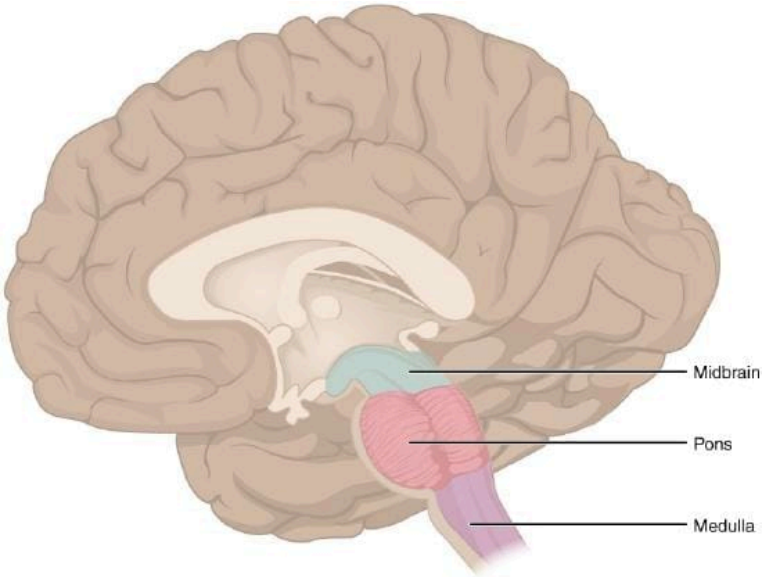

Figure 1.5.4.12: The brainstem includes the midbrain, pons, and medulla

Midbrain

The **midbrain** coordinates sensory representations of sight (visual system- the **superior colliculi**), sound (auditory system- the **inferior colliculi**), and somatosensory perceptual spaces, translating these inputs before sending them to the forebrain.

Pons

The **pons** ("bridge") is the main connection with the cerebellum. It relays messages between other parts of the brain (primarily the cerebrum and cerebellum) and sends messages to paralyze major body muscles during REM sleep. Some researchers have hypothesized that the pons plays a role in dreaming. Some of the functions of the pons are shared by the medulla, such as

regulating several crucial functions including cardiovascular system and respiratory systems, and heartbeat and breathing rates.

Medulla

The **medulla** (also called the medulla oblongata) controls several subconscious homeostatic functions such as breathing, heart and blood vessel activity, swallowing, and digestion.

Limbic System

The **limbic system** is a collection of structures of the cerebrum and diencephalon that are involved in emotion, motivation and memory. Although still under debate, the structures most often recognized as belonging to this system are the cingulate gyrus, hippocampus, amygdala, olfactory structures, and various nuclei of the diencephalon. Here we will focus on the cingulate gyrus, the hippocampus, and the amygdala (Figure 1.5.4.13). The **cingulate gyrus** (colored green in the figure) is located on the midsagittal surface of the cortex, immediately superior to the corpus callosum and surrounding the diencephalon. The cingulate gyrus focuses attention on events that are emotionally salient. The **hippocampus** (colored purple in the figure) is a nucleus shaped like a seahorse, hence its name. The hippocampus is essential for forming memories and storing them long-term and is located deep in the temporal lobe. Lastly, the **amygdala** (also called the amygdaloid body, colored blue in the figure) is connected to the anterior end of the hippocampus and is involved in multiple aspects of emotion, including encoding memories related to highly emotional states. The amygdala is especially important for the emotion fear.

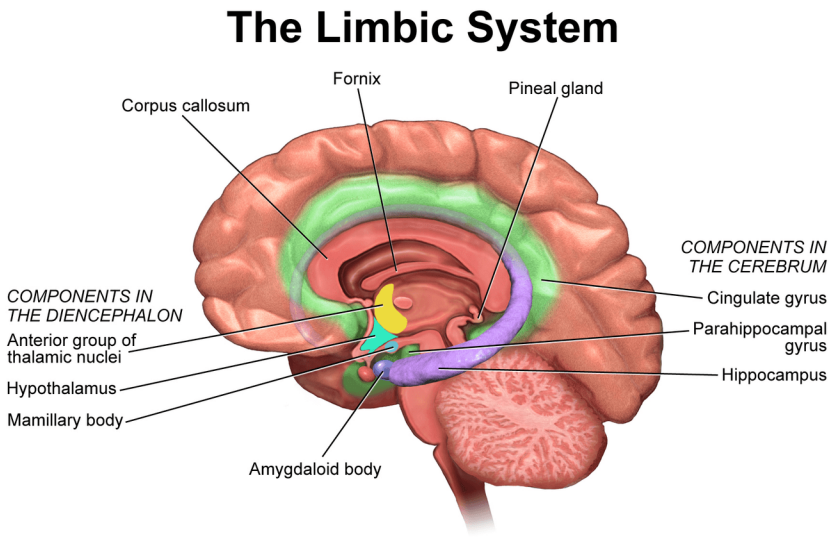

Figure 1.5.4.13: The Limbic System includes components from both the diencephalon (anterior group of thalamic nuclei, hypothalamus, and mammilary body) and the cerebrum (cingulate gyrus, parahippocampal gyrus, hippocampus, and amygdaloid body). Structures additionally labeled for reference are the corpus callosum, fornix, and pineal gland.

Cerebellum

The **cerebellum**, as the name suggests, is the “little brain”, just below the cerebrum and at the back of the brain behind the brainstem. It is covered in gyri and sulci like the cerebrum, and looks like a miniature version of that part of the brain Figure 1.5.4.14. The cerebellum is largely responsible for comparing information from the cerebrum with sensory feedback from the periphery through the spinal cord. It accounts for approximately 10 percent of the mass of the brain. The cerebellum coordinates body movements and is involved in movements that are learned with repeated practice. For example, when you hit a softball with a bat or touch type on a keyboard you are using your cerebellum. Many nerve pathways link the cerebellum with motor neurons throughout the body.

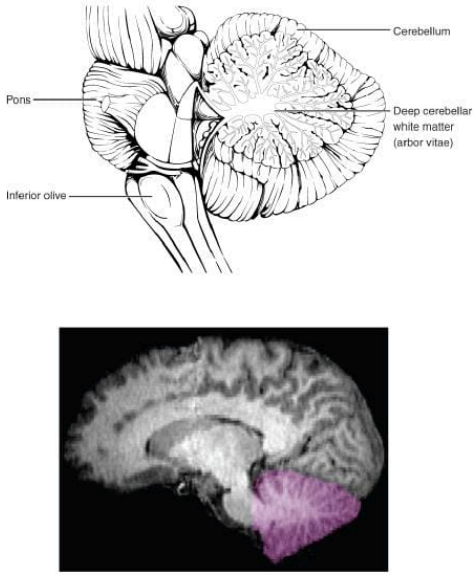

Figure 1.5.4.14: **The cerebellum.** The cerebellum is situated on the posterior surface of the brainstem. Descending input from the cerebellum enters through the large white matter structure of the pons. Ascending input from the periphery and spinal cord enters through the fibers of the inferior olive. Output goes to the midbrain, which sends a descending signal to the spinal cord.

Spinal Cord

The above description of the CNS is concentrated on the structures of the brain, but the **spinal cord** is another major organ of the system. The spinal cord is a long, thin, tubular bundle of nervous tissues that extends from the brainstem down through the center of the back and pelvis. It is highlighted in yellow in Figure 1.5.4.15.

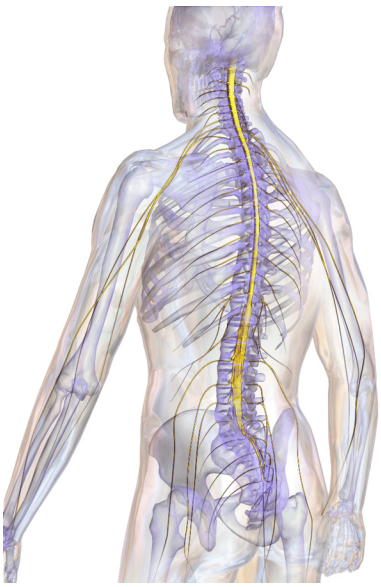

Figure 1.5.4.15: The spinal cord (shown in yellow) runs from the inferior aspect of the brain to the lower back. Spinal nerves are shown in black, and bones are shown in blue.

Structure of the Spinal Cord

The center of the spinal cord consists of **gray matter**, which is made up mainly of neuron cell bodies, including interneurons and motor neurons. The gray matter is surrounded by **white matter** that consists mainly of myelinated axons from motor and sensory neurons. Sensory neuron axons enter the posterior side through the **dorsal (/posterior) nerve root**. Motor neuron axons emerge from the anterior side through the **ventral (/anterior) nerve root**. Note that it is common to see the terms dorsal (dorsal = back)

and ventral (ventral = belly) used interchangeably with posterior and anterior, particularly in reference to nerves and the structures of the spinal cord. The **central canal** travels through the center of the spinal cord. The central canal is filled with **cerebrospinal fluid** (CSF). Figure 1.5.4.16 shows the gray matter, white matter, central canal, dorsal roots and ventral roots of the spinal cord.

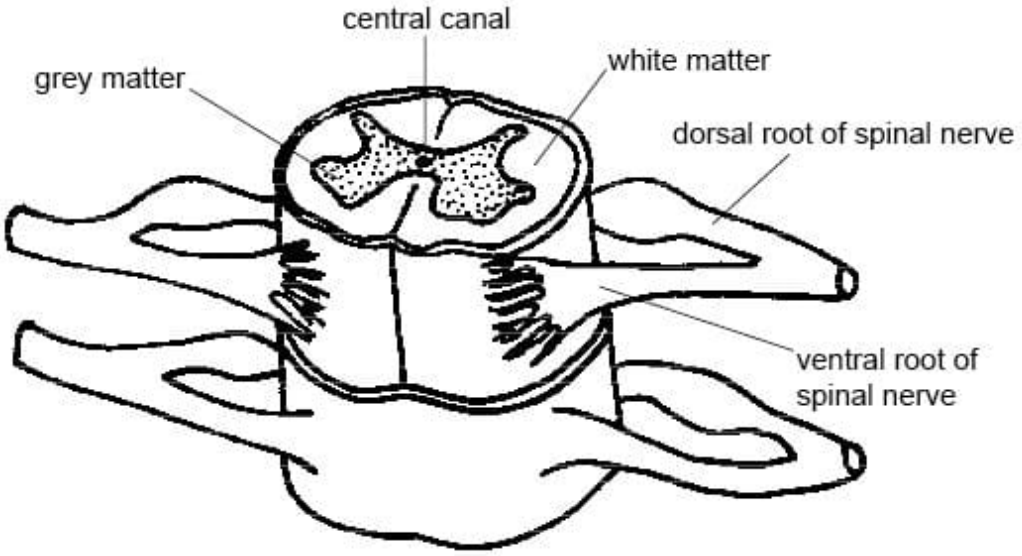

Figure 1.5.4.16: Cross section of spinal cord showing the central canal, gray and white matter, and the dorsal and ventral roots of the spinal nerves.

At each level of the spinal cord, the dorsal and ventral roots come together to form spinal nerves. Because the spinal cord is shorter than the vertebral column it is enclosed within, nerve roots must travel lower to exit at the associated vertebra. Spinal nerves connect the spinal cord to the PNS and enter/exit from the spinal cord between vertebrae (Figure 1.5.4.17).

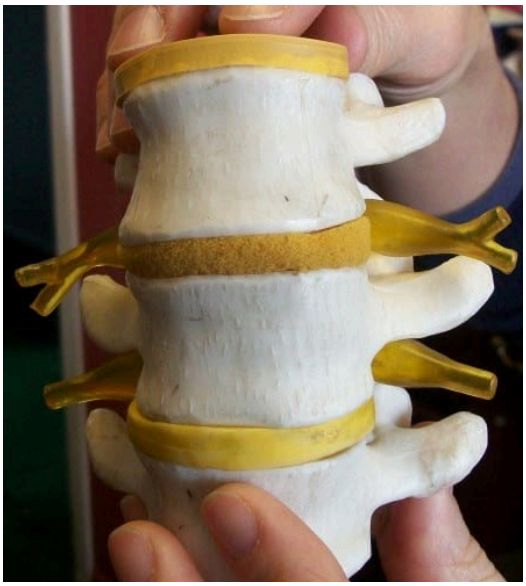

Figure 1.5.4.17: This model shows three vertebrae (white) with branching spinal nerves (yellow) emerging from either side of the spinal cord between vertebrae. Also shown in yellow are pancake-like disks between vertebrae that help cushion and maintain space between adjacent bony vertebrae.

Gray Horns

In cross-section, the gray matter of the spinal cord has the appearance of an ink-blot test, with the spread of the gray matter on one side replicated on the other—a shape reminiscent of a bulbous capital “H” or a butterfly. As shown in Figure 1.5.4.18, the gray matter is subdivided into regions that are referred to as horns.

The **posterior horn** is responsible for sensory processing. The **anterior horn** sends out motor signals to the skeletal muscles. The **lateral horn**, which is only found in the thoracic, upper lumbar, and sacral regions, is the central component of the sympathetic division of the autonomic nervous system.

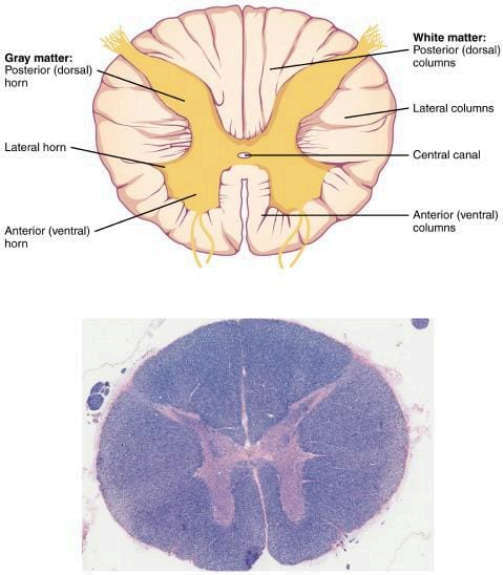

Figure 1.5.4.18: **Cross-section of Spinal Cord** The cross-section of a thoracic spinal cord segment shows the posterior (dorsal), anterior (ventral), and lateral horns of gray matter, as well as the posterior (dorsal), anterior (ventral), and lateral columns of white matter. Light Microscopy × 40 magnification.

Functions of the Spinal Cord

The spinal cord serves as an information superhighway. It passes messages from the body to the brain and from the brain to the body. Sensory (afferent) nerves carry nerve impulses to the brain from sensory receptor cells everywhere in and on the body. Motor (efferent) nerves carry nerve impulses away from the brain to glands, organs, or muscles throughout the body.

The spinal cord also independently controls certain rapid responses called **reflexes** without any input from the brain. A sensory receptor responds to a sensation and sends a nerve impulse along a sensory nerve to the spinal cord. In the spinal cord, the message passes to an interneuron and from the interneuron to a motor nerve, which carries the impulse to a muscle. The muscle contracts in response. These neuron connections form a reflex arc, which requires no input from the brain. No doubt you have experienced such reflex actions yourself. For example, you may have reached out to touch a pot on the stove, not realizing that it was very hot. Virtually at the same moment that you feel the burning heat, you jerk your arm back and remove your hand from the pot.

Injuries to the Spinal Cord

Physical damage to the spinal cord may result in **paralysis,** which is a loss of sensation and movement in part of the body. Paralysis generally affects all the areas of the body below the level of the injury because nerve impulses are interrupted and can no longer travel back and forth between the brain and body beyond that point. If an injury to the spinal cord produces nothing more than swelling, the symptoms may be transient. However, if nerve fibers (axons) in the spinal cord are badly damaged, the loss of function may be permanent. Experimental studies have shown that spinal nerve fibers attempt to regrow, but tissue destruction usually produces scar tissue that cannot be penetrated by the regrowing nerves, as well as other factors that inhibit nerve fiber regrowth in the central nervous system.

Feature: My Human Body

Each year, many millions of people have a stroke, and stroke is the second leading cause of death in adults. **Stroke,** also known as **cerebrovascular accident**, occurs when poor blood flow to the brain results in the death of brain cells. There are two main types of strokes:

- **Ischemic** strokes occur due to a lack of blood flow because of a blood clot in an artery going to the brain.
- **Hemorrhagic** strokes occur due to bleeding from a broken blood vessel in the brain.

Either type of stroke may result in paralysis, loss of the ability to speak or comprehend speech, loss of bladder control, personality changes, and many other potential effects, depending on the part of the brain that is injured. The effects of a stroke may be mild and transient or more severe and permanent. A stroke may even be fatal. It generally depends on the type of stroke and how extensive it is.

Are you at risk of stroke? The main risk factor for stroke is age: about two-thirds of strokes occur in people over the age of 65. There is nothing you can do about your age, but most other stroke risk factors can be reduced with lifestyle changes or medications. The risk factors include high blood pressure, tobacco smoking, obesity, high blood cholesterol, diabetes mellitus, and atrial fibrillation.

Chances are good that you or someone you know is at risk of a stroke, so it is important to recognize a stroke if one occurs. Stoke is a medical emergency, and the more quickly treatment is given, the better the outcome is likely to be. In the case of ischemic strokes, the use of clot-busting drugs may prevent permanent brain damage if administered within 3 or 4 hours of the stroke. Remembering the signs of a stroke is easy. They are summed up by the acronym FAST, as explained in Figure 1.5.4.19.

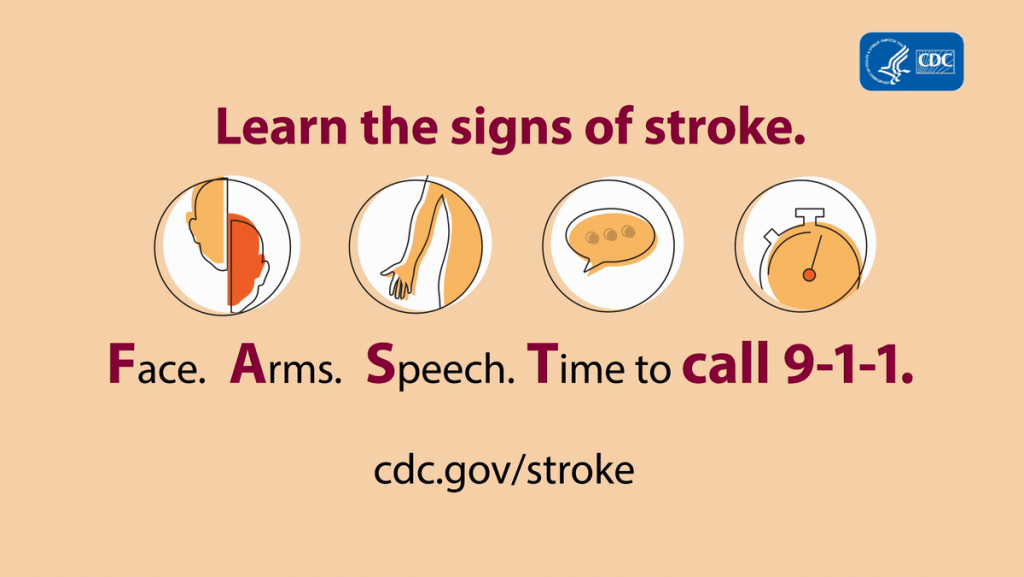

Figure 1.5.4.19: The signs of stroke are abbreviated as FAST, where F stands for droopy face, A stands for arm weakness, S stands for slurry speech, and T stands for time to call 911.

Summary

The central nervous system (CNS) includes the brain and spinal cord, described in greater detail in this module. The adult brain is separated into three major regions: the cerebrum, the brainstem, and the cerebellum. The cerebrum is the largest portion and is divided into two halves called hemispheres by the longitudinal fissure. The two hemispheres are connected by the corpus callosum, the major pathway for communication between the hemispheres.

The cerebral cortex, a continuous layer of gray matter covering the cerebrum, is the location of important cognitive functions. The cerebral cortex is separated into the frontal, parietal, temporal, and occipital lobes. The frontal lobe is responsible for executive functions and movements. The parietal lobe is involved in body sensations, reading, and arithmetic. The temporal lobe has regions crucial for memory formation, and contains cortical areas that process audition (hearing) and olfaction (smell). The occipital lobe is where visual processing begins.

The brainstem is composed of the diencephalon, midbrain, pons, and medulla. The brainstem serves as an "information highway", since all of the information coming from the body to the brain and the information from the cerebrum to the body go through the brainstem. The two major regions of the diencephalon are the thalamus and the hypothalamus. The thalamus is a relay between the cerebrum and the rest of the nervous system. The hypothalamus coordinates metabolic processes through the autonomic

and endocrine systems. The midbrain coordinates sensory representations of sight, sound and somatosensation. The pons is the main connection between the cerebrum and the cerebellum. The pons and the medulla together regulate the cardiovascular and respiratory systems. The medulla also has important functions for swallowing and digestion.

The limbic system includes structures of the cerebrum and diencephalon that are responsible for emotion, motivation, and memory. The main structures are the cingulate gyrus, the hippocampus and the amygdala.

The cerebellum is connected to the brain stem and compares information from the cerebrum with sensory feedback from the spinal cord. The cerebellum coordinates body movements and is involved in movements that are learned with repeated practice.

The spinal cord extends from the brainstem down through the center of the back and pelvis. Sensory neuron axons enter through the dorsal (/posterior) nerve root and motor neuron axons emerge from the ventral (/anterior) nerve root. Gray matter (containing of neuron cell bodies) is located in the center of the spinal cord, surrounded by white matter (myelinated axons). The gray matter is subdivided into the posterior, anterior, and lateral horns. The spinal cord passes messages from the body to the brain and from the brain to the body. Sensory (afferent) nerves carry nerve impulses to the brain from sensory receptor cells everywhere in and on the body. Motor (efferent) nerves carry nerve impulses away from the brain to glands, organs, or muscles throughout the body. The spinal cord also independently controls reflexes without any input from the brain. Physical damage to the spinal cord may result in paralysis, which may be permanent.

1.5.5: The Peripheral Nervous System

Learning Objectives

1. Describe the structures found in the PNS
2. Distinguish between somatic and autonomic structures
3. Name the twelve cranial nerves and explain the functions associated with each
4. Describe the sensory and motor components of spinal nerves
5. Explain the functions of the sympathetic and parasympathetic divisions of the autonomic system

Overview

This module discusses the peripheral nervous system (PNS) in greater depth, including nervous tissues, the two major systems the PNS divides into (the somatic nervous system and the autonomic nervous system), names and functions of the twelve cranial nerves, and characteristics of the 31 pairs of spinal nerves. The subdivisions of the autonomic nervous system (the sympathetic nervous system and the parasympathetic nervous system) and their functions are also covered, as well as a brief mention of disorders of the PNS.

What Is the Peripheral Nervous System?

The **peripheral nervous system (PNS)** consists of all the nervous tissue that lies outside of the central nervous system (CNS). The main function of the PNS is to connect the CNS to the rest of the organism. It serves as a communication relay, going back and forth between the CNS and muscles, organs, and glands throughout the body. Figure 1.5.5.1 illustrates both the central and peripheral nervous systems, including many representative **spinal nerves**. Although an overview of spinal nerves is discussed in greater detail below, the identification and functions of specific spinal nerves are beyond the scope of this section.

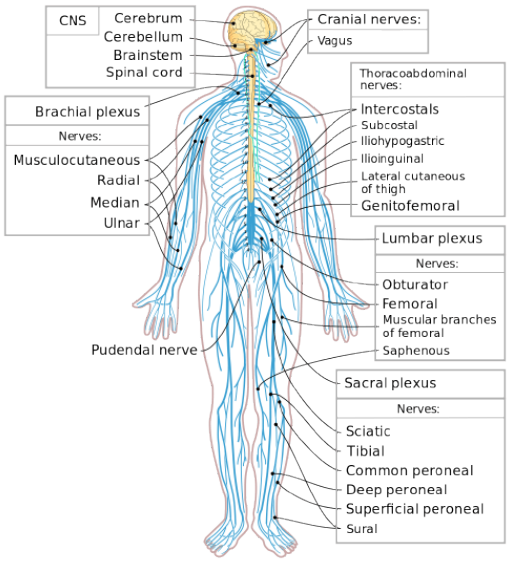

Figure 1.5.5.1: The central nervous system (CNS) is shown in yellow: Cerebrum, Cerebellum, Brainstem, Spinal cord. Some representative nerves of the peripheral nervous system (PNS) are shown in blue.

The representative nerves pictured are Cranial nerves: Vagus. Brachial plexus nerves: Musculotaneous, Radial, Median, Ulnar; Thoracoabdominal nerves: Intercostals, Subcostal, Iliohypogastric, Ilioinguinal, Lateral cutaneous of thigh, Genitofemoral; Lumbar plexus nerves: Obturator, Femoral, Muscular branches of femoral, Saphenous; Sacral plexus nerves: Sciatic, Tibial, Common peroneal, Deep peroneal, Superficial peroneal, Sural. The Pudendal nerve is also pictured.

Tissues of the Peripheral Nervous System

The primary structures that make up the PNS are nerves and ganglia. Ganglia are clusters of neuron cell bodies outside the CNS; they act as relay points for messages transmitted through nerves of the PNS. Nerves are cable-like bundles of axons that make up the majority of PNS tissues. Nerves are generally classified based on the type of information they carry (which coincides with the direction in which their nerve impulses travel) as sensory, motor, or mixed nerves. See an example of a sensory and motor nerve in Figure 1.5.5.2. (Note that the interneuron that is usually located between the sensory and motor neuron is not shown in this figure.)

- **Sensory nerves** transmit information from sensory receptors in the body to the CNS. Sensory nerves are also called afferent nerves.
- **Motor nerves** transmit information from the CNS to muscles, organs, and glands. Motor nerves are also called efferent nerves.
- **Mixed nerves** contain axons from both sensory and motor neurons, so they transmit information in both directions and have both afferent and efferent functions.

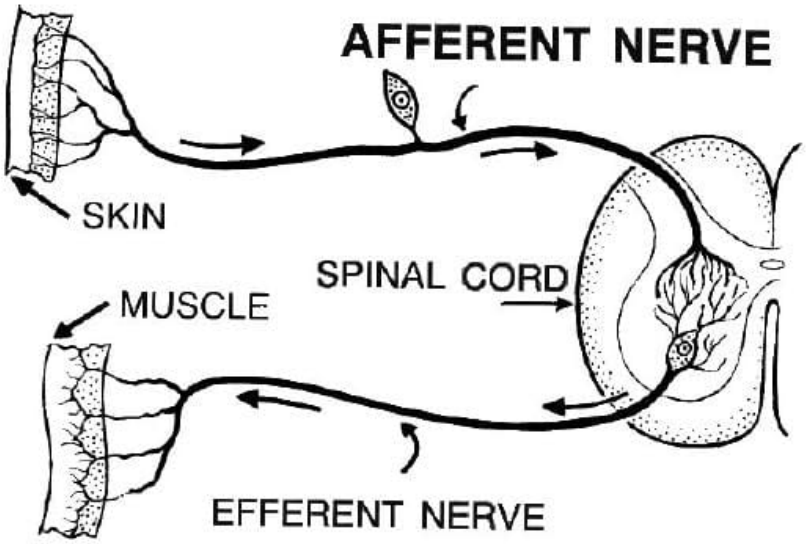

Figure 1.5.5.2: A sensory nerve is an afferent nerve. The one pictured here sends nerve impulses from sensory receptors in the skin to the CNS. A motor nerve is an efferent nerve. This one sends nerve impulses from the CNS to a muscle.

Divisions of the Peripheral Nervous System

The PNS is divided into two major systems, called the autonomic nervous system and the somatic nervous system. Both systems of the PNS interact with the CNS and include sensory and motor neurons, but they use different circuits of nerves and ganglia.

Somatic Nervous System

The **somatic nervous system** primarily senses the external environment and controls voluntary activities for which decisions and commands come from the cerebral cortex of the brain. For example, when you feel too cold, decide to turn on the heater, and walk across the room to the thermostat, you are using your somatic nervous system. In general, the somatic nervous system is responsible for all of your conscious perceptions of the outside world, and all of the voluntary motor activities you perform in response. Whether it's playing piano, driving a car, or playing basketball, you can thank your somatic nervous system for making it possible. Structurally, the somatic nervous system consists of 12 pairs of cranial nerves and 31 pairs of spinal nerves.

Cranial Nerves

Cranial nerves (Figure 1.5.5.3) are in the head and neck and connect directly to the brainstem. There are twelve cranial nerves, which are designated CN I through CN XII (the "CN" stands for "Cranial Nerve") using the Roman numerals for 1 through 12, based on their anatomical location on the inferior view of the brain, from anterior to posterior. Sensory cranial nerves sense smells, tastes, light, sounds, and body position and sensations. Motor cranial nerves control muscles of the face, tongue, eyeballs, throat, head, and shoulders. The motor nerves also control the salivary glands and swallowing. Four of the 12 cranial nerves participate in both sensory and motor functions as mixed nerves, having both sensory and motor functions. See Table 1.5.5.1 for a brief summary of the functions of each cranial nerve.

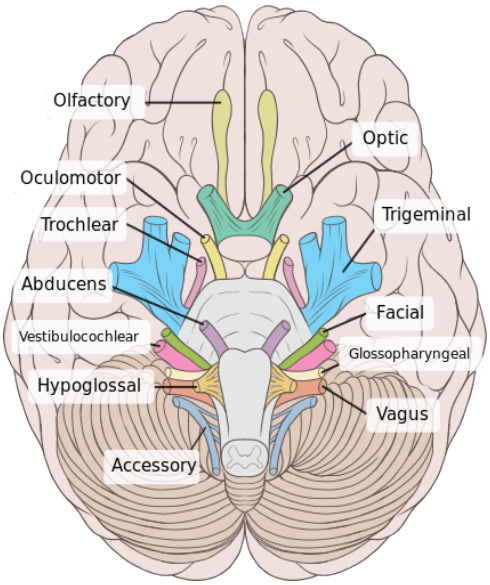

Figure 1.5.5.3: The twelve pairs of cranial nerves are located on the inferior aspect of the human brain.

Table 1.5.5.1: Cranial Nerves

Mnemonic	#	Name	Function (Sensory/Motor/Both)	Central connection (nuclei)	Peripheral connection (ganglion or muscle)
On	I	Olfactory	Smell (S)	Olfactory bulb	Olfactory epithelium
Old	II	Optic	Vision (S)	Hypothalamus/ thalamus/ midbrain	Retina (retinal ganglion cells)
Olympus'	III	Oculomotor	Eye movements; lens and pupil movements (M)	Oculomotor nucleus	Four of the extraocular muscles; levator palpebrae superioris; ciliary ganglion (autonomic)
Towering	IV	Trochlear	Eye movements (M)	Trochlear nucleus	Superior oblique muscle (eyeball)
Tops	V	Trigeminal	Sensory/ motor – face (B)	Trigeminal nuclei in the midbrain, pons, and medulla	Trigeminal
A	VI	Abducens	Eye movements (M)	Abducens nucleus	Lateral rectus muscle (eyeball)
Finn	VII	Facial	Motor – face; Taste (B)	Facial nucleus, solitary nucleus, superior salivatory nucleus	Facial muscles; Geniculate ganglion; Pterygopalatine ganglion (autonomic)
And	VIII	Auditory (Vestibulocochlear)	Hearing/ balance (S)	Cochlear nucleus, Vestibular nucleus/ cerebellum	Spiral ganglion (hearing); Vestibular ganglion (balance)
German	IX	Glossopharyngeal	Motor – throat; Taste (B)	Solitary nucleus, inferior salivatory nucleus, nucleus ambiguus	Pharyngeal muscles; Geniculate ganglion; Otic ganglion (autonomic)
Viewed	X	Vagus	Motor/ sensory – viscera (autonomic) (B)	Medulla	Terminal ganglia serving thoracic and upper abdominal organs (heart and small intestines)
Some	XI	(Spinal) Accessory	Motor – head and neck (M)	Spinal accessory nucleus	Neck muscles

Mnemonic	#	Name	Function (Sensory/Motor/Both)	Central connection (nuclei)	Peripheral connection (ganglion or muscle)
Hops	XII	Hypoglossal	Motor – lower throat (M)	Hypoglossal nucleus	Muscles of the larynx and lower pharynx

Spinal Nerves

The nerves connected to the spinal cord are the **spinal nerves**. The arrangement of these nerves is much more regular than that of the cranial nerves. All of the spinal nerves are combined sensory and motor axons that separate into two nerve roots. The sensory axons enter the spinal cord as the **dorsal nerve root**. The motor fibers, both somatic and autonomic, emerge as the **ventral nerve root**. The sensory neuron cell bodies (soma) are grouped in enlargements of the dorsal nerve root called **dorsal root ganglia**. See Figure 1.5.5.4 to locate these structures on a segment of the spinal cord. (As noted in the central nervous system module, it is common to see the terms dorsal (dorsal = back) and ventral (ventral = belly) used interchangeably with posterior and anterior in reference to nerves and the structures of the spinal cord.)

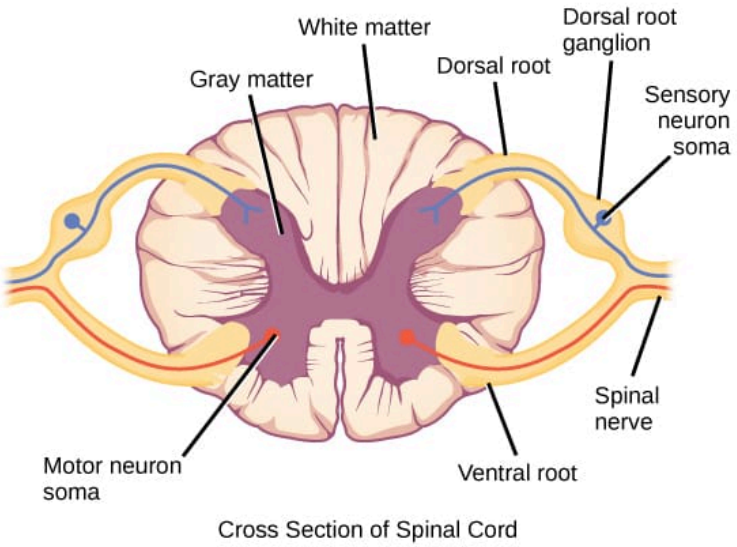

Figure 1.5.5.4: **Spinal nerves**: Spinal nerves contain both sensory and motor axons. The cell bodies of sensory neurons are located in dorsal root ganglia. The cell bodies of motor neurons are found in the ventral portion of the gray matter of the spinal cord.

Each sensory neuron has one projection with a sensory receptor ending in skin, muscle, or sensory organs, and another that synapses with a neuron in the dorsal spinal cord. Motor neurons have cell bodies (soma) in the ventral gray matter of the spinal cord that project to muscle through the ventral root. These neurons are usually stimulated by interneurons within the spinal cord, but are sometimes directly stimulated by sensory neurons. Spinal nerves include the motor nerves that stimulate skeletal muscle contraction, allowing for voluntary body movements.

There are 31 pairs of spinal nerves, named for the level of the spinal cord at which they emerge, one on each side of the body. There are eight pairs of cervical nerves designated C1 to C8, twelve thoracic nerves designated T1 to T12, five pairs of lumbar nerves designated L1 to L5, five pairs of sacral nerves designated S1 to S5, and one pair of coccygeal nerves. The nerves are numbered from the superior to inferior positions, and each emerges from the vertebral column through the intervertebral foramen at its level. Thus, each spinal nerve corresponds to a segment of the spinal cord, carrying both sensory and motor information (as mentioned above) for the areas of the body represented. As such, all of the spinal nerves are mixed nerves and contain both sensory and motor neuron axons. Figure 1.5.5.5 illustrates the body areas represented by the spinal nerves and Figure 1.5.5.6 lists some of the functions of the spinal nerves.

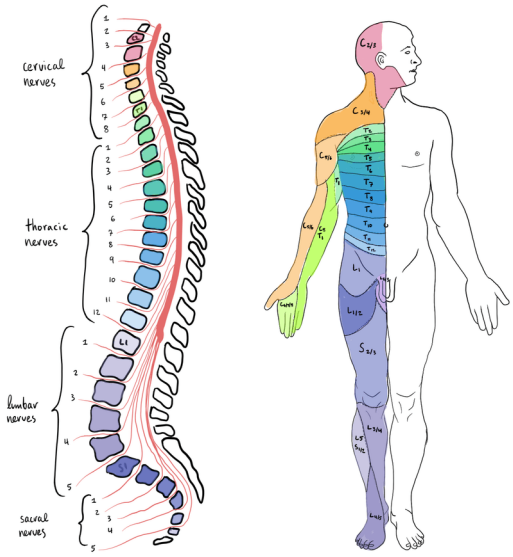

Figure 1.5.5.5: Spinal cord segments and body representation.

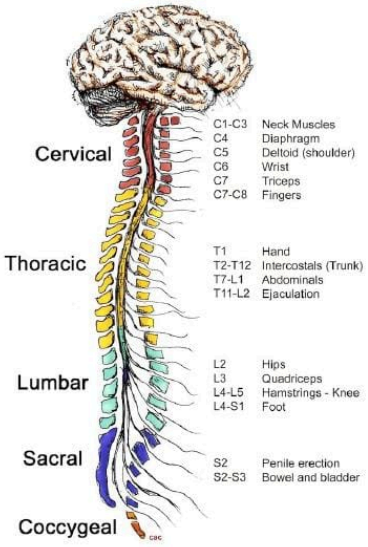

Figure 1.5.5.6: Vertebral location and some functions of spinal nerves.

Autonomic Nervous System

The **autonomic nervous system** primarily senses the internal environment and controls involuntary activities. It is responsible for monitoring conditions in the internal environment and bringing about appropriate changes in them. In general, the autonomic nervous system is responsible for all the activities that go on inside your body without your conscious awareness or voluntary participation.

Structurally, the autonomic nervous system consists of sensory and motor nerves that run between the CNS (especially the hypothalamus in the brain) and internal organs (such as the heart, lungs, and digestive organs) and glands (such as the pancreas and sweat glands). Sensory neurons in the autonomic system detect internal body conditions and send messages to the brain. Motor nerves in the autonomic system function by controlling the contractions of smooth or cardiac muscle or glandular tissue. For example, when sensory nerves of the autonomic system detect a rise in body temperature, motor nerves signal both the smooth muscles in blood vessels near the body surface to undergo vasodilation, and the sweat glands in the skin to secrete more sweat, to cool the body.

The autonomic nervous system, in turn, has two subdivisions: the sympathetic division and parasympathetic division. The functions of the two subdivisions of the autonomic system are summarized in Figure 1.5.5.5. Both affect most of the same organs

and glands, but they generally do so in opposite ways.

- The **sympathetic division** controls the fight-or-flight response. Changes occur in organs and glands throughout the body that prepare the body to fight or flee in response to a perceived danger. For example, the pupils dilate, saliva production decreases, air passages in the lungs become wider (the bronchia dilate), heart rate speeds up, more blood flows to the skeletal muscles, and the digestive system temporarily shuts down. With regard to urinary and sexual functions, the sympathetic division relaxes the urinary bladder and stimulates orgasm in both men and women.
- The **parasympathetic division** returns the body to normal after the fight-or-flight response has occurred. For example, pupils constrict, saliva production increases, air passages in the lungs narrow (the bronchia constrict), heart rate slows down, blood flow to the skeletal muscles is reduced, and the digestive system is stimulated to start working again. The parasympathetic division also maintains the internal homeostasis of the body at other times. With regard to urinary and sexual functions, the parasympathetic division constricts the urinary bladder and stimulates genital tissue erection in both men and women.

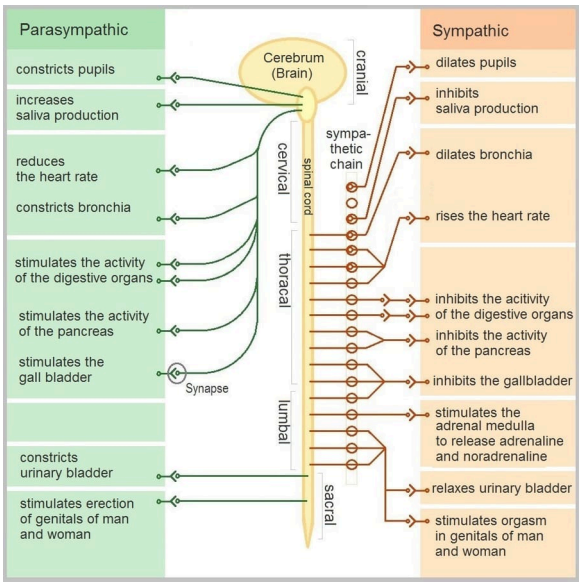

Figure 1.5.5.7: This diagram summarizes the structures and functions controlled by the parasympathetic and sympathetic divisions of the autonomic nervous system. The image shows how eyes, salivary gland, heart rate, bronchi, digestive system, bladder, and genitalia are affected in opposite ways by the two systems.

Disorders of the Peripheral Nervous System

Unlike the CNS, which is protected by bones, meninges, and cerebrospinal fluid (CSF), the PNS has no such protections. The PNS also has no blood-brain barrier to protect it from toxins and pathogens in the blood. Therefore, the PNS is more subject to injury and disease than is the CNS. Causes of nerve injury include diabetes, infectious diseases such as shingles, and poisoning by toxins such as heavy metals. Disorders of the PNS often have symptoms such as loss of feeling, tingling, burning sensations, or muscle weakness. If a traumatic injury results in a nerve being transacted (cut all the way through), it may regenerate, but this is a very slow process and may take many months.

Summary

The peripheral nervous system (PNS) is composed of the groups of neurons (ganglia) and bundles of axons (nerves) that are outside of the brain and spinal cord. The PNS connects the CNS to the rest of the body.

Sensory (/afferent) nerves transmit information from sensory receptors in the body to the CNS. Motor (/efferent) transmit information from the CNS to muscles, organs, and glands. Mixed nerves transmit information in both directions and have both sensory (/afferent) and motor (/efferent functions). The PNS is divided into the autonomic nervous system and the somatic nervous system.

The somatic nervous system senses the external environment and controls voluntary activities, and consists of 12 pairs of cranial

nerves (connected to the brain) and 31 pairs of spinal nerves (connected to the spinal cord). Cranial nerves can be strictly sensory, strictly motor, or a combination of the two functions. The olfactory nerve (CN I) is responsible for smell and the optic nerve (CN II) is responsible for vision. The oculomotor nerve (CN III) is responsible for eye movements, lifting the upper eyelid, and controlling the size of the pupil. The trochlear nerve (CN IV) and the abducens nerve (CN VI) are both responsible for eye movement, but control different extraocular muscles. The trigeminal nerve (CN V) is responsible for cutaneous (skin) sensations of the face and controlling the muscles of mastication (chewing). The facial nerve (VII) is responsible for the muscles involved in facial expressions, as well as part of the sense of taste. The vestibulocochlear nerve (VIII) is responsible for the senses of hearing and balance. The glossopharyngeal nerve (IX) is responsible for controlling muscles in the throat, as well as part of the sense of taste. The vagus nerve (CN X) is responsible for contributing to homeostatic control of the organs of the thoracic and upper abdominal cavities. The accessory nerve (CN XI, along with cervical spinal nerves) is responsible for controlling the muscles of the neck. The hypoglossal nerve (CN XII) is responsible for controlling the muscles of the lower throat and tongue.

Spinal nerves are all mixed nerves with both sensory and motor fibers. The sensory axons enter the spinal cord as the dorsal nerve root and the motor fibers (both somatic and autonomic) emerge as the ventral nerve root. The sensory neuron cell bodies (soma) are located in dorsal root ganglia. Spinal nerves emerge from the spinal cord and are numbered from superior to inferior positions.

The autonomic nervous system senses the internal environment and controls involuntary activities. It is divided into the sympathetic division and parasympathetic division. Both affect most of the same organs and glands, but in opposite ways. The sympathetic division controls the fight-or-flight response and the parasympathetic division returns the body to normal after the fight-or-flight response has occurred.

The PNS does not have the same protections (bones, meninges, CSF, blood-brain barrier) that the CNS has, so it is more prone to injury and disease. If a nerve is transacted, it may regenerate, but this is a very slow process.

1.5.6: Communication and the Endocrine System

Learning Objectives

1. Explain the difference between chemical signals in the nervous system and chemical signals in the endocrine system
2. Understand the reciprocal interactions between the influence of hormones on behavior and behavior on hormones
3. Identify at least three endocrine glands and describe their primary functions

Overview

Throughout the nervous system, neurons communicate via electrical and chemical signals. Another form of chemical communication is the secretion of hormones into the bloodstream, which is accomplished via endocrine glands located in the endocrine system. This chapter introduces the endocrine system and the major endocrine glands found in the brain and the body.

Communication in the Nervous System versus the Endocrine System

Nerve impulses are covered in depth in the nervous system communication chapter. Briefly, neurons in the nervous system communicate via electrical and chemical signals. When a neuron transmits an electrical signal, called a nerve impulse (or action potential), it travels down the axon and causes neurotransmitters to be released into the synapse. This chemical signal then influences the receiving cell in either an excitatory or inhibitory manner. A cell that receives nerve impulses from a neuron may be excited to perform a function, inhibited from carrying out an action, or otherwise controlled. In this way, the information transmitted by the nervous system is specific to particular cells and is transmitted very rapidly. In fact, the fastest nerve impulses travel at speeds greater than 100 meters per second! Compare this to the chemical messages carried by the hormones that are secreted into the blood by endocrine glands (below). These hormonal messages are “broadcast” to all the cells of the body, and they can travel only as quickly as the blood flows through the cardiovascular system.

Neural Transmission versus Hormonal Communication

Hormones are similar in function to neurotransmitters, the chemicals used by the nervous system in coordinating animals’ activities (as mentioned above). However, hormones can operate over a greater distance and over a much greater temporal range than neurotransmitters. Neural and hormonal communication both rely on chemical signals, but several important differences exist. Communication in the nervous system is analogous to traveling on a train. You can use the train in your travel plans as long as tracks exist between your intended origin and destination. Likewise, neural messages can travel only to destinations along existing nerve tracts. Hormonal communication, on the other hand, is like traveling in a car. You can drive to many more destinations than train travel allows because there are many more roads than railroad tracks. Similarly, hormonal messages can travel anywhere in the body via the circulatory system; any cell receiving blood is potentially able to receive a hormonal message.

Not all cells are influenced by each and every hormone. Rather, any given hormone can directly influence only cells that have specific hormone receptors for that particular hormone. Cells that have these specific receptors are called target cells for the hormone. When a hormone engages its receptor, a series of subsequent events either activates enzymes or turns genes on or off to regulate protein synthesis. The newly synthesized proteins may then activate or deactivate other genes, causing additional effects. Importantly, sufficient numbers of appropriate hormone receptors must be available for a specific hormone to produce any effects. For example, testosterone is important for male sexual behavior. If men have too little testosterone, their sexual motivation may be low, which can be restored by testosterone treatment. However, if men have normal or even elevated levels of testosterone yet display low sex drive, then it might be possible for a lack of receptors to be the cause, in which case treatment with additional hormones will not be effective.

Another difference is that neural messages are all-or-none events that have rapid onset and offset: neural signals can take place in milliseconds. For example, the nervous system regulates immediate food intake and directs body movement, changes in the body that are relatively rapid. In contrast, hormonal messages are graded events that may take seconds, minutes, or even hours to occur. Hormones can mediate long-term processes, such as growth, development, reproduction, and metabolism.

Interactions Between Hormones and Behavior

The scientific study of the interaction between hormones and behavior is called behavioral endocrinology. This interaction is bidirectional: hormones can influence behavior, and behavior can sometimes influence hormone concentrations. Hormones are chemical messengers produced and released by specialized glands called endocrine glands (see below). Hormones are released from these glands into the blood, where they travel to act on target structures anywhere in the body, influencing the nervous system to regulate an individual's behaviors (such as aggression, mating, and parenting). Examples of hormones that influence behavior include steroid hormones such as testosterone (a common type of androgen), estradiol (a common type of estrogen), progesterone (a common type of progestin), and cortisol (a common type of glucocorticoid). Several types of protein or peptide (small protein) hormones also influence behavior, including oxytocin, vasopressin, prolactin, and leptin.

There are many ways that hormones influence behavior and behavior feeds back to influence hormone secretion. Some examples include hormones in the mediation of food and fluid intake, social interactions, salt balance, learning and memory, stress coping, as well as psychopathology including depression, anxiety disorders, eating disorders, postpartum depression, and seasonal depression. Some other hormone-behavior interactions that are related to reproductive behaviors are described in Chapter 13.1.

Introduction to the Endocrine System

As the endocrine system is not a part of the nervous system, this section may surprise you. However, as textbook author James W. Kalat states, “Hormonal influences resemble synaptic transmission in many ways, including the fact that many chemicals serve both as neurotransmitters and hormones” (Kalat, 2019, page 59). Thus, to understand many of the topics that will be covered in upcoming chapters, you will need a basic understanding of the endocrine system.

The **endocrine system** is a system of glands called **endocrine glands** that release chemical messenger molecules called **hormones** into the bloodstream. Other glands of the body, including sweat glands and salivary glands, also secrete substances but not into the bloodstream. Instead, they secrete them through ducts that carry them to nearby body surfaces. These other glands are called **exocrine glands.**

Endocrine hormones must travel through the bloodstream to the cells they affect, and this takes time. Because endocrine hormones are released into the bloodstream, they travel throughout the body wherever blood flows. As a result, endocrine hormones may affect many cells and have body-wide effects. Endocrine hormones may cause effects that last for days, weeks, or even months.

Major Glands of the Endocrine System

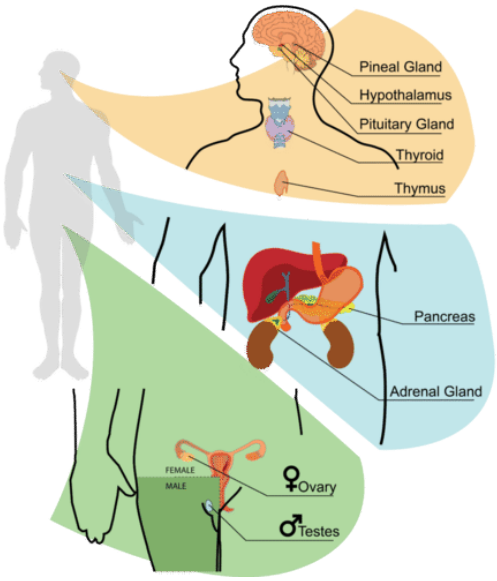

Figure 1.5.6.1: Endocrine Glands. All of the glands in this figure are part of the endocrine system. Note that the ovary and testis are the only endocrine glands that differ in males and females.

The major glands of the endocrine system are shown in Figure 1.5.6.1. The glands in the figure are described briefly in the rest of

this section. Refer to the figure as you read about the glands in the following text.

Endocrine Glands in the Brain

The **pituitary gland** is located at the base of the brain. It is controlled by the nervous system via the brain structure called the **hypothalamus**, to which it is connected by a thin stalk (called the **infundibulum**). The pituitary gland consists of two lobes, called the anterior (front) lobe and posterior (back) lobe. The posterior lobe, composed of nervous tissue, stores and secretes hormones synthesized by the hypothalamus, specifically the hormones oxytocin and vasopressin (also called antidiuretic hormone).

The anterior lobe, composed of glandular tissue, synthesizes and secretes many of its own endocrine hormones, also under the influence of the hypothalamus. One endocrine hormone secreted by the anterior pituitary gland is growth hormone, which stimulates cells throughout the body to synthesize proteins and divide. Most of the other endocrine hormones secreted by the anterior pituitary gland are called **tropic hormones** because they control other endocrine glands. Generally, tropic hormones direct other endocrine glands to secrete either more or less of their own hormones, such as adrenocorticotrophic hormone (ACTH) stimulating the adrenal gland to produce the "stress" hormone cortisol. This is why the pituitary gland is often referred to as the “master gland” of the endocrine system. Since the hypothalamus is the structure that controls both the anterior and posterior parts of the pituitary, you can think of it as the "master" of the "master gland".

The **pineal gland** (also called the **epithalamus**) is a tiny gland located near the center of the brain. It secretes the hormone melatonin, which controls the sleep-wake cycle and several other processes. The production of melatonin is stimulated by darkness and inhibited by light. Cells in the retina of the eye detect light and send signals to a structure in the hypothalamus named the **suprachiasmatic nucleus** (SCN). Nerve fibers carry the signals from the SCN to the pineal gland via the autonomic nervous system.

Endocrine Glands in the Body

Each of the other major glands of the endocrine system is summarized briefly below. Several of these endocrine glands are also discussed in greater detail as they relate to other topics in separate chapters.

- The **thyroid gland** is a large gland in the neck. Thyroid hormones such as **thyroxine** increase the rate of metabolism in cells throughout the body. They control how quickly cells use energy and make proteins.
- The **thymus gland** is located in front of the heart. It is the site where immune system cells called T cells mature. T cells are critical to the adaptive immune system, facilitating the body's adaption to specific pathogens.
- The **pancreas** is located near the stomach. Its endocrine hormones include **insulin** and **glucagon**, which work together to control the level of glucose in the blood. The pancreas also secretes digestive enzymes into the small intestine.
- The two **adrenal glands** are located above the kidneys. Adrenal glands secrete several different endocrine hormones, including the hormone **epinephrine** (also known as adrenaline), which is involved in the fight-or-flight response. Other endocrine hormones secreted by the adrenal glands have a variety of functions. For example, the hormone **aldosterone** helps to regulate the balance of minerals in the body. The "stress" hormone **cortisol** is also an adrenal gland hormone.
- The paired **gonads** include the **ovaries** in females and **testes** in males. They secrete sex hormones, such as **testosterone** (in males) and **estrogen** (in females). These hormones control sexual maturation during puberty and the production of **gametes** (sperm or egg cells) by the gonads after sexual maturation.

Summary

Neurons communicate via electrical and chemical signals. The endocrine system also communicates via chemical signals, using hormones traveling through the bloodstream. Hormones are secreted by endocrine glands, and have similar features to neurotransmitters (which are released at synapses between neurons in the nervous system). Both neural and hormonal communication rely on chemical signals. However, hormones can operate over a greater distance (anywhere in the body via the circulatory system) and over a much greater time length, and can thus mediate long-term processes. A particular hormone can only influence cells that have receptors for that specific hormone. The interaction between hormones and behavior is bidirectional: hormones can influence behavior, and behavior can sometimes influence hormone concentrations.

A basic understanding of the endocrine system is necessary to understand many of the topics covered in other chapters. Endocrine glands in the brain include the pituitary gland (located at the base of the brain), the hypothalamus (immediately above the pituitary gland), and the pineal gland (near the center of the brain). The pituitary gland is controlled by the hypothalamus, to which it is connected by a thin stalk (the infundibulum). The pituitary gland consists of an anterior (front) lobe and a posterior

(back) lobe. The posterior lobe (composed of nervous tissue) stores and secretes hormones synthesized by the hypothalamus, specifically oxytocin and vasopressin (also called antidiuretic hormone). The anterior lobe (composed of glandular tissue) synthesizes and secretes many of its own endocrine hormones, one of which is growth hormone, which stimulates cells throughout the body to synthesize proteins and divide. Most of the anterior pituitary gland hormones control other endocrine glands, such as adrenocorticotrophic hormone (ACTH), which stimulates the adrenal gland to produce cortisol. The pineal gland secretes the hormone melatonin, which controls the sleep-wake cycle.

Some major endocrine glands in the body include the thyroid gland, the thymus gland, the pancreas, the adrenal glands, and the gonads. The thyroid gland is in the neck and secretes hormones that control how quickly cells use energy and make proteins. The thymus gland is located in front of the heart, and is the site where T cells (of the immune system) mature. T cells facilitate the body's adaption to specific pathogens. The pancreas is located near the stomach. Its endocrine hormones (insulin and glucagon) work together to control the level of glucose in the blood. The two adrenal glands (located above the kidneys) secrete several different endocrine hormones, including the hormone epinephrine (adrenaline), involved in the fight-or-flight response, and the "stress" hormone cortisol. The paired gonads include the ovaries in females and testes in males. The gonads secrete sex hormones (such as testosterone in males and estrogen in females), which control sexual maturation during puberty and the production of gametes (sperm or egg cells).

The human brain contains about 86 billion neurons and roughly 80% of these are found in a part of the brain called the cerebellum (Herculano-Houzel, 2009). Yet, case studies of individuals lacking a cerebellum indicate that for the most part, these individuals function relatively well, sometimes not even discovering their lack of a cerebellum until adulthood. There are other examples of functional and mostly 'normal' individuals missing large parts of their brains or even the connection fibers between the left and right sides of the brain (the corpus callosum). Although perhaps less than standard, the brains of these individuals can adapt and function despite a catastrophic loss of brain cells. Compensatory mechanisms often take over allowing other brain regions to perform tasks normally carried out by missing or damaged parts. This tells us something very important about the human brain. We may be tempted to compare it to a machine or a computer. However, our brains are almost nothing like the machines that we know and have created. Removing 80% of a car or a computer would hinder normal operation and make the machine unrecognizable.

The human brain, which is part of our nervous system, is astonishing and mysterious. Our quest to understand it has been an ongoing human endeavor for centuries. Despite tremendous progress, we are just scratching the surface in fully understanding this complex system. We have acquired basic knowledge of how some nervous system functions map onto specific locations/regions of the brain, but much remains to be learned. While there is good evidence of a strong association of brain function to brain structure, it is also clear from the examples above that for the most part our brains do not fit into a one-to-one ratio of region to function. Complex tasks such as learning, memory, reasoning, fear, compassion, love and hate and everything that makes us human are carried out by multiple brain regions connected through intricate and complex networks. And most importantly, these

complex networks in the human brain can reorganize to compensate when something goes wrong.

So, what exactly is a nervous system? It may be surprising to you, but this question still raises debates among neuroscientists and philosophers. The nervous system is in many ways an input-output device that processes and responds to internal and external information. Yet, it is so much more. It can anticipate, fine-tune, process and store information for days, weeks and lifetimes. Some scientists have proposed that we possess an internal model of the world and our reality. Thus, information flowing in and out of our nervous systems works to constantly adjust this model. Dr. David Eagleman, a renowned neuroscientist states “The brain's internal model deduces information and makes assumptions, allowing guesswork to take the place of constant assessment” (Eagleman, 2015).

We organize the nervous system into a central and peripheral division. Together they work to receive/send, process, and interpret/modify information to ultimately regulate all that we do: how we move, how we feel, what we say and how we think. From breathing to walking, running to learning, and reasoning, we are entirely defined by our nervous systems.

This chapter will focus on the human nervous system and aims to give you the big picture, an overview of its structure and function. In subsequent chapters you will zoom in on details. We will start with the building blocks of the nervous system (its cellular composition) and then go on to the organization of the nervous system and its two main divisions, the central nervous system (CNS) and the peripheral nervous system (PNS). This chapter will lay the foundation for your journey through neuroscience, providing you with basic knowledge about anatomy and function. In later chapters, you will have the opportunity to delve into more detail.

1.6.2: Building a Nervous System

Learning Objectives

By the end of this section, you should be able to

- 1.1.1 Describe the similarities and differences between neurons, glia, and all eukaryotic cells.
- 1.1.2 Name and describe the functional specializations of a neuron.
- 1.1.3 Describe the different types of glia and their function.

Across the animal kingdom, nervous systems are constructed using the same basic cell types: neurons and in most cases glia. Although neurons and glia come in different shapes and sizes, they share the fundamental features of all eukaryotic cells. In this section, we will explore how nervous system cells are both similar and different from other cells.

Brain cells are eukaryotic cells

The first cell is thought to have arisen on earth at least 3.8 billion years ago. Today we classify cellular life into three domains: Bacteria, Archaea and Eukarya. All cells on this planet contain a barrier to the outside world called a cell membrane and genetic material (DNA). However, unlike prokaryotic cells, which are members of the Bacteria and Archaea domains, eukaryotic cells belong to the Eukarya domain which has as its major cellular feature membrane-bound organelles. Membrane-bound organelles allow for functional compartmentalization and specialization. DNA is segregated in the nucleus where it is copied (via a process called replication) and/or converted into mRNA (messenger RNA). Once converted (transcribed) into mRNA, this material exits the nucleus. It is outside of the nucleus that the translation of mRNA to protein occurs in eukaryotic cells Figure 1.2.

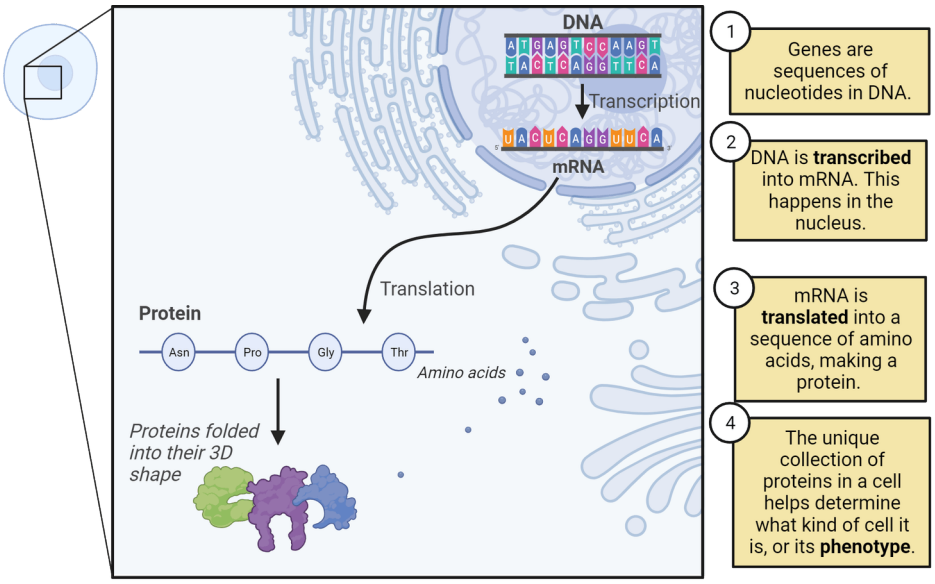

Figure 1.2 The Central Dogma

Brain cells, neurons and glia, also adhere to the characteristics specified above and are fundamentally just eukaryotic cells. However, neurons have additional features that make them uniquely specialized for communication, a feature which defines nervous systems. Before we get into the specifics of neurons and glia, let us establish a few fundamentals of eukaryotic cells.

Introduction to the central dogma: cell identity is determined by gene expression

The human body is thought to consist of trillions of cells. Because a single fertilized egg gives rise to all the cells in the adult body, every cell within an organism contains basically the same unique DNA genome. Yet, the human body is not made of identical cells. Depending on the organ system, cells differ in their shape, size, function, and modes of interaction. What makes a heart or liver cell different from a brain cell is not the DNA contained in its nucleus, which is identical in both. Rather, the difference is due to the selective process of transcription of DNA into RNA. Which parts of the DNA are read, and by extension which parts of the DNA are excluded, is the first step in making proteins. The chosen regions of DNA are transcribed into mRNA and translated into specific proteins.

One way to envision the genome is as a comprehensive cookbook containing all the written instructions of life and found in every cell. However, only certain recipes (DNA parts called genes) are chosen to ultimately be cooked (made into proteins) in different kitchens (different cells). Cell identity therefore arises from cell-specific gene choices. This is called gene regulation and is controlled by both intrinsic (within cells) and extrinsic factors (the environment that the cell matures in). For example, a neuron may require a specific channel protein that allows electrical communication while a pancreatic cell requires the expression of an insulin gene to regulate glucose levels in our body. Furthermore, different types of neurons found in different brain regions require different proteins to produce unique chemical messages known as neurotransmitters (e.g. dopamine versus acetylcholine). Proteins do all the work in our cells. This information flow of DNA to RNA to protein is called the central dogma. The central dogma is universal and is a feature of all living cells on our planet: DNA is transcribed into RNA which can be translated into proteins. The process of translation is facilitated by ribosomes which are large macromolecular complexes found floating inside cells or attached to organelles like the endoplasmic reticulum (see below).

Organelles: carry out functions of cells

Brain cells, like all eukaryotic cells contain a complement of organelles necessary for the proper cell function. This includes a nucleus (houses the DNA), endoplasmic reticulum, Golgi apparatus, lysosomes, mitochondria (singular is mitochondrion) and a few others (Figure 1.3). Cells store genetic material in their nucleus, transport materials across the cell membrane and within the cell, produce energy in the form of ATP, breakdown and build macromolecules, and communicate and interact with other cells. Organelles serve in these multiple functional roles. Of notable importance are the mitochondria, which facilitate most of the processes of cellular respiration that produce ATP. While the human brain only takes up about 2% of body mass, it uses about ~25% of daily energy production. Neurons can have up to 2 million mitochondria each and thus have the capability to produce a large amount of ATP. This high ATP demand is needed for the basic function of neurons and the communication between neurons (see Chapter 2 Neurophysiology).

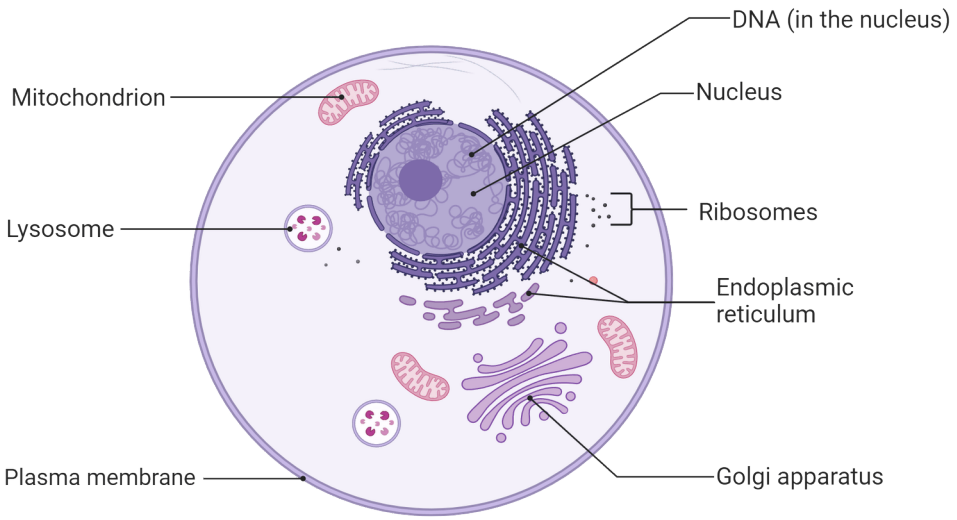

Figure 1.3 Typical eukaryotic cell

Neurons

The human brain is made up of ~86 billion neurons. Neurons are highly specialized for communication that occurs via electrical and chemical signals. With some exceptions, neurons have special structural features that branch from the cell body (soma), called axons and dendrites (Figure 1.4). Functionally, neurons receive and integrate signals, and send information in both electrical and chemical forms. Neurons communicate with their partners at regions called synapses.

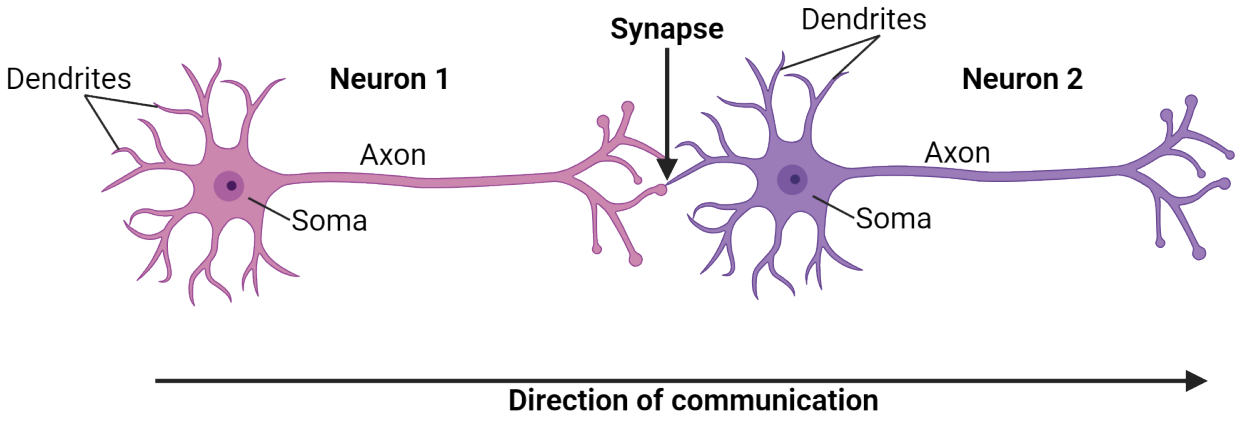

Figure 1.4 Basic neuronal structure

Neurons come in many shapes and sizes. When asked to describe a neuron, most students would draw a multipolar neuron containing one axon and several dendrites branching from the cell body (for example a motor neuron). This is the classic depiction found in the popular press and many biology texts. However, the nervous system contains other neuronal varieties, including bipolar neurons (two processes jetting off from the cell body; one dendrite and one axon; olfactory (smell) neuron being an example) and unipolar neurons (a single process from the cell body; dendrite and axon are continuous; often used for sending sensory information) (Figure 1.5). Neuronal shape and structure can inform function. For example, bipolar neurons are uniquely suited for providing a pathway between input and outputs in the visual system.

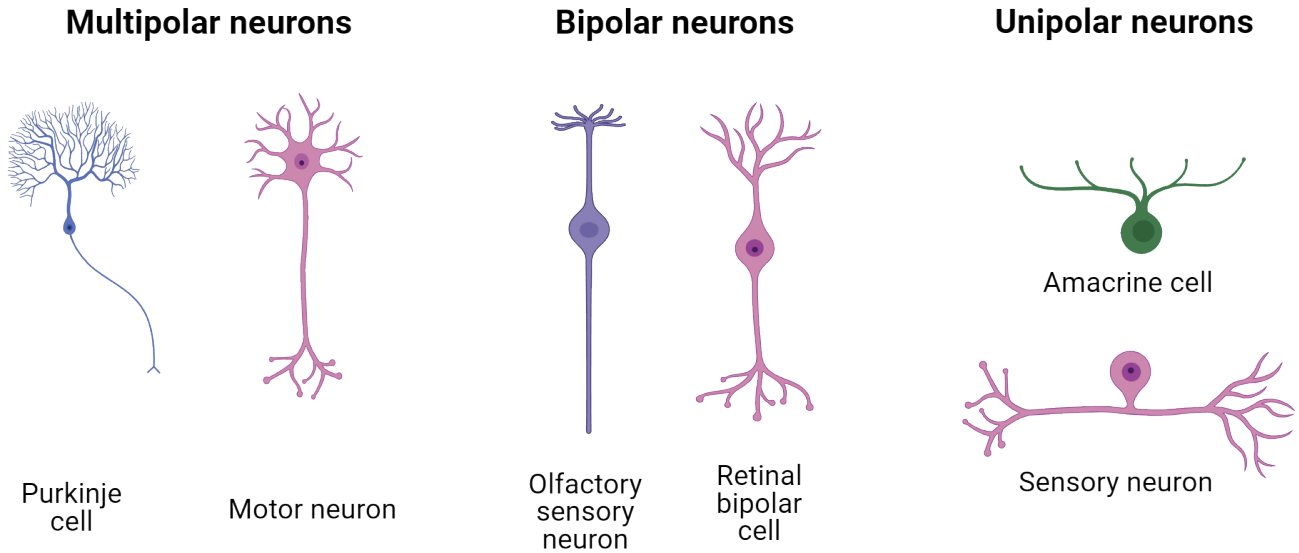

Figure 1.5 Neuron heterogeneity

Neuroscientists have used many lenses for classifying neurons, grouping them by size, shape, or the connections they make (e.g. whether those connections have predominantly inhibitory or excitatory effects). For example, afferent neurons (e.g., sensory neurons) carry messages towards the central nervous system (CNS). Efferent neurons (e.g., motor neurons) carry messages away from the CNS. Interneurons allow communication within the nervous system and are located between sensory and motor neurons.

Classification of neurons remains difficult, though, in part because they are so dynamic. Huge efforts are underway to catalog all the different types of neurons in the brain

Whatever their morphology or function, neurons have all the typical eukaryotic organelles, all of which are found in the cell body, called the soma (Figure 1.6). Below, we will discuss in more detail the unique cellular features of neurons, using a common multipolar neuron depiction to help visualize them.

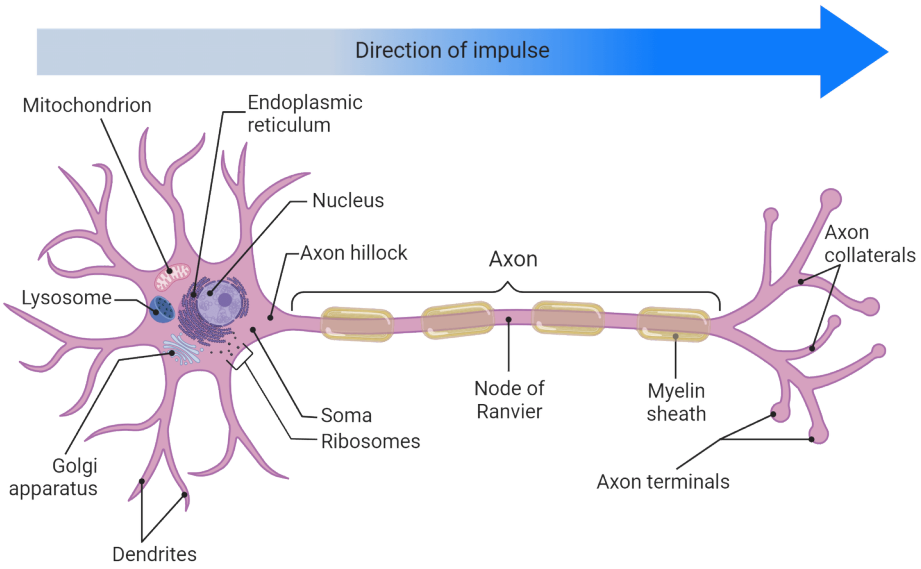

Figure 1.6 Parts of a neuron

Dendrites

Dendrites are branches/processes that extend from the cell bodies (or soma) of most neurons. The word dendrite comes from Greek and means tree. We often talk about neurons having tree-like branching, arborization (also a tree analogy). Functionally, dendrites are specialized for receiving information at a synapse and transferring that information toward the cell body. Dendritic branching can be extensive or can be more minimal depending on the type of neuron. In some animal nervous systems, dendrites are studded with bumps called dendritic spines, which provide specialized compartmentalization for synapses and, among other functions, seem to be important in learning and memory (Figure 1.7).

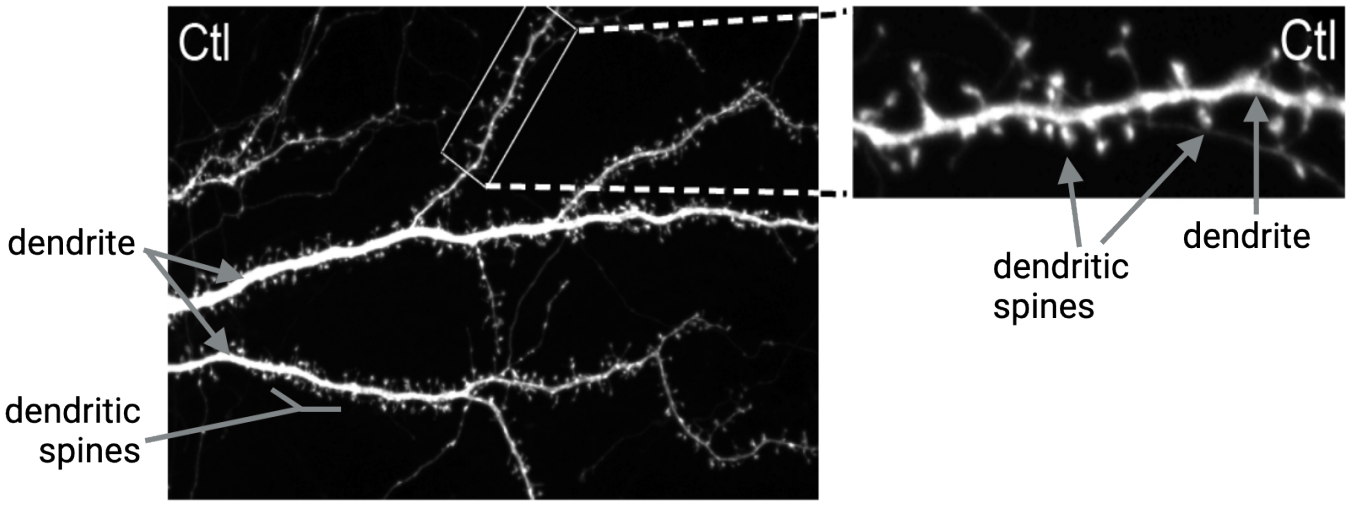

Figure 1.7 Dendritic spines Dendrites are covered in dendritic spines. Spines have many different shapes and sizes. They also change over time. Image credit: Platholi J, Herold KF, Hemmings HC Jr, Halpain S (2014) Isoflurane Reversibly Destabilizes Hippocampal Dendritic Spines by an Actin-Dependent Mechanism. PLoS ONE 9(7): e102978. https://doi.org/10.1371/journal.pone.0102978. CC BY 4.0.

Axons

A neuron can have thousands of dendrites, but only one axon. An axon is a branch that like dendrites, emerges from the soma or cell body of the neuron. At the point of connection with the soma, the axon region is called the axon hillock (Figure 1.6). Functionally, axons are specialized for sending information. Some cells, such as those in the retina, lack axons or have axons that are very hard to identify. An axon emerging from the soma can branch out at its terminal end to communicate with multiple cell partners. These branches are called axon collaterals and at the ends of these collaterals are axon terminals. Axons can vary in length depending on their location. For example, axons extending from the spinal cord to your toes are very long in comparison to axons found within the brain. Axons can be surrounded by a fatty substance called myelin, which helps insulate axons and allows more efficient/faster sending of signals over long distances in the body. Multiple sclerosis (MS) is an autoimmune disease where an individual's immune system attacks myelin, causing neuronal communication slow-down and disruption. This leads to severe motor problems in the affected individual.

Not all axons in our nervous system are myelinated, especially those that travel shorter distances. Interestingly, there are many types of animals including some vertebrates that do not have myelin at all. Other biological adaptations, such as larger diameters of axons, are used in these cases to create efficient communication.

The Synapse

The synapse is the place where one neuron communicates with its partner. Neurons do not touch other neurons/cells directly, but rather interact via the space between them called a synaptic cleft. Neurons can form synapses not only with neurons, but also glands (neuroglandular junctions) and muscles (neuromuscular junctions). (Figure 1.8).

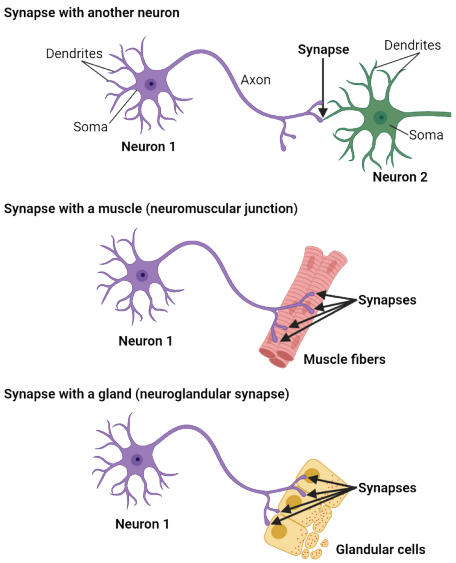

Figure 1.8 Types of synapses

In the case of neuronal synapses, axons can synapse with dendrites (axo-dendritic) (Figure 1.8), with other axons (axo-axonic) or with the soma (axo-somatic). The number of synapses that one neuron can participate in varies from tens to thousands. In chemical synapses, the presynaptic side of the synapse sends chemical signals (neurotransmitters) from one neuron to the postsynaptic side (membrane of the receiving cell). Most synapses are chemical synapses, but another type of synapse exists: the electrical synapse. It allows communication via channel proteins that physically connect adjacent cells and no neurotransmitter is utilized (see Chapter 2 Neurophysiology).

Glia

The name glia comes from the Greek word for ‘nerve glue’. Historically, these cells were first identified as connective cells that “glued” neurons together. However, over many years of research, glia have emerged as key players of the nervous system with a variety of sophisticated functions and not just nerve glue. Glia are non-neuronal cells in the nervous system that make up ~30-60% of the total brain mass. They are found in both the central and peripheral nervous systems. In many parts of the nervous system, they outnumber neurons. Glia are not thought to generate electrical signals, but function to support neuronal signaling (regulate the spread of signals in the brain). They can function to guide developing neurons to their proper destination. They can provide nutrients and other chemicals to the neurons that they surround. There is a rich and evolving literature around the interesting roles that glia play in the nervous system, but we will limit ourselves to a general overview. Below we will discuss the major types of glia: astrocytes, microglia, oligodendrocytes, and Schwann cells (Figure 1.9).

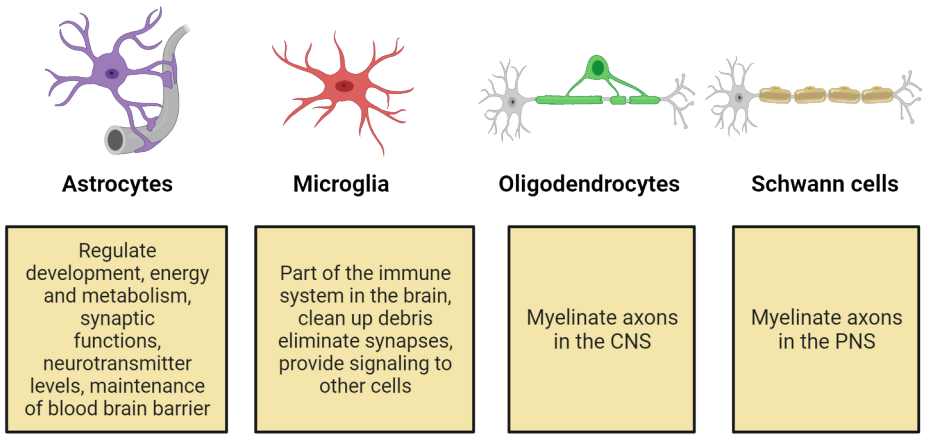

Figure 1.9 Types of glia and example functions

Astrocytes

Astrocytes have a characteristic star shape and represent the most abundant fraction of glial cell type in the adult human brain. Astrocytes have many functions, such as the maintenance of the blood-brain barrier. The blood-brain barrier (BBB) is a structure that filters chemicals and pathogens entering the brain. For example, the larger and less water soluble a molecule is, the less likely it is to cross this barrier (Figure 1.10). In addition, these glial cells provide neurons with metabolic and structural support and help modulate neuronal function in some cases. One very important role for astrocytes involves recycling neurotransmitters by reuptake back into neurons (Figure 1.10). Dysfunction of astrocytes has been associated with pathological conditions including epilepsy, brain tumors and neurodegenerative diseases like Alzheimer's disease.

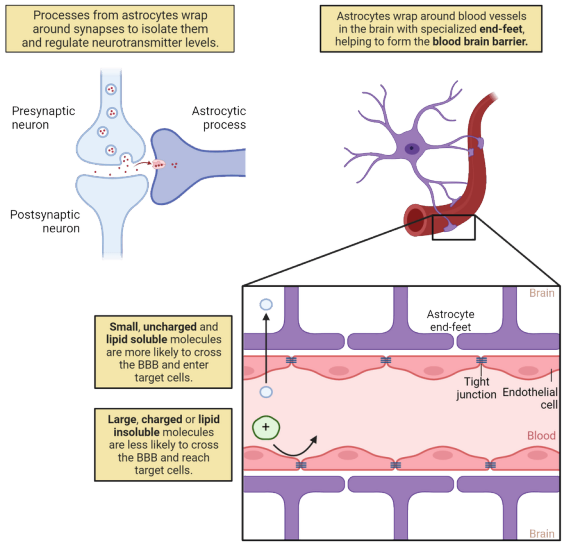

Figure 1.10 Astrocytic functions

Microglia

Microglia serve an immunological role in the nervous system and act like phagocytic cells. Phagocytes are cells that ingest foreign particles like bacteria, for example (see Chapter 17 Neuroimmunology). Microglia are named for being very small. They destroy invaders that get through the blood-brain barrier and then clear out damaged neurons and unused synapses and thus play an

important role in synaptic pruning and elimination of extra synapses during brain development. Improper synaptic pruning may be involved in neuropsychiatric disorders such as autism and schizophrenia.

Oligodendrocytes

Myelin is the insulating axon wrapping made up of lipid and protein, and oligodendrocytes are the myelinating cells of the central nervous system. Each oligodendrocyte provides myelin for several neurons. The axon of one neuron can be myelinated by multiple oligodendrocytes. As you will see in later chapters, myelin wrapped around axons is necessary for rapid communication in the nervous system (see Chapter 2 Neurophysiology).

Schwann Cells

Schwann cells are the main glial cells of the peripheral nervous system and serve similar functions to oligodendrocytes. Unlike oligodendrocytes, one Schwann cell provides myelin for the axon of a single neuron (see Figure 1.9).

History of Neuroscience: Visualizing Brain Cells: from Cajal to Brainbow

Throughout this section, we have discussed the cellular components of the nervous system and the unique specializations that allow neurons to communicate with each other. In the late 1880s, a debate brewed in the field of neuroscience. Without sophisticated tools and relying on simply observing the human brain, it was almost impossible to ascertain its components. Camillo Golgi, a prominent scientist of his time and the inventor of the Golgi stain (see below), championed a brain model where the building material of the brain was a single, dense, intricate, and continuous network akin to a material like gauze. This was called the reticular theory. On the other side of the debate was another Spanish scientist, Ramon y Cajal. Based on his findings, Cajal championed the Neuron Doctrine—the idea that the brain was composed of individual, unconnected cells. Ultimately, Cajal's theory proved to be correct. Our ability to visualize the brain has advanced and deepened our understanding of Neuroscience. Beginning with the Golgi stain, this section will outline some common approaches to visualizing brain cells (Figure 1.11).

Chemical Stains: Focus on the Golgi Stain

The driver of scientific progress is often fueled by technical discoveries (a new instrument, a new technique) that allow scientists

to visualize, analyze or probe. The Golgi stain (silver nitrate) was first discovered by Camillo Golgi as a way to visualize neurons in postmortem tissue. Its improvement and application to brain tissue by Ramon y Cajal in the late 1880s opened the door to our ability to see brain cells as individual entities for the first time. A unique feature of this technique is that, if applied to a forest of neurons, only a few random cells will become stained and stand out when visualized under a microscope. The reason for this selectivity is still unknown to this day. The neurons that do get stained become visible in a very complete way, allowing visualization of cell bodies/soma, dendrites, and axons (Figure 1.11).

Cajal's work revolutionized the field of neuroscience. For the first time, it was clear that neurons were separated from other individual cells and that they were morphologically distinct in different brain regions. He used Golgi's own methods to refute Golgi's belief that brain cells were a continuous cellular web. Through his careful work, Cajal gained many additional insights, including the fact that neurons were polarized (receiving information on their dendrites and cell bodies and sending information via axons). The Golgi stain continues to be a valuable tool for modern day neuroscientists. In addition to the Golgi stain, we have a number of chemical stains that can be used to visualize neural tissue, including but not limited to Nissl and H&E (Hematoxylin and Eosin) staining for cell bodies and nuclei and Luxol fast blue for myelin.

Immunofluorescence

All the chemical stains mentioned above allow scientists to visualize parts of a neuron such as a nucleus, cell body or processes. However, as we learned in the first section of this chapter, the types of genes expressed within a cell dictate its function. If a scientist is interested in determining the distribution of a specific protein (like an enzyme that produces a certain type of neurotransmitter) or the presence of myelin proteins, a more specific method of visualization is necessary. Immunofluorescence is a technique that uses antibodies (designed against a specific protein of interest) equipped with fluorescent tags (which come in many different colors) to localize and visualize a protein of interest using a fluorescent microscope (Figure 1.11) (see Methods: Immunohistochemistry). There are well established antibodies that can be used as neuronal cell markers that allow scientists to distinguish neurons from glia, visualize synaptic connections, measure protein expression levels in different neurons, etc. We have the technology to generate antibodies to almost any protein that we are interested in studying, giving scientists a large toolkit to answer basic questions in neuroscience.

GFP Labeling/Brainbow

Following its discovery in the 1960s, green fluorescent protein (GFP) has been used to label cells, organelles and specific proteins. Because we know the exact DNA sequence that codes for the green fluorescent protein and because all living cells on this planet use the same genetic code (see central dogma above), we can insert the GFP DNA directly or attach it to any sequence that we may want to express in a cell. Once that DNA is taken up and expressed, the cell will glow green wherever the protein is found in the cell. The GFP DNA can be introduced into cells grown in culture or brain slices using specialized delivery tools like viruses. The GFP DNA can also be genetically engineered into gametes (reproductive cell of an animal or plant) prior to fertilization, which leads to GFP transgenic mice allowing visualization of specific regions in the brain throughout the lifetime of an animal. Beyond just green, genetic manipulations of the GFP DNA have been developed to introduce the genetic machinery to randomly mix colors (such as green, cyan and yellow fluorescent proteins) in individual neurons thereby creating a palette of different color combinations and shades, allowing visualization of whole neuronal circuits. This process produces a Brainbow, where each individual neuron stands out due to a different shade of color (Figure 1.11).

Neuroscience in the Lab

Counting Neurons

As you read this textbook, perhaps you will be inspired to check on a number or an idea and wonder where exactly does the textbook knowledge come from. Dr. Suzana Herculano-Houzel is a scientist who did just that. When she began her scientific career in the 1990s, she kept finding the following fact: "the human brain has 100 billion neurons". She wondered where this number came from and when she could not find a definitive study to cite, she embarked on a journey that has defined her career. Dr. Herculano-Houzel devised a way to easily and quickly count cells in any brain by first liquifying the brain, taking a small amount of this liquid, staining the nuclei and counting these under a microscope. From these experiments she determined that the human brain has 86 billion neurons and not 100 billion like most textbooks stated.

Dr. Herculano-Houzel has since examined the brains of other primates, mammals and birds, and learned some remarkable things (see Chapter 4 Comparative Neuroscience) is central to many of the most interesting brain functions like memory, problem solving, reasoning and emotions. Perhaps the scaled-up number of neurons in this region of our brain contributes to all the incredible and unique features that make us human.

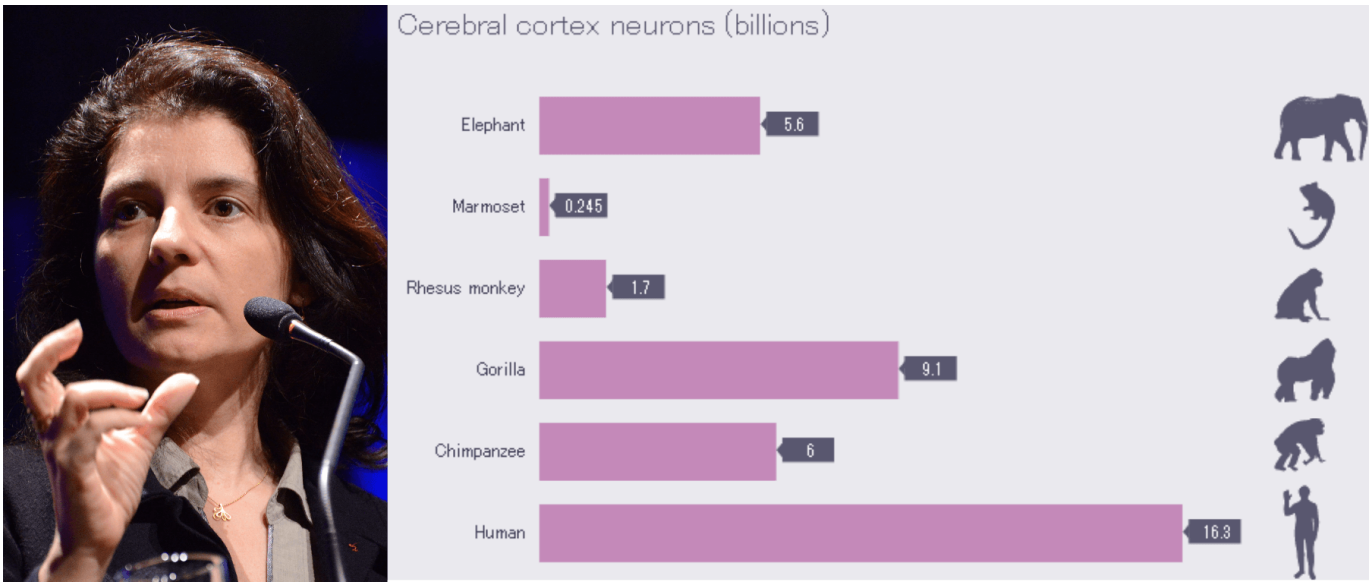

Figure 1.12 Neuron numbers across species Dr. Suzanne Hurculano-Houzel devised a way to count the total number of neurons in the cortex across species. 1.6.3: Organization of the Nervous System

Learning Objectives

By the end of this section, you should be able to

- 1.2.1 Compare the general designs of animal nervous systems.
- 1.2.2 Describe the divisions of the human nervous system and its basic anatomical organization.
- 1.2.3 Describe the basic organization of a simple neural circuit.

The ways in which nervous systems across the animal kingdom are organized are both different and extremely similar. The section below will highlight some of the differences between vertebrates and invertebrates, and then shift to a more detailed discussion of vertebrate organization. All vertebrate (mammals, birds, reptiles, amphibians and fish) brains have the same basic number of brain divisions. This section will focus on understanding this basic organizational theme, with a focus on the human nervous system.

Neuroscience across species: neural nets, ganglia and centralized brains

All multicellular organisms with the exception of sponges have neurons and nervous systems, albeit varying in structure and complexity. Large differences are observed between animals with or without a backbone (vertebrates vs. invertebrates). Two general principles in nervous system organization across the animal kingdom include: neural nets and ganglia (Figure 1.13).

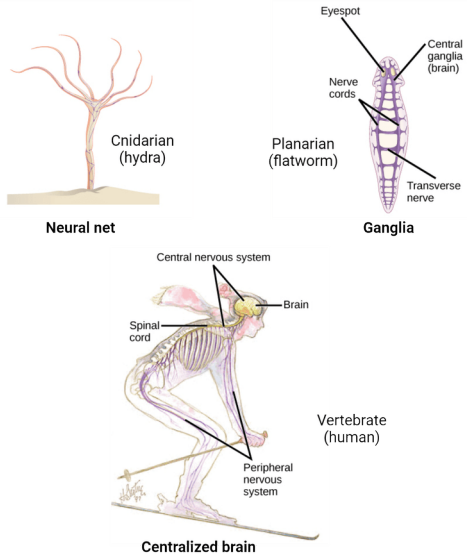

Figure 1.13 Diversity of the nervous system organization Image credit: OpenStax Biology 2e, 35.1: Neurons and glial cells; credit Human, modification of work by NIH.

Cnidaria (includes hydra, corals, jellyfish, and anemones) have neural nets. These are the simplest—and, considered evolutionarily, the oldest—form of nervous system organization. We can describe them as mesh-like systems of separate, yet interconnected neurons (not clustered into nerves or centralized). Nerve nets can be diffuse or can be connected to each other via long nerve cords, as in the case of flatworms. Nerves are defined as bundles of fibers (axons) that transmit information.

Nerve cords can be arranged in a ladder-like conformation and connected to ganglia. Ganglia are structures that contain collections of neuronal cell bodies and are found in animals more complex than Cnidaria, such as flatworms. Many invertebrates actually have more than one ganglia, each with specific functions, such as control of different muscles or, in the case of earthworms, different body segments. Often there is a cerebral ganglion which serves a more coordinative role. In contrast, vertebrates have a spinal cord encased in vertebral bones. The spinal cord runs along their back and most of the nervous system

that is important for complex behavior is centralized and concentrated in a brain located in the head.

Animal symmetry

Humans and many other animals, including other vertebrates and some invertebrates, have bilateral body plans meaning that the left and right sides of the body are mirror images of each other. Other animals like jellyfish and sea stars are arranged centrally around a gastrointestinal core. This is called radial symmetry. While bilateral organisms often have one nerve cord and centralized ganglia or a brain that controls both sides of the body, radially symmetrical organisms lack a central brain and have radial nerves (sea star) or nerve nets (hydra) (Figure 1.13 and Figure 1.14).

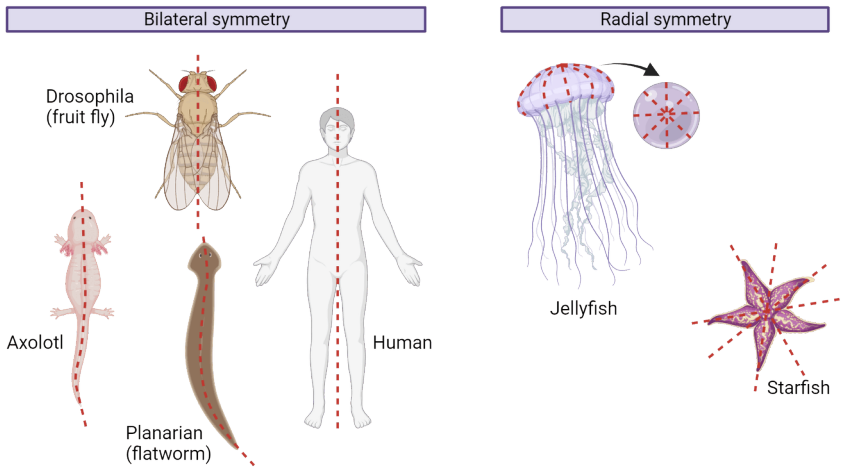

Figure 1.14 Bilateral vs radial symmetry

Centralization and cephalization

Nervous systems of animals with bilateral symmetry exhibit centralization and cephalization. Centralization refers to a nervous system organization where neurons are consolidated into specific areas of integration rather than just being randomly arranged throughout the body. Cephalization refers to the concentration of the nervous system at the anterior part of the body or the head. Flatworms, considered one of the simplest organisms with bilateral symmetry, exhibit both centralization and cephalization, having ganglia at the anterior end of their body (Figure 1.13). All vertebrate nervous systems contain a central nervous system (CNS) (brain and spinal cord) and a peripheral nervous system (PNS) (peripheral motor and sensory nerves).

The basic organization and structure of the vertebrate nervous system

The human nervous system shares the same basic plan found in all vertebrates and we humans are not unique in our brain organization. The human brain is a vertebrate brain and basically a large primate brain. Our nervous system can be divided according to anatomical structures and/or functional regions. This section will introduce the CNS and PNS and highlight some important features of the two systems (Figure 1.15).

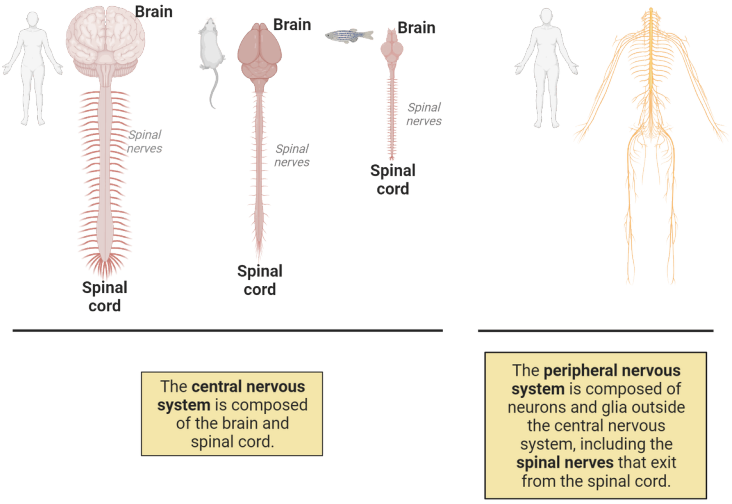

Figure 1.15 Vertebrate nervous system organization

CNS and PNS

The human nervous system, like other vertebrate nervous systems, is organized into the central nervous system (CNS), which is composed of the brain and spinal cord, and peripheral nervous system (PNS), which includes all nerves and ganglia outside of the spinal cord and brain. Groups of neurons are segregated into nuclei in the CNS and ganglia in the PNS. Axon bundles are called nerves in the PNS and tracts in the CNS (Figure 1.16). Ascending tracts take information to the brain and descending tracts away from the brain. Vertebrate nervous systems are highly centralized with higher neural functions like memory, learning, perception and movement carried out within the brain. The spinal cord sends sensory information to the brain and conveys motor commands from the brain to the entire body. In addition, there are circuits found in the spinal cord that perform local processing and allow for simple behaviors such as reflexes to occur without the direct involvement of the brain. The spinal cord also contains central pattern generator circuitry that allows for rhythmic behavior such as walking (see Chapter 10 Motor Control). The PNS is responsible for carrying messages between the CNS and all body parts, including muscles, organs, and the body periphery in general. A more detailed discussion of the CNS and PNS can be found below.

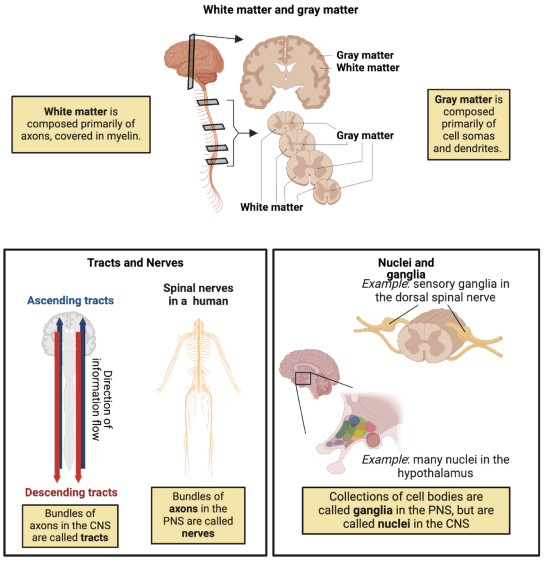

Figure 1.16 Nervous system basics

Gray and white matter

The nervous system is made up of gray and white matter (Figure 1.16). This terminology refers to gross histological distinctions. Gray matter, named for its pinkish-gray color, has a high concentration of neuronal cell bodies, dendrites and axons that are not myelinated. White matter is composed of axon fibers covered in myelin, giving it its whitish color. Gray matter is found in the outermost layer of the brain and centrally within the spinal cord. White matter is in the deeper tissues of the brain and surrounds the gray matter in the spinal cord.

Meninges

The CNS is covered in bone. A skull encases the brain while the spinal cord is housed in a collection of 33 small bones called vertebrae. Between the bones and the nervous tissue of the CNS, there are layers of cushiony tissue called the meninges. The three layers of the meninges are dura mater, arachnoid mater and pia mater. The dura mater layer is found directly against the skull and vertebrae, and is the thickest layer of the three meninges (Figure 1.17).

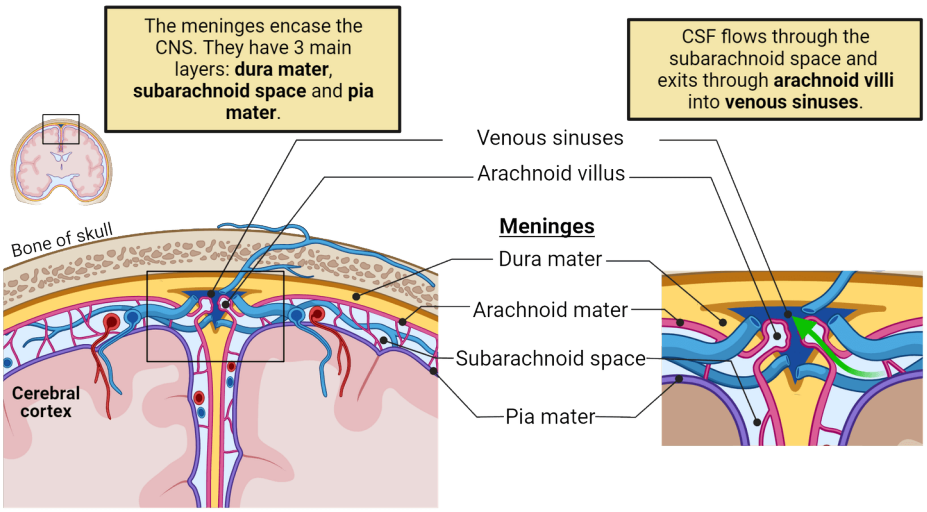

Figure 1.17 The meninges

Ventricles

Ventricles are interconnected cavities or open spaces located in the brain and spinal cord that contain cerebrospinal fluid (CSF). They serve two main functions: 1) to cushion the brain and 2) to allow exchange of materials between the brain and blood vessels. CSF is produced by the choroid plexus, a tissue rich in blood vessels found in the lining of the ventricles. It is a clear liquid, essentially filtered blood. Spinal taps are medical procedures to remove a small amount of CSF to test for medical conditions or infections in the brain. The ventricular system is composed of 4 ventricles and an aqueduct (Figure 1.18). Think of the ventricles as being similar to the great lakes: independent bodies of water but connected by rivers (aqueduct). The 2 large lateral ventricles in each cerebral hemisphere (left and right) connect to a third ventricle (in the diencephalon) which opens into the cerebral aqueduct (in the midbrain) and a fourth ventricle (in the hindbrain). The fourth ventricle extends to the central canal which is filled with CSF and runs across the spinal cord. CSF fills the ventricular system and circulates over the brain and spinal cord. It flows through the subarachnoid space and exits through the arachnoid villi into venous sinuses, a group of blood channels found throughout the brain. Eventually CSF is reabsorbed into the circulatory system. CSF is also found surrounding the brain below the arachnoid membrane called the subarachnoid space (Figure 1.18).

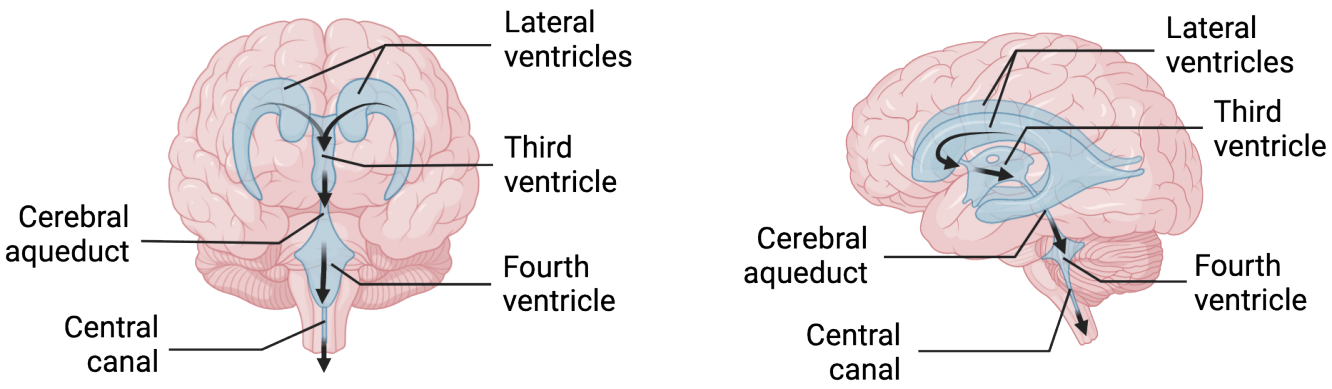

Figure 1.18 The cerebrospinal fluid (CSF)

Vascular system of the brain

The human brain requires a disproportionate amount of energy in the form of ATP to function properly. ATP production requires oxygen, which is supplied by a constantly circulating blood supply. As a result, the brain has a complex system of blood vessels. Three main arteries (anterior, middle and posterior cerebral) are the main suppliers of blood to the cerebral hemispheres. The anterior and middle arteries arise from the carotid arteries on the left and right sides of the neck. The vertebral arteries run through the spinal column in the neck to provide blood to the brain and spinal cord, and give rise to the basilar artery. There are many vessels and capillaries that branch off from the main arteries delivering nutrients and removing waste (Figure 1.19). The endothelial cells that form the walls of brain capillaries are extremely well connected to each other and form the blood-brain barrier (BBB), which we discussed in the previous section. This serves as a layer of protection not found in other organs that prevents the flow of some substances like toxins or drugs and also protects against infections.

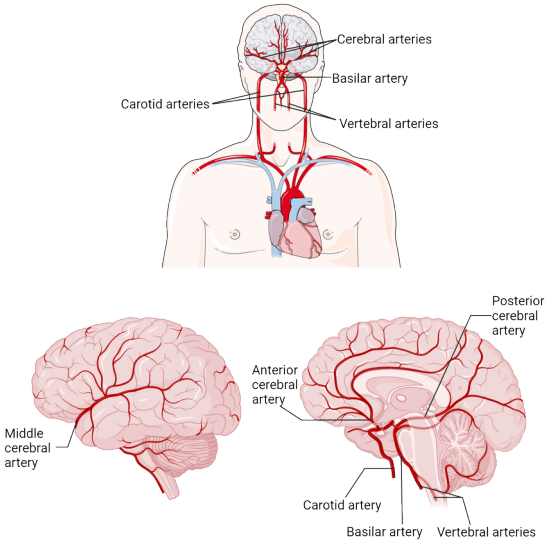

Figure 1.19 Brain vasculature Image credit: Torso has labels added, original by Laboratoires Servier - Smart Servier website: Cardiovascular system, CC BY-SA 3.0, https://commons.wikimedia.org/w/inde...urid=127936249

Neural circuits

Neurons do not function independently. Rather, neurons are organized into simple or complex functional arrangements called neural circuits. A neural circuit represents a group of neurons connected by synapses that process specific types of information. Circuits range from very simple to exceptionally complex. One of the big challenges in modern neuroscience is to understand the complex ways in which circuits are built and function. Large scientific efforts are focusing on the enormous task of building detailed maps of brain circuitry. In this section, we will explore the basic building blocks and functionality of a simple circuit and

introduce you to the research focused on more complex circuitry.

Basic building blocks of neural circuits

While neural circuits vary in function, anatomic arrangements and complexity, we can establish some basic principles. As introduced in 1.1 Building a Nervous System, afferent (sensory) neurons carry information about the inside of the body and external environment to the brain or spinal cord while efferent (motor) neurons carry information from other neurons away from the brain/spinal cord or specific circuit. Interneurons serve as a bridge between other neurons and are found in the CNS. They are local circuit neurons that make intra-circuit connections and can act as regulators or adjustors to the circuit (Figure 1.20).

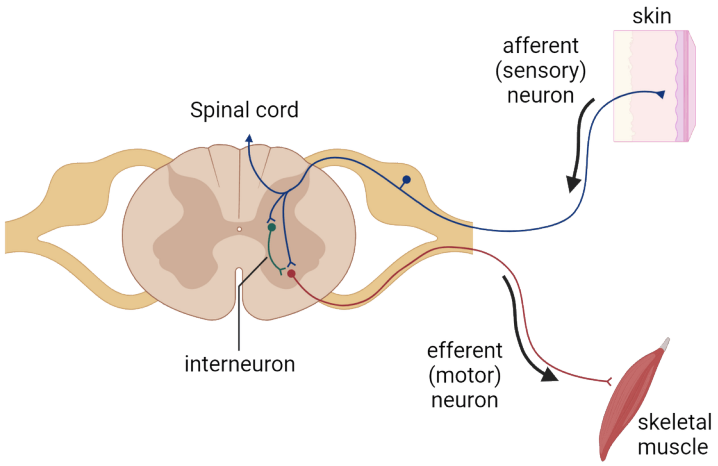

Figure 1.20 Afferent, efferent and interneurons

Simple human circuit example

A reflex arc is a simple neuronal circuit that controls a reflex beginning with a sensory neuron at a receptor (for example, pain receptors on a finger) and ending with a motor neuron at an effector (like a muscle). Reflex arcs are important for the generation of fast reactions to external stimuli such as accidentally placing your finger into an open flame or on a hot surface. Reflex actions are essential to the survival of organisms. To prevent bodily damage, a movement or response that is almost instantaneous and involuntary is required.

In a reflex arc, the sensory neurons do not pass information directly to the brain but rather information travels to the spinal cord, which, in turn, causes direct activation of spinal motor neurons. These neurons can then activate muscles that allow your hand to move away from the hot surface. Of course, information about such an event must eventually get to the brain to allow learning and future avoidance. Another example of a simple human circuit is the knee-jerk reflex (Figure 1.21), which allows for involuntary movement of the leg in response to a sharp tap to the tendon below the knee cap. The knee-jerk reflex is an example of a reflex pathway that is both excitatory and inhibitory (once the extensor muscle on the thigh contracts, the flexor muscle on the back of the thigh must relax). Stimulation of stretch receptors via the tap leads to afferent sensory neuron(s) activation, which in turn synapses either onto interneurons or directly onto efferent motor neurons that cause contraction of the extensor muscles. The interneuron serves to inhibit the motor neurons that connect to flexor muscles which keeps the flexor muscle relaxed. This combined action leads to leg extension (Figure 1.21). This reflex prevents knee collapse in the event of a sudden leg bend.

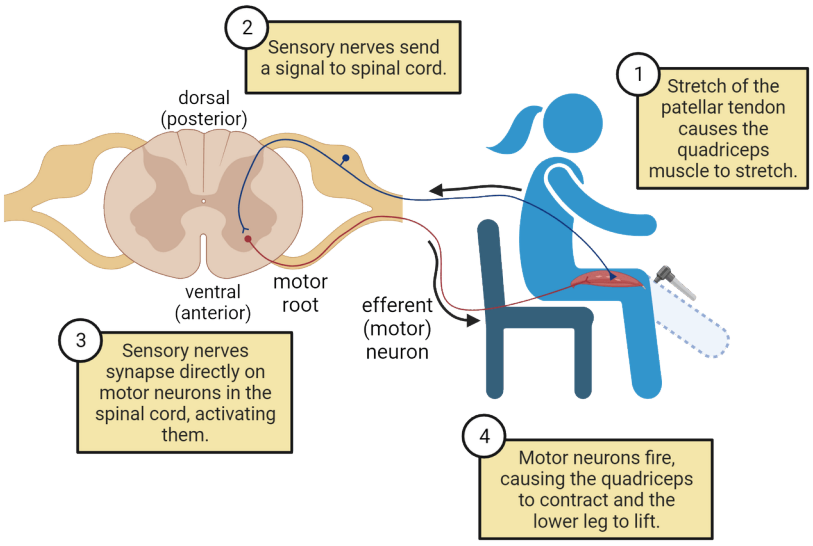

Figure 1.21 Simple circuit example

Mapping complex brain circuits

A major goal in neuroscience is the mapping of complex neural circuits in the human brain. Because the human brain is exceptionally complex with its 86 billion neurons, each communicating with hundreds or even thousands of other neurons, this is an extremely difficult endeavor. Scientists hope to one day complete the task of mapping the human brain connectome (a comprehensive map of neuronal connections in the brain akin to a wiring diagram). In the meantime, neuroscientists have been using simple animals like worms and flies to develop wiring maps that can provide clues to how brains work in general. Presently, two comprehensive wiring diagrams have been published: the roundworm (*C. elegans*) nervous system which has a very small number of neurons (302 neurons and 7000 connections) and most recently the entire brain of a fruit fly larva (*D. melanogaster*), made up of 3016 neurons and 548,000 connections.

There are several large, international, ongoing human mapping projects. These include the Human Connectome Project started in 2009 whose aim was to build a healthy human brain connectome and develop connectomes related to human disease. Building onto the Human Connectome Project, the BRAIN Initiative was started in 2013 with the aim of producing a dynamic picture of the brain which would map individual brain cells and the circuits that they take part in both time and space. The goal with such large projects and initiatives is to provide a deeper understanding of brain function and as a result develop new treatments for brain disorders. In 2021, the BRAIN initiative unveiled a detailed atlas of a small brain region, the mammalian primary motor cortex, derived from studies in mice, monkeys and humans.

1.6.4: The Central Nervous System- CNS

Learning Objectives

By the end of this section, you should be able to

- 1.3.1 Correctly identify nervous system anatomical and directional orientation.
- 1.3.2 Summarize the general steps and structures in the development of the human nervous system.
- 1.3.3 Explain the basic organization of the spinal cord.

The central nervous system (CNS) is made up of the brain and spinal cord. Unlike the PNS, the CNS is encased in bone (skull and vertebral column). In addition to the brain and spinal cord, the retina (the neural tissue of the eye) is also considered to be an extension of the CNS. This section will introduce the CNS with a focus on development. You will find a detailed discussion of the brain including anatomy and function in its own section, 1.4 The Brain: Structure and Function. This section will begin by introducing some basic terminology that will be useful to you throughout this text.

Anatomical orientation and planes of orientation

Specific terminology is applied to describing anatomical structures and orientation in the nervous system. Dorsal is an anatomical direction that refers to both the back of the spinal cord and to the top of the brain. The opposite of dorsal is ventral which means toward the bottom of the brain or the front of the spinal cord. Superior and inferior refer to above or below another structure. The bend in the human neuraxis causes a dissociation between the dorsal/ventral and superior/inferior directions. Anterior means toward the face and head, and posterior means toward the back or toward the feet. Rostral is toward the brain and or the top of the spinal cord while the opposite, caudal, is towards the back of the brain. Medial means toward the middle or center while lateral means left or right of another structure (toward the outside) (Figure 1.22). Ipsilateral means the same side and contralateral means the opposite side. For example, the right motor cortex controls the left side of the body and the left motor cortex controls the right side of the body (contralateral).

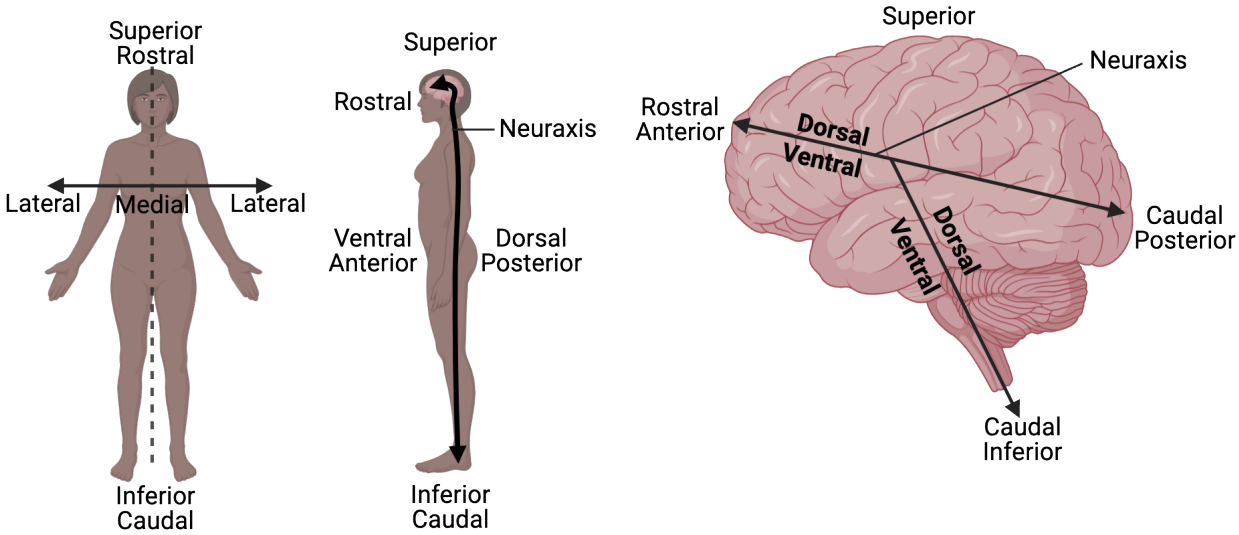

Figure 1.22 Anatomical orientation

There are three planes for sectioning the brain for anatomical analysis: coronal sectioning (cutting the brain front to back); sagittal sectioning (cutting the brain left to right) and horizontal or axial sectioning (cutting the brain top to bottom) (Figure 1.23).

Developmental perspective: vertebrate nervous system development

Neurodevelopment is a complex and multi-step process that requires a tremendous amount of coordination. Turning on the right genes at the right time is crucial and any missed steps or abnormal development can have catastrophic consequences. The embryonic development of the vertebrate nervous system begins with the outer tissue of the embryo called the ectoderm. At about 3 weeks in development, the ectoderm begins to thicken and form a flat structure called the neural plate. During the 3rd and 4th week of development, the neural plate begins to invaginate into a groove that eventually closes to form a neural tube. In the initial stages of formation, the neural tube is made up of one layer of cells (epithelial), which serve as the progenitors (embryonic neural stem cells) of glia and neurons. The neural tube elongates to form the spinal cord while the anterior region enlarges and expands to form the brain. Three swellings or bulges eventually become apparent, which become the prosencephalon (forebrain), mesencephalon (midbrain) and rhombencephalon (hindbrain). As development progresses, the prosencephalon subdivides into the telencephalon and the diencephalon. The mesencephalon does not further subdivide. The rhombencephalon becomes the myelencephalon and the metencephalon. The spinal cord forms from the end of the neural tube next to the myelencephalon. By 11 weeks of deveopment, the shape of the human brain is similar to a brain at birth. In the sections that follow, we will discuss the adult structures that derive from the five embryonic regions above (Figure 1.24). More details on development can be found later in this text (see Chapter 5 Neurodevelopment).

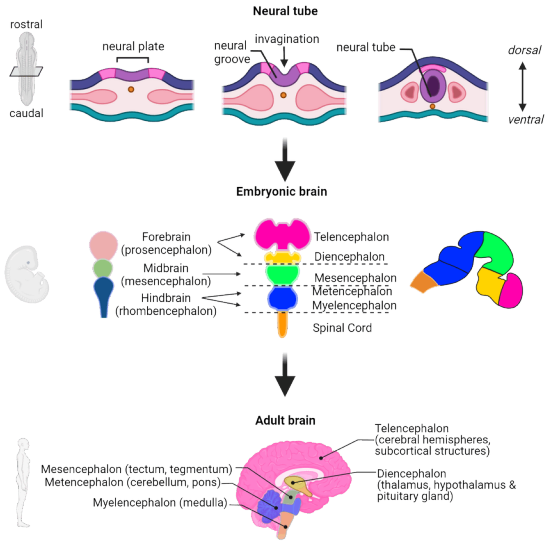

Figure 1.24 Development of human nervous system

Telencephalon and diencephalon

The telencephalon becomes the cerebral hemispheres, which makes up the largest part of the brain (~85% of the total brain mass). The cerebral hemispheres include the cerebral cortex, the outermost layer of the cerebrum. The word cortex comes from Latin for 'bark' and represents an extremely thin layer that if flattened is the size of a regular pillowcase. Below the cortex are deeper, subcortical structures that include the hippocampus, amygdala, and basal ganglia. The lateral ventricles arise from the telencephalon. The posterior part of the forebrain is the diencephalon. This eventually becomes the thalamus, hypothalamus, and posterior pituitary gland. Additionally, the diencephalic cavity becomes the third ventricle (see 1.2 Organization of the Nervous System for ventricles).

Mesencephalon, metencephalon and myelencephalon

The mesencephalon (midbrain) forms into the tectum and tegmentum. These eventually form the roof and floor of the cerebral aqueduct which arises from the mesencephalic cavity. Behind the mesencephalon are the hindbrain divisions: 1) metencephalon, which becomes the cerebellum and the pons, and 2) myelencephalon, which becomes the medulla. The mesencephalon and myelencephalon develop from the rhombencephalon whose cavity becomes the fourth ventricle (see 1.2 Organization of the Nervous System).

Spinal cord

The spinal cord forms from the neural tube and retains this tube-like shape once fully developed. It extends from the medulla oblongata in the brainstem down the body as a solid structure that ends in the middle of the lower back and continues as a spray of fibers called cauda equina. The cauda equina is part of the PNS rather than the CNS and it sends and receives information to and from the pelvic organs and lower limbs.

The spinal cord is enclosed by three membrane layers (the meninges) and is encased in the vertebral column made up of bony vertebrae separated by intervertebral discs. Each of these vertebrae has an opening that allows 31 spinal nerves to pass on each side. The spinal cord is divided into 5 major regions: cervical, thoracic, lumbar, sacral and coccyx. Each spinal nerve is named based on which of the 4 major regions of the spinal cord it is connected to. The area of the skin innervated by the spinal nerve is the nerve's dermatome. These are named according to the 5 major regions above (for example T1-T12 is thoracic) (Figure 1.25). The central canal (which is continuous with the 4th ventricle, see 1.2 Organization of the Nervous System) runs through the spinal cord and is filled with cerebrospinal fluid. It provides cushioning and a transportation system to the spinal cord.

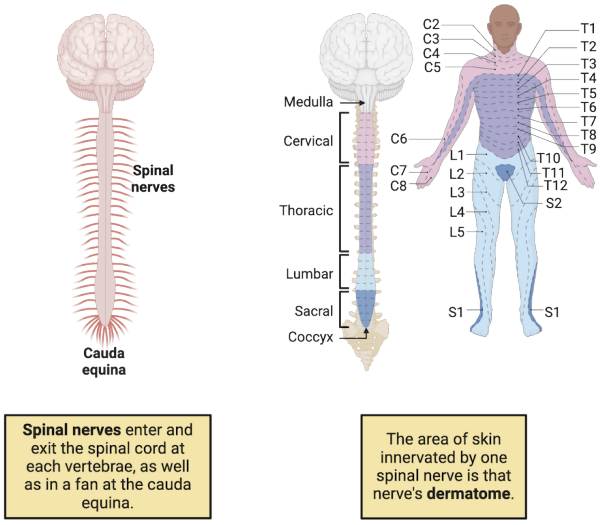

Figure 1.25 Spinal nerve organization

Gray and white matter in the spinal cord

When looking at a cross section of the spinal cord, the center contains gray matter while the white matter is found towards the outside. The gray matter contains glia, interneurons, and motor neuron cell bodies, and it is butterfly-shaped. In keeping with this analogy, the wing areas are called horns. Dorsal and ventral horns are found on each side of the cord (Figure 1.26).

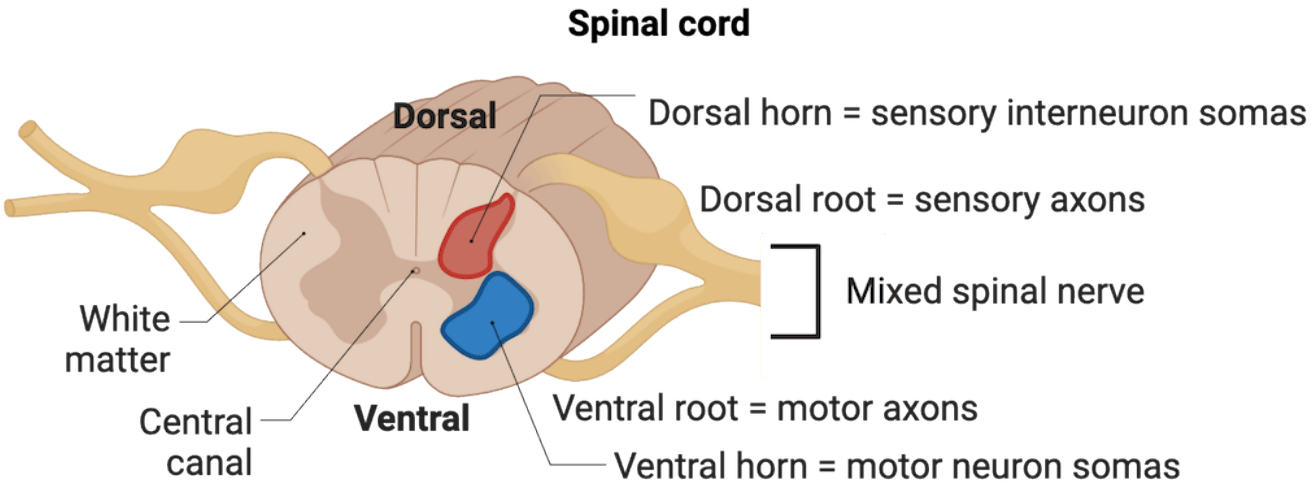

Figure 1.26 Spinal cord organization

The white matter consists of myelinated nerve tracts (axons) that travel up and down the spinal cord (Figure 1.27). Along the spinal cord, the 31 pairs of spinal nerves emerge at regular intervals laterally serving each side of the body (Figure 1.25). There are two distinct nerve bundles, roots that branch off. The dorsal roots contain sensory neurons that project from the body to the spinal cord whose cell bodies are organized in a ganglion called the dorsal root ganglion which is adjacent to the spinal cord. The ventral roots house motor neurons that leave the spinal cord and project to muscles (motor) (Figure 1.26).

Ascending and descending pathways

Information that travels to the brain is divided along compartmentalized pathways via tracts. Ascending and descending tracts

make up the white matter. Sensory information travels via ascending pathways from sensory receptors to processing centers in the brain. These sensory tracts carry specific information, for example pain and temperature or pressure and crude touch or fine touch, vibration, and proprioception. The sensory tracts are made of 1st, 2nd and 3rd order neurons connected to each other. The 1st order neurons receive the sensory information at the periphery. These pass information to the 2nd order neurons in the spinal cord. Eventually 3rd order neurons pick up information from the 2nd order neurons in the thalamus and carry it to the cortex (see 1.4 The Brain: Structure and Function). Motor information moves via descending pathways that carry commands from specialized CNS centers to skeletal muscles. Upper motor neurons originate in the cerebral cortex and travel down to the spinal cord, while the lower motor neurons begin in the spinal cord and send information to the periphery. Motor tracts can be specialized in regulation of voluntary movement or balance and posture (Figure 1.27).

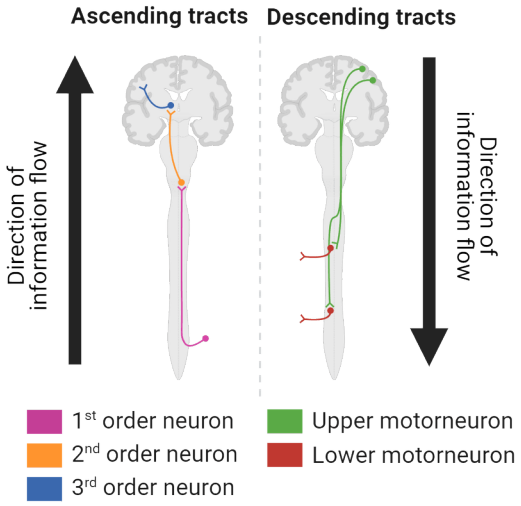

Figure 1.27 Sensory and motor tracts

1.6.5: The Brain- Structure and Function

Learning Objectives

By the end of this section, you should be able to

- 1.4.1 Connect the embryological divisions of the brain to their adult derivatives.
- 1.4.2 Describe and explain the basic structure and function of the cerebrum, limbic system, basal ganglia, the diencephalon, brainstem and cerebellum.

As described earlier, during the development of the central nervous system at about 50 days post conception, 5 major embryonic divisions can be observed: the telencephalon and diencephalon (forebrain); mesencephalon (midbrain); metencephalon and myelencephalon (hindbrain). The section below will describe the adult brain in its general structure and function organized from the 5 embryonic origins (Figure 1.28 , also see Figure 1.24).

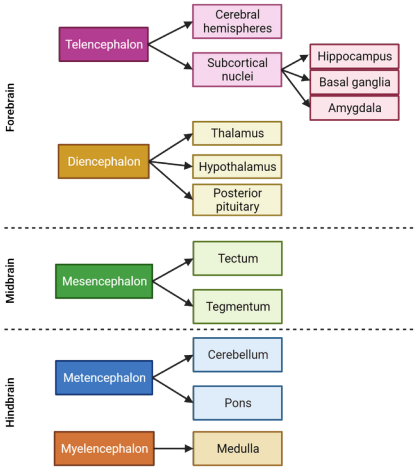

Figure 1.28 Overview of brain regions

As you read through this section, you will encounter descriptions of specific brain regions being responsible for specific functions. For example, every student who has taken introductory psychology or biology may tell you that the amygdala is responsible for emotional memory and the cerebellum for movement coordination. Assigning behavior to specific structure(s) is only a small picture of how behavior emerges from neural function. We must be cautious about assuming that specific structures are responsible for certain functions only. The brain has great potential for flexibility and parts of the brain can switch functions. For example, individuals blinded early in life may exhibit enhancement of other senses like hearing and touch. In these individuals, the visual cortex, which is normally responsible for vision, switches function and now responds to touch. As you continue your studies in neuroscience, you will begin to understand more nuance and complexity in correlating brain structure and function. For now, this section will introduce some canonical and sweeping generalities about brain function.

Cerebrum and cerebral cortex

The telencephalon becomes the cerebrum, the largest part of the brain, divided into two halves, or hemispheres, and makes up about three fourths of the total brain volume (Figure 1.24 and Figure 1.29). In the human nervous system, the left hemisphere controls the right half of the body, and the right hemisphere controls the left side of the body. The right and left cerebral hemispheres are connected by a thick fiber bundle (collection of axons) called the corpus callosum. This allows information to pass from one side to the other side of the brain. The cerebrum includes the cerebral cortex and cerebral nuclei (clusters of neurons). In many animals, the cortex is smooth. However, in larger brains like ours, the cortex is wrinkled and thin (on average

about 2.5 mm). It is folded, to create an increased surface area, thus maximizing the amount of cortex in the brain. This folding leads to the formation of ridges or bumps called gyri (gyrus is the singular) and grooves called sulci (singular is sulcus). The deeper grooves of the brain are called fissures (Figure 1.29). The two hemispheres are divided by the longitudinal fissure. The two lateral ventricles (see 1.4 The Brain: Structure and Function) are located in the cerebrum.

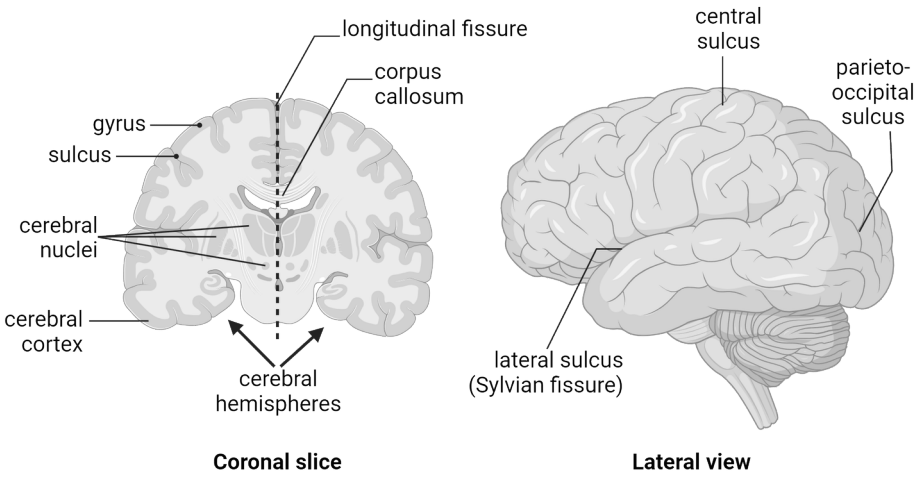

Figure 1.29 Basic cortical features

The cerebral cortex is packed with neurons, about 16 billion of the total 86 billion neurons in the human brain, and is composed mostly of gray matter. In humans, the cerebral cortex houses most higher brain functions and complex cognition. This includes reasoning, language, consciousness, perception, emotion, personality, decision-making, and memory. Neurons in the cortex are typically arranged in six layers. Each layer contains unique neuron types and architecture. The cortex is divided into specific functional areas: sensory, association and motor areas. The sensory areas receive sensory information from touch, sight, hearing, smell and taste. The association areas help integrate sensory information to give meaning to the incoming information. Finally, the motor areas initiate and regulate voluntary movement.

Lobes of the cerebral cortex

Different areas in the cerebral cortex are associated with specific functions. Each hemisphere's cerebral cortex is divided into four lobes: frontal, temporal, parietal, and occipital (Figure 1.30). Each of these four lobes is involved in a number of functions. This section highlights the major functions but is not necessarily comprehensive.

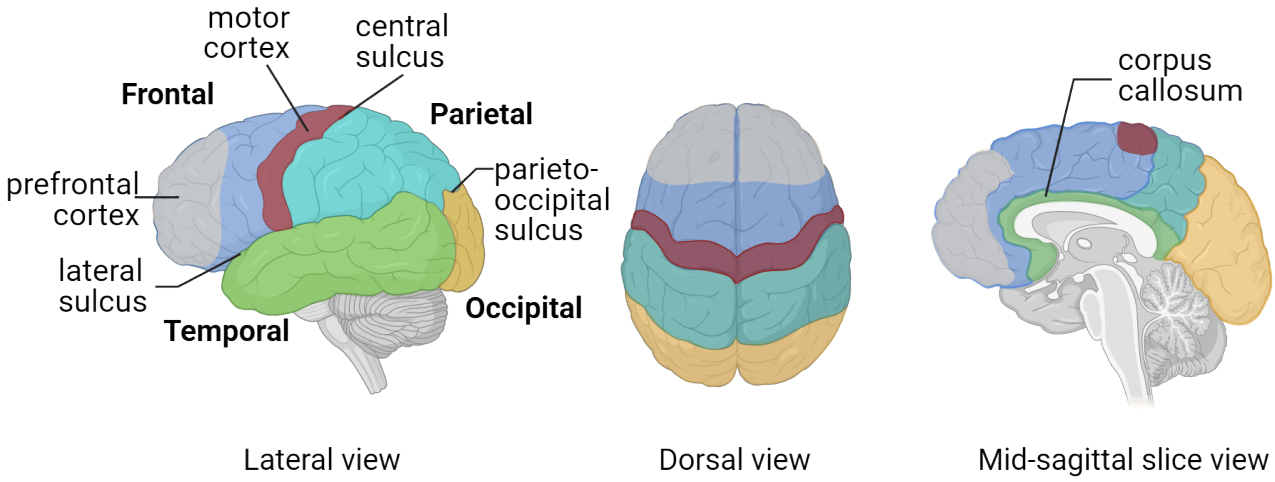

Figure 1.30 Lobes of the cortex

The largest of the four lobes is the frontal lobe. It also contains the olfactory bulb, which is key for our sense of smell. Towards the posterior end of the frontal lobe are the premotor and motor regions that help plan and carry out movement throughout the body. The primary motor cortex sends axons through the brain and into the spinal cord via a descending tract (corticospinal tract). Once these axons reach the brainstem (the stalk of the brain that joins with the spinal cord, see 1.3 The Central Nervous System: CNS), they crossover so that movement on the left side of the body is controlled by the right side of the brain and vice versa. The prefrontal cortex of the frontal lobe is crucial for personality; higher level-cognition and decision making, problem solving, attention and also some memory functions.

The frontal and parietal lobes are separated by a central sulcus (Figure 1.29). The parietal lobe is important for somatic sensation integration. The somatosensory cortex, which is found in the anterior part of the parietal lobe, receives information about touch on all areas of our body. In addition, the parietal lobe has a role in our ability to know the location of our body is space, also known as proprioception.

The occipital lobe is located posterior and inferior to the parietal lobe and primarily functions in vision processing. It contains a primary visual cortex and other areas necessary for visual processing of color, movement and patterns.

The temporal lobe is the second largest in size following the frontal lobe. It is located underneath the frontal and parietal lobes and is key for language, memory, hearing and face perception. It is divided from the other lobes by a lateral sulcus called the Sylvian fissure (Figure 1.29).

Hemispheres

In addition to the cortex which covers the cerebral hemispheres, the inner core of the cerebral hemispheres is composed of white matter. The cerebral hemispheres are largely redundant in function with a few small exceptions. For example, in most humans the left hemisphere controls language and speech while the right interprets spatial, visual information and face recognition (see Chapter 6 Vision). The left and right hemispheres are divided by a deep longitudinal fissure and are connected by axonal tracts called cerebral commissures. Tracts that cross the midline of the brain are called commissures. As mentioned above, the largest of these is the corpus callosum, which connects the two hemispheres and allows information to be passed between sides (Figure 1.30). If the corpus callosum is damaged or purposely severed (rare approach to treat epilepsy), it leads to a condition called split-brain syndrome. This is characterized by neurological abnormalities related to communication between the two sides of the brain. For example, a split-brain patient may not be able to read a specific word when it is presented to the right hemisphere but can identify the drawing that goes with that word.

Limbic System and Basal Ganglia

Underneath the cerebral cortex are a group of specialized brain areas called subcortical structures or nuclei. Two major subcortical structure systems are the limbic system and the basal ganglia, which also derive from the telencephalon.

Limbic System

The limbic system is a collection of structures that border the brainstem and are located under the cerebral cortex (Figure 1.31). The word limbic is derived from the Latin “limbus,” which means border. The limbic system is an anatomical concept and continues to be somewhat controversial when it comes to brain anatomy. Interestingly, neuroscientists can’t fully agree on a set of criteria for regions that count as part of the limbic system. Not even anatomy is set in stone.

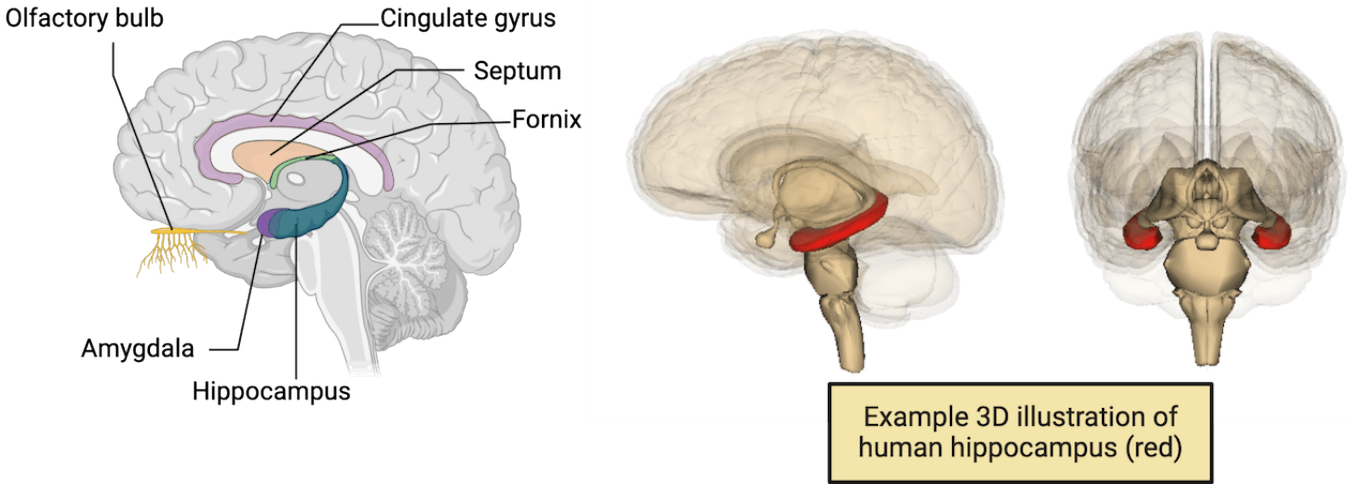

Figure 1.31 Limbic system Image credit: 3D images by Life Science Databases(LSDB) from Anatomography, website maintained by Life Science Databases (LSDB). CC BY-SA 2.1 jp, https://commons.wikimedia.org/w/inde...?curid=7887124.

Traditionally, the limbic system is defined as a connected set of structures that is involved in emotion, aggression, appetites and sexual behavior. While still up for debate, it is generally agreed that the limbic system includes the hippocampus, amygdala, and the cingulate gyrus. The cingulate gyrus is part of the cortex and sits right above the corpus callosum and is very important for emotional and cognitive functions. The amygdala is especially important for fear emotions and fear memory. The hippocampus is associated with memory and specifically the ability to form long term memories. Additional regional structures of the limbic system may include the fornix (connects hippocampus to hypothalamus), septum (often linked to emotion) and olfactory bulb (important for our sense of smell).

Basal Ganglia

Basal ganglia (nuclei) are a group of structures that play an important role in controlled and coordinated movements (Figure 1.32). This includes initiating and facilitating movement while also inhibiting unwanted movement. In addition, some regions of the basal ganglia are also important in motivation, reward and addiction. The basal ganglia system can be subdivided into the caudate nucleus and putamen (collectively called the striatum), globus pallidus and subthalamic nucleus. The striatum receives commands from the cortex and passes them along to the other regions of the basal ganglia.

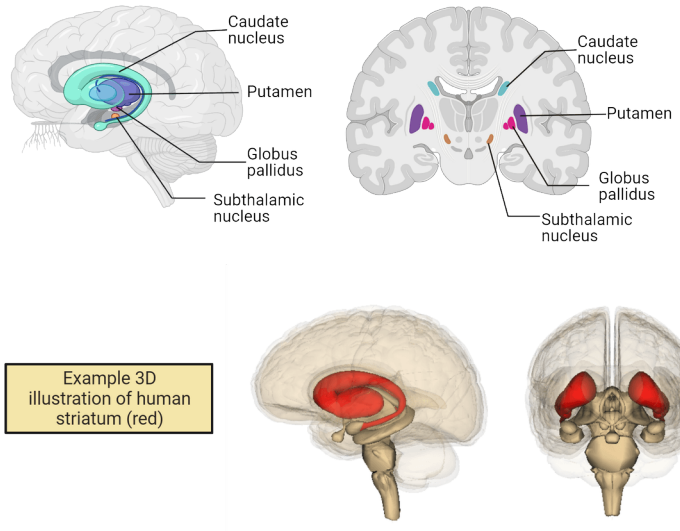

Figure 1.32 Basal ganglia Image credit: 3D Images by Life Science Databases(LSDB) from Anatomography, website maintained by Life Science Databases(LSDB). CC BY-SA 2.1 jp, https://commons.wikimedia.org/w/inde...?curid=7928108.

Eventually basal ganglia information goes to the thalamus which relays information back to the cortex. Damage to the basal

ganglia causes movement dysfunctions and is associated with neurodegenerative diseases like Parkinson's and Huntington's diseases.

Diencephalon

The diencephalon is made up of the thalamus and hypothalamus, located inferior to the cerebrum and next to the third ventricle. The thalamus provides a relay station for sensory information coming in from the spinal cord and PNS, heading to the cortex. The hypothalamus is important for homeostasis control of basic functions (Figure 1.33).

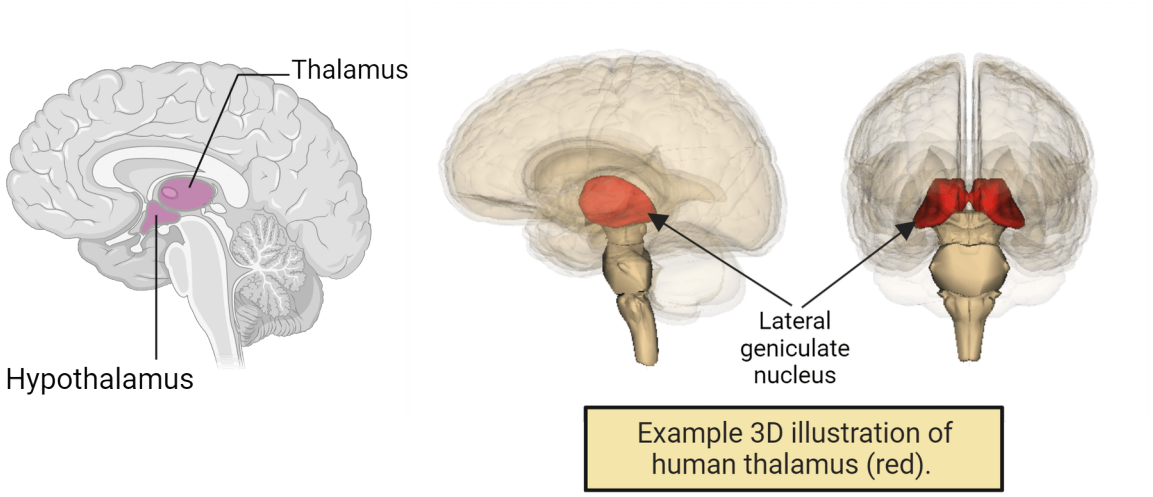

Figure 1.33 Diencephalon Image credit: 3D thalamus images by Life Science Databases (LSDB) from Anatomography, website maintained by Life Science Databases(LSDB). CC BY-SA 2.1 jp, commons.wikimedia.org/w/inde...?curid=7845016.

Thalamus

The thalamus is an oval structure, made of two symmetrical parts, one in each hemisphere (Figure 1.33). It is the sensory relay station and gateway to and from the cerebral cortex. All sensory information goes through the thalamus with the exception of olfaction (smell). The thalamus is composed of many nuclei that receive sensory information from the body and sorts, processes, and directs the information to the appropriate cortical sensory areas. As an example of one thalamic nucleus, the lateral geniculate nucleus (LGN) receives visual information from the retina via the optic nerve (see cranial nerves) and sends it to the primary visual cortex found in the occipital lobe (see Chapter 6 Vision). The thalamus not only sends information to the cortex but also receives information from the cortex for control and regulation (often associated with motor commands).

Hypothalamus

The hypothalamus is located ventral to the thalamus (Figure 1.33). Like the thalamus, it contains several nuclei. It is responsible for regulation of hormones and maintenance of homeostatic mechanisms such as those that keep our bodies at the right temperature and having the right levels of sugar. The hypothalamus regulates the release of hormones from the pituitary gland and thus plays a direct role in connecting the nervous system to the endocrine (hormonal) system of the body. Overall, the hypothalamus is important for many vital functions including: thermoregulation, sex, thirst, hunger, sleep. It is a key regulator of the autonomic nervous system (see 1.5 The Peripheral Nervous System: PNS below).

Brainstem

The brainstem connects the cerebrum to the spinal cord and also to the cerebellum. It is composed of the midbrain and the hindbrain. The hindbrain is further divided into the pons and medulla oblongata. The fourth ventricle is found at the caudal region of the pons and the dorsal region of the medulla. The brainstem is crucial for vital functions which are discussed below. Stretching

from the midbrain to the medulla and into the spinal cord is a network of nuclei and neurons called the reticular formation. These diffusely distributed neurons function in several physiological states such as arousal, consciousness, sleep-wake cycles, heart and respiratory control, and even some pathways involved in pain (Figure 1.34).

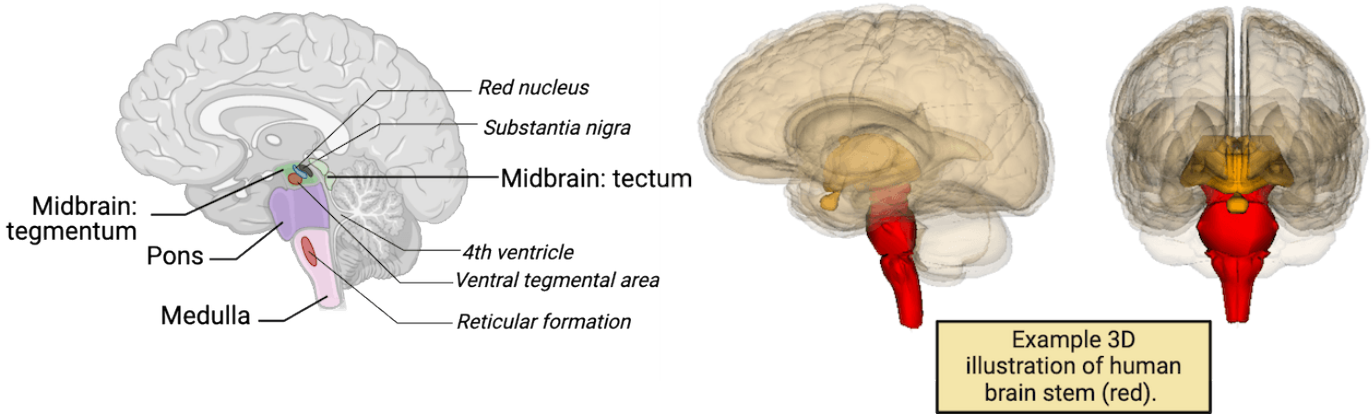

Figure 1.34 Brainstem Image credit: 3D Images by Life Science Databases (LSDB) from Anatomography website maintained by Life Science Databases (LSDB). CC BY-SA 2.1 jp, commons.wikimedia.org/w/inde...?curid=7788515.

Midbrain

The midbrain has its embryonic origins in the mesencephalon. It is located anterior to and above the pons, and has both sensory and motor components (Figure 1.34). The midbrain is involved in auditory and visual sensory processing. The top of the midbrain is the tectum (from the Latin word for roof) and the bottom is the tegmentum (from the Latin word for floor) with the cerebral aqueduct passing right through its center. Other regions in the midbrain include the substantia nigra and the ventral tegmental area (VTA). The substantia nigra (one on each side of the brainstem) are considered to be part of the basal ganglia circuitry (1.5 The Peripheral Nervous System: PNS) and are named from the Latin words for 'black substance' due to the pigment that is found naturally in neurons in this region. The substantia nigra is rich in dopamine neurons and extremely important for motor control. Damage to the substantia nigra (death of dopamine neurons in this region) is associated with Parkinson's disease, a neurodegenerative movement disorder. Adjacent to the substantia nigra is the red nucleus which also plays a role in motor coordination. The VTA is found adjacent to the substantia nigra and also houses dopamine neurons. This region is part of the reward circuitry in the brain.

Pons

The pons and cerebellum originate from the embryonic metencephalon. The pons is superior to the medulla oblongata (Figure 1.34). It contains many tracts and nuclei and provides a connection between the cerebellum and the medulla. The word pons is derived from the Latin word for 'bridge' and is so named because of the transverse fibers that appeared as a bridge between the cerebellar hemispheres. Due to its many nuclei and tracts, the pons is associated with many different functions. For example, the pons is important for the regulation of sleep and basic bodily functions such as breathing. The pons is associated with 4 of the 12 pairs of cranial nerves and is important for facial expressions, chewing and control of eye movement.

Medulla oblongata

The medulla oblongata derives from the myelencephalon. The medulla is possibly the most important part of our brain as it is essential in the control of vital body functions like breathing, heart rate and blood pressure Figure 1.34. Additional functions include swallowing, vomiting, and digestion. The medulla contains a number of nuclei in addition to ascending and descending tracts of the spinal cord. Like the pons, it is also associated with cranial nerves (4 of them). These are key for gag reflexes and muscle control that allows for the turning of the head, speaking and swallowing. Of note is the vagus nerve (10th cranial nerve), which is one of the most important nerves in our body. It is a main component of the parasympathetic system and provides sensory and motor circuitry connecting the brain to the neck, lungs, heart and gut. The vagus nerve provides an important back and forth connection between the CNS and the enteric nervous system (the brain-gut axis). It can relay signals from the microbiota (collection of bacteria) in our gut to our brain. Some research suggests that disruption of the microbiota-gut-brain

axis may play a role in depression and other psychiatric disorders. Interestingly, the vagus nerve has been studied as a target for treating these types of disorders. Stimulation of the vagus nerve is an approved treatment for hard-to-treat depression.

Cerebellum

The cerebellum (aka little brain) is a structure that originates in the metencephalon and functions in motor coordination and some forms of simple learning. Like the cerebrum, the cerebellum is also divided into two hemispheres Figure 1.35. The cerebellum is divided via a midline connector called the vermis (the Latin word for worm). While the cortex gives motor commands, the cerebellum coordinates smooth/timely movement and fine-tunes/adjusts movement based on incoming sensory information such as proprioceptive information. It is necessary for balance and fine motor control, as well as learning and memory of motor tasks, such as learning to ride a skateboard or learning to dance. This motor coordination can be inhibited by alcohol intoxication. Lack of coordination due to intoxication can be assessed by standard tests (finger to nose tests, walking in a straight line, etc.). Alcohol misuse or overuse can cause cerebellar dysfunction and excessive amounts of alcohol consumption actually leads to permanent changes/degeneration in the cerebellum. Furthermore, alcohol exposure during development leads to cerebellar defects such as those observed in children born with FAS (fetal alcohol symptom). The cerebellum has a specific arrangement of three cell layers. While the human brain contains about 86 billion neurons, roughly 80% of these are found in the cerebellum. Note that the cerebellum only makes up 10% of brain volume. Interestingly, case studies of individuals lacking a cerebellum indicate that for the most part, these individuals function relatively well, often not even discovering their lack of a cerebellum until adulthood. (Figure 1.35)

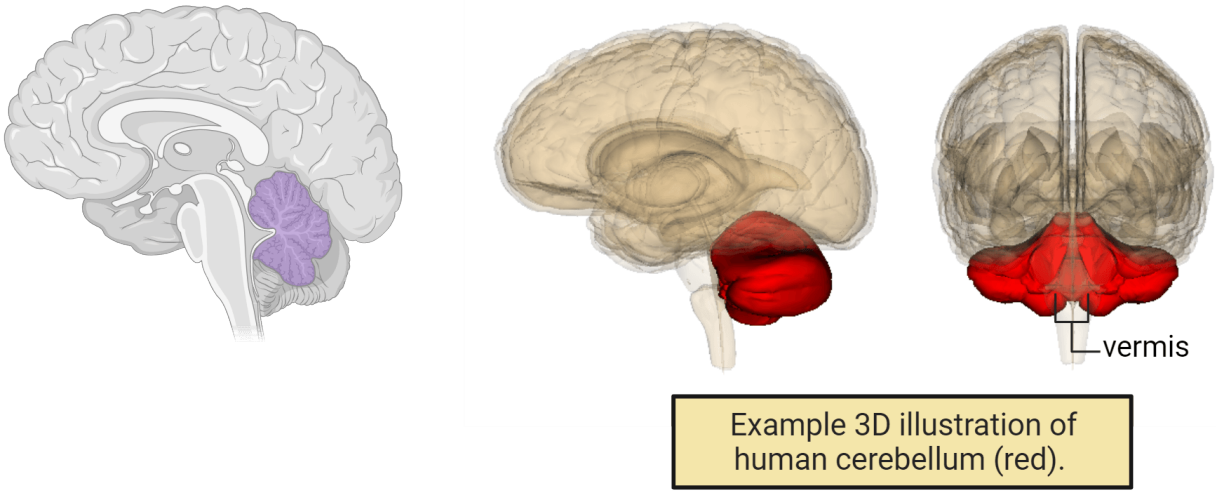

Figure 1.35 Cerebellum Image credit: 3D Images by Life Science Databases(LSDB) from Anatomography website maintained by Life Science Databases (LSDB). CC BY-SA 2.1 jp, commons.wikimedia.org/w/inde...?curid=7768824.

Brain lateralization

Hemispheric lateralization refers to different brain functions and/or behaviors being controlled by one hemisphere rather than the other. Most of the evidence for this type of specialization is related to language control. For example, there are two left hemisphere specific regions that are important for language: a region called Broca's area associated with speech production and speech articulation and Wernicke's area associated with language comprehension. Other examples of lateralization include handedness, the preference of the right or left hand for different tasks. Beyond that, the differences that have been found in associating different behaviors to one or the other hemispheres are generally small.

Visualizing the human brain

A number of imaging techniques have been developed to aid neuroscientists and medical professionals to visualize the human brain at the level of structure and function. Structural techniques such as PET, CT and MRI scans result in images of anatomical features of the brain while functional techniques such as functional MRI (fMRI) produce images that represent neural activity

(see Methods: fMRI). Functional imaging techniques can be used in experiments where a subject performs a specific behavior or cognitive task, allowing scientists to correlate brain anatomy with function. Brain imaging techniques are important experimental tools, allowing us to delve deeper into the inner workings of the brain. Imaging can also be used for diagnosing and studying brain disorders. However, it is important to remember that the brain is exceptionally complicated and that these techniques are not perfect in measurement or definitive in conclusion. Each has its own advantages and limitations. For example, PET and CT scans are sensitive and prone to motion artifacts and fMRI measurements are an indirect measurement of brain activity (increased blood flow and oxygenation) (Figure 1.36).

Sex as biological variable: Are male and female brains structurally different?

Sexual dimorphisms are defined as differences between males and females of the same species: for example, body size or anatomical differences. Sexual dimorphisms have been well established in some vertebrate brains. For example, male and female brains of some bird species like canaries and zebra finches can exhibit some structural dimorphisms. Specifically, there are three vocal control areas in the brains of these birds that are strikingly larger in males than in their female counterparts(forebrain vocal nuclei) and correlate with singing behavior (Figure 1.37). Both canary and zebra finch males sing but females do not. This singing behavior is key to courtship in these two species of birds. The males sing to impress the females.

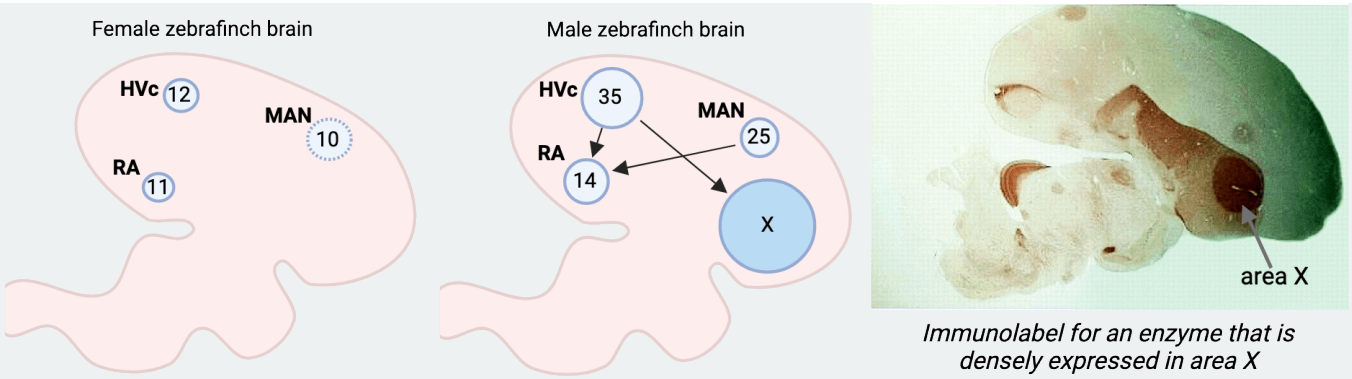

Figure 1.37 Male v. female zebrafinch brain 3 key forebrain vocal control nuclei are larger in male than female zebrafinch brains. One region is present in males and completely absent in females. Image credit: Immunolabel image (labels added) from: Bolhuis JJ, Zijlstra GG, den Boer-Visser AM, Van Der Zee EA. Localized neuronal activation in the zebra finch brain is related to the strength of song learning. Proc Natl Acad Sci U S A. 2000 Feb 29;97(5):2282-5. doi: 10.1073/pnas.030539097. PMID: 10681421; PMCID: PMC15792. Copyright 2000 National Academy of Sciences.

What about humans? The question of structural differences between human male and female brains has been investigated throughout the history of neuroscience and continues to be a hot topic. A very large meta study that combined 30 years of data (Eliot, 2021) concluded that male and female brains are not structurally different in a meaningful way. Male and female head sizes are different as proportioned by body size. Dr. Eliot and her collaborators have shown that, apart from the basic variation in size (male brains are ~11% bigger than female brains), there aren't meaningful or consistent differences in brain structures between males and females across diverse populations (Eliot, 2021). They conclude that there is no clear structural brain dimorphism in humans between male and female brains.

Beyond structure, does this mean human male and female brains are exactly the same? Definitely not. Sex hormones, genes and environment play a large role in brain development. There are aggregate differences between human males and females in numerous molecular and cellular functions in the brain. In Chapter 11 Sexual Behavior and Development, we will dive much further into this topic, including the hormonal, genetic and environmental contributors to sex differences in the brain.

1.6.6: The Peripheral Nervous System - PNS

Learning Objectives

By the end of this section, you should be able to

- 1.5.1 Demonstrate an understanding of the overall structure and function of the peripheral nervous system (PNS).
- 1.5.2 Explain the difference between the somatic and autonomic divisions of the peripheral nervous system (PNS).
- 1.5.3 Describe the difference between the sympathetic and parasympathetic divisions of the autonomic nervous system.

When you enter a dimly lit room, your pupils enlarge. When you are nervous before an exam, your heart might start racing and your palms get sweaty. These are just two examples of your peripheral nervous system in action. The PNS contains all the neural tissue outside of the brain and spinal cord. It is an extensive network of nerves that contacts almost every nook and cranny of our bodies. The PNS contains sensory and motor neurons not only linking the CNS to the external world but also to our internal visceral tissues (such as the heart, lungs, stomach). The PNS and CNS are in constant back and forth communication. This relationship is vital for the proper function of an organism.

Afferent and efferent divisions

The PNS is made up of afferent (sensory) and efferent (motor) components. The afferent division brings information from the periphery (receptors found within skin, joints, muscle, visceral organs) to the spinal cord and brain via sensory nerves. The information brought in by afferent neurons is decoded and processed by the CNS. The efferent component, on the other hand, utilizes motor neurons that transmit information from the CNS to the periphery. This includes our muscle tissue (effectors) causing muscle contraction and thus voluntary body movements. In addition, the efferent division also controls smooth muscle in visceral organs, cardiac muscle and glands. It can function with or without consciousness (voluntary or involuntary).

Cranial and spinal nerves

A substantial portion of the PNS is made up by cranial and spinal nerves that transmit efferent and afferent information. There are 12 pairs of cranial nerves that emerge from the back of the brain, and 31 pairs of spinal nerves that emerge from the spinal cord (Figure 1.38).

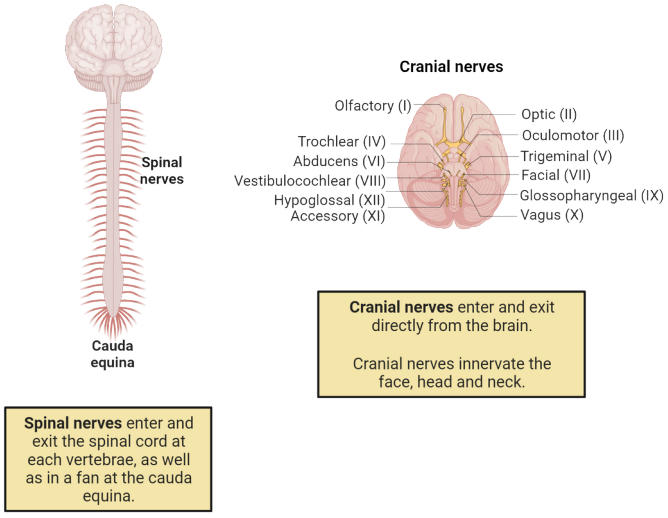

Figure 1.38 Spinal and cranial nerves

The cranial nerves pass through the cranium (skull) via holes called foramina and canals. Most of the cranial nerves control the head and neck including the jaw, throat, tongue, neck and face. They also carry visual (optic), smell (olfactory) and taste (gustatory) information, and participate in hearing and balance (vestibulocochlear). Of the 12 cranial nerves, 3 are exclusively sensory (afferent), 5 are exclusively motor (efferent) and the remaining 4 cranial nerves are both motor and sensory. Nerve number X (10) is called the vagus nerve (named for the word 'wandering'). It wanders/extends very far and innervates the heart and intestines, receiving and sending information regarding internal organs. The vagus nerve has been actively researched and doctors can stimulate it with electricity to treat a number of disorders including difficult to treat cases of epilepsy and depression.

The spinal nerves arise from the spinal cord as nerve roots (ventral and dorsal). They jet out through the openings of the vertebral column thus serving both sides of the body. Like the cranial nerves, the spinal nerves carry both sensory information and motor information to and from the spinal cord. The spinal nerves are named based on the spinal column region from which they exit. There are 8 neck (cervical), 12 trunk (thoracic), 5 lower back (lumbar), 5 pelvic (sacral) and 1 bottom (coccyx) spinal nerve (Figure 1.25).

Ganglia

The nerve cell bodies that are found in the PNS are organized into structures called ganglia which can be seen as enlargements along the peripheral nerves. The word ganglia originates from the Latin word for 'swelling'. Functionally, PNS ganglia serve as relay points for information being received and transmitted. They fall into two major categories: sensory ganglia and autonomic ganglia. The sensory ganglia (of spinal nerves and some cranial nerves) contain thousands of cell bodies of neurons that extend their processes to the periphery. These are generally unipolar neurons (see 1.1 Building a Nervous System above) that receive input from the periphery and send that information via axons to the spinal cord and the brain. The other category of PNS ganglia are the autonomic ganglia, which contain the cell bodies of autonomic nervous system neurons (ANS) and can be found in both the sympathetic and parasympathetic divisions of the ANS (Figure 1.39).

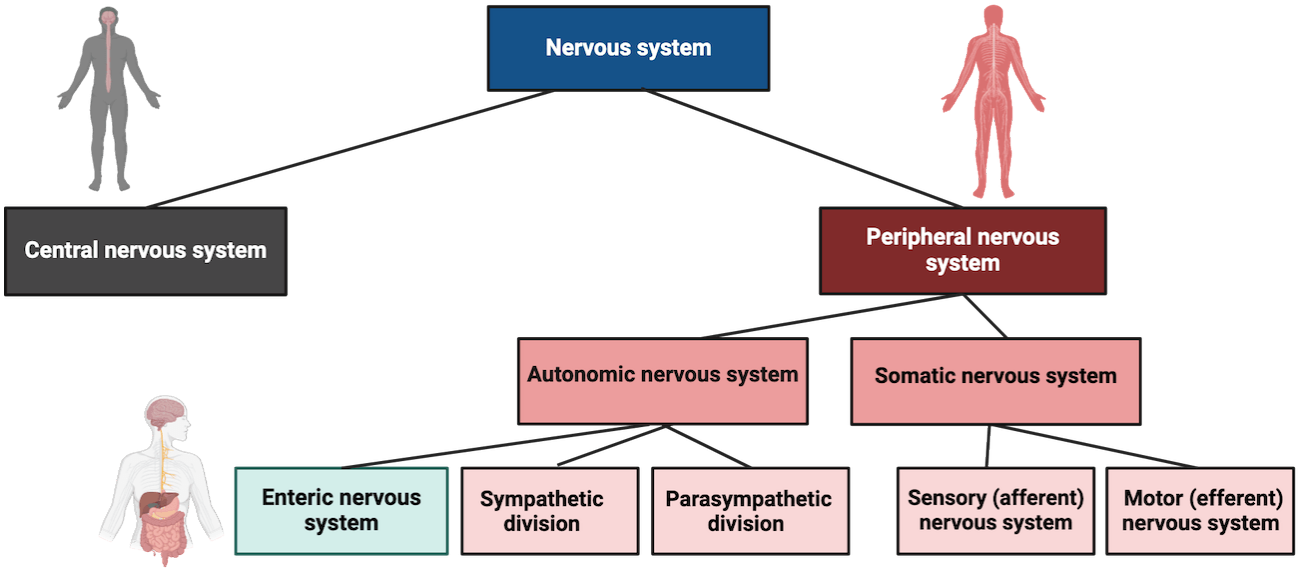

Figure 1.39 Nervous system divisions

The somatic and autonomic divisions of the PNS

The PNS can be divided into the somatic nervous system (SNS) and the autonomic nervous system (ANS). Both systems have motor and sensory components and both systems utilize the neurotransmitter acetylcholine. The ANS also uses norepinephrine. The main function of the SNS is the control of voluntary muscles and thus conscious actions such as walking. It consists of sensory and motor nerves. It receives somatosensory information from our skin, muscles, bones and joints, and targets skeletal muscles via motor innervation (Figure 1.40). The cell bodies of these motor neurons are found in the gray matter of the spinal cord.

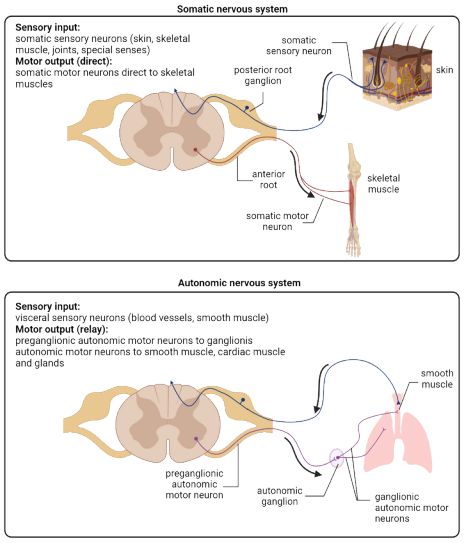

Figure 1.40 Somatic vs autonomic nervous system

The ANS controls generally involuntary (autonomic, meaning self-governing) processes such as our breathing and heartbeat. It primarily controls the internal organs of the body, cardiac and smooth muscles, and glands (Figure 1.41). We often hear the ANS referred to as a visceral system. The reason for this is because it communicates with visceral organs. These are organs in the chest, abdomen, and pelvis. Visceral sensory neurons monitor changes in temperature and stretch of visceral organs allowing the CNS to control and regulate their action via visceral motor outputs. We can further divide the ANS into three distinct parts: sympathetic, parasympathetic, and enteric systems. The sympathetic and parasympathetic systems have generally antagonistic or opposite functions in regulating organ functions. The same organs are innervated by both the parasympathetic and sympathetic systems causing opposite effects. These two systems differ in function, anatomical organization, and types of neurotransmitters that they use. We will briefly discuss each of these systems below (Figure 1.41).

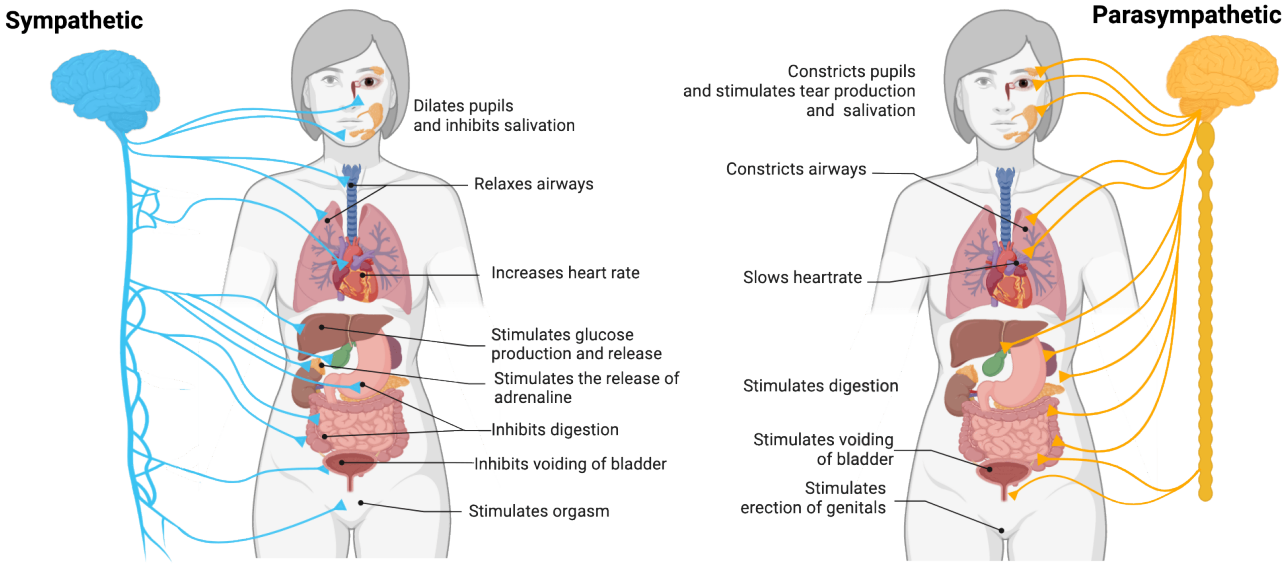

Figure 1.41 Sympathetic and Parasympathetic systems

Sympathetic nervous system

The sympathetic system underlies the fight or flight response. This is a threat/emergency response mechanism which is not unique to only humans. The sympathetic nervous system is responsible for a lot of body functions related to hyperarousal such as increases in heart rate and blood pressure, inhibition of salivation/digestion and pupil dilation (Figure 1.41). At the same time, non-necessary functions like digestion are put on hold while the body gets more blood flow to muscles. The sympathetic nervous

system neurons arise from the thoracic and lumbar regions of the spinal cord. Fibers extend from the spinal region to its target organ such as the heart, liver, intestines, stomach, bladder, glands, etc.

Parasympathetic nervous system

The parasympathetic system acts in exact opposition to the sympathetic system and helps the body relax and digest. The parasympathetic system is responsible for slowing the heartbeat, stimulating salivation, digestion, urination, etc. (Figure 1.41). Like the sympathetic nervous system, it also targets organs like the heart, intestines, bladder, etc. but causes opposite effects. The neurons of the parasympathetic nervous system arise from the brain (cranial nerves) and the sacral spinal cord region.

The enteric nervous system

The enteric nervous system is a net-like system of neurons that orchestrates gastrointestinal function via innervation of the digestive tract. It has more neurons than the spinal cord and is exceptionally complex. For example, it uses 30 different neurotransmitters. It is not entirely controlled by the CNS but is connected to the CNS via a communication network called the brain-gut axis. The enteric nervous system has both sensory and motor properties and controls the digestive system, smooth muscle, and glands (Figure 1.42).

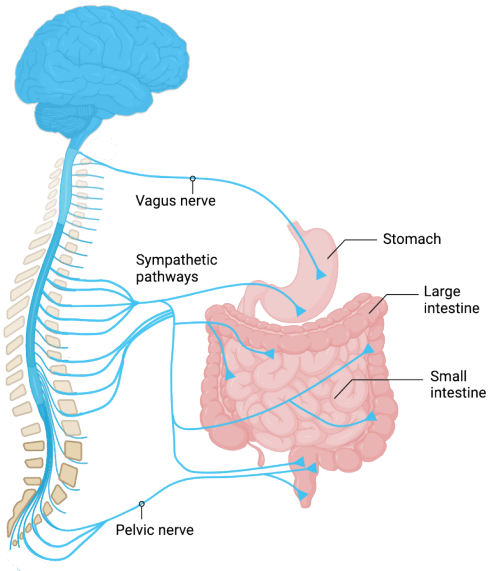

Figure 1.42 Enteric nervous system

View this Interactive Content online

The basic cellular building blocks of the nervous system are neurons and glia. While sharing all features of eukaryotic cells, including membrane bound organelles and the central dogma, neurons and glia differ in some important ways that allow them to serve the functions of the nervous system. Neurons are specialized for communication via chemical and electrical signals with other cells. Glia serve in a number of support roles that are vital for neurons, including signaling. Our ability to visualize these cells and their architecture has revolutionized modern neuroscience.

1.2 Organization of the Nervous System

Nervous systems vary across the animal kingdom in design and complexity. From neural nets to ganglia to centralized brains, there is a great deal of diversity. At the same time, due to evolution, all nervous systems share fundamental similarities. The human nervous system is a typical vertebrate system divided into a peripheral and central nervous system. Both are composed of white (myelinated axons) and gray matter (neuron cell bodies, dendrites and unmyelinated axons). Neurons do not operate in isolation but rather interact with each other in neural circuits that can vary in complexity. Neuroscientists have been working to understand the neural circuitry found in nervous systems by developing wiring maps or connectomes. There are several large circuit mapping projects underway seeking to map the human brain.

1.3 The Central Nervous System: CNS

The CNS is composed of the brain and spinal cord and is responsible for receiving and processing information from the PNS and ultimately controlling the entire body. It develops from a section of the ectoderm called the neural plate which eventually becomes the neural tube and ultimately separates into different brain regions and the spinal cord. The spinal cord is divided into 5 anatomical regions and houses ascending and descending nerve tracts, horns and roots.

1.4 The Brain: Structure and Function

The human brain is derived from 3 major embryonic divisions (the forebrain, midbrain and hindbrain), which is further subdivided into 5 regions during development. The adult brain derivatives can be organized according to these 5 regions. While we can assign some general functions to major brain regions, we should view the brain as having built in ‘degeneracy’—a behavior or brain function can be supported by multiple regions of the brain rather than a stringent one-to-one function to region ratio.

1.5 The Peripheral Nervous System: PNS

The peripheral nervous system is composed of the somatic and autonomic divisions and includes all the nerves and ganglia outside of the brain and spinal cord. The somatic division is under voluntary control and sends commands from the central nervous system to muscles, for example. The autonomic division is generally involuntary and controls functions such as heart rate and digestion. The autonomic system can be further divided into the sympathetic, parasympathetic and enteric nervous systems.

1.6.8: Key Terms

1.1 Building a Nervous System

neuron, glia, DNA, mRNA, nucleus, neurotransmitters, ribosomes, endoplasmic reticulum, Golgi apparatus, lysosome, mitochondria, soma, axon, dendrite, afferent, efferent, interneurons,dendritic spines, axon hillock, axon collaterals, axon terminals, synapse, synaptic cleft, neuroglandular junction, neuromuscular junction, astrocytes, microglia, phagocytes, oligodendrocytes, Schwann cell, myelin, immunofluorescence, Golgi stain, GFP

1.2 Organization of the Nervous System

neural nets, ganglia, nerve cord, bilateral, radial symmetry, centralization, cephalization, central nervous system (CNS), peripheral nervous system (PNS), nerves, nuclei, tracts, gray matter, white matter, meninges, dura mater, arachnoid, pia mater, cerebrospinal fluid, lateral ventricles, third and fourth ventricles, central canal, cerebral aqueduct, arachnoid villi, venous sinuses, anterior cerebral, middle, cerebral and posterior cerebral arteries, basilar artery, vertebral artery, blood-brain barrier, neural circuit, reflex arc

1.3 The Central Nervous System: CNS

retina, dorsal, ventral, superior, inferior, neuraxis, anterior, posterior, rostral, caudal, medial, ipsilateral, contralateral, coronal, saggital, horizontal, cerebral cortex, ectoderm, neural plate, neural tube, prosencephalon, mesencephalon, rhombencephalon, telencephalon, diencephalon, metencephalon, myelencephalon, cauda equina, dermatome, cervical, thoracic, lumbar, sacral, coccyx, dorsal horn, ventral horn, dorsal root, ventral root, ascending and descending tracts

1.4 The Brain: Structure and Function

cerebral hemispheres, cerebral cortex, corpus callosum, cerebral nuclei, gyri, fissures, sulci, longitudinal fissure, frontal, temporal, parietal, occipital lobes, motor cortex, brain stem, prefrontal cortex, central sulcus, proprioception, Sylvian fissure, cerebral commissures, basal ganglia, limbic system, hippocampus, amygdala, cingulate gyrus, fornix, septum, olfactory bulb, caudate nucleus, putamen, globus pallidus, subthalamic nucleus, thalamus, hypothalamus, lateral geniculate nucleus (LGN), brainstem, reticular formation, midbrain, tectum, tegmentum, substantia nigra, red nucleus, ventral tegmental area (VTA), pons, medulla, vagus nerve, cerebellum, vermis, Broca's area, Wernicke's area, forebrain vocal nuclei, PET, CT, MRI, fMRI

1.5 The Peripheral Nervous System: PNS

sensory ganglia, autonomic ganglia, somatic nervous system, autonomic nervous system, sympathetic nervous system, parasympathetic nervous system, enteric nervous system

1.6.10: Multiple Choice (IVETTE DELETE OR KEEP?)

1.1 Building a Nervous System

1.
Which of the following molecules does the work in cells?

a. DNA
b. mRNA
c. Proteins
d. Golgi

2 .
Neurons:

a. come in many shapes and sizes.
b. all have one axon and many dendrites.
c. all have one dendrite and many axons.
d. all have multiple axons and multiple dendrites.

3.
The part of the neuron that is specialized for receiving information is:

a. the axon.
b. the cell body.
c. the dendrites.
d. the axon hillock.

4 .
Which are the primary myelinating cells of the central nervous system?

a. Astrocytes
b. Microglia
c. Oligodendrocytes
d. Schwann cells

5.
Which cell type is most important for helping to form the blood-brain barrier?

a. Astrocytes
b. Microglia
c. Oligodendrocytes
d. Schwann cells

6 .
Which cell type is most important for helping to clear debris from injury in the central nervous system?

a. Astrocytes
b. Microglia
c. Oligodendrocytes
d. Schwann cells

1.2 Organization of the Nervous System

7.
Which feature is consistent across all organisms that have a nervous system?

a. Ganglia
b. Neural nets
c. Bilateral symmetry
d. None of these

8 .
The property of a nervous system describing an organization where neurons are consolidated into specific areas of integration rather than just being randomly arranged throughout the body is called what?

a. Cephalization
b. Centralization
c. Symmetry
d. Concentration

9.
Where in the central nervous system would you find cerebral spinal fluid?

a. In the dura mater
b. In the subarachnoid space
c. In the pia mater
d. In the nerves

10 .
Cerebral spinal fluid:

a. sloshes back and forth in the ventricular system.
b. flows in one direction through the ventricles, into to central canal and subarachnoid space.
c. flows in one direction from the subarachnoid space into the ventricles and then into to central canal.
d. is still, like a lake or pool.

11.
The human connectome:

a. is well understood.
b. is relatively simple.
c. is still being mapped and incredibly complex.
d. is very similar to that of the roundworm *C. elegans*.

12 .
The brain requires large amounts of blood to maintain its functions. This blood derives from 2 main arteries. The more ventral artery is called _____ while the more dorsal artery is _____.

a. carotid artery / vertebral artery
b. cerebral arteries / vertebral artery
c. ventral cerebral artery / dorsal cerebral artery
d. vertebral artery / carotid artery

1.3 The Central Nervous System: CNS

13.
My left hand is _____ to my right hand.

a. medial
b. lateral
c. contralateral
d. ipsilateral

14 .
Divisions of the central nervous system:

a. begin early in development.
b. only emerge in adulthood.
c. are composed only of brain vs spinal cord.
d. are defined as neural tube and spinal cord.

15.
Which embryonic brain region becomes the cerebral hemispheres?

a. Telencephalon
b. Diencephalon
c. Mesencephalon
d. Metencephalon

16 .
Sensory neurons enter the spinal cord from the _____ side.

a. lateral
b. medial
c. ventral
d. dorsal

17.
Which kind of pathways bring information from the periphery to the brain?

a. Descending
b. Ascending
c. Peripheral
d. Lateral

1.4 The Brain: Structure and Function

18 .
Which lobe of the cortex is most important for decision making and problem solving?

a. Frontal
b. Temporal
c. Parietal
d. Occipital

19.
Which lobe of the cortex is important for language, memory, and hearing?

a. Frontal
b. Temporal
c. Parietal
d. Occipital

20 .
The _____ lobe of the cortex is most important for vision.

a. frontal
b. temporal
c. parietal
d. occipital

21.
Brain regions important for motor control are found:

a. in the frontal lobe.

b. in the subcortical nuclei.
c. in the brainstem.
d. in all of these.

22 .
Which brain function shows strong lateralization?

a. Memory
b. Sensory integration
c. Vision
d. Language

23.
Cranial nerves carry what kind of information?

a. Sensory
b. Motor
c. Sensory and motor
d. Neither sensory or motor

24 .
The part of the peripheral nervous system that helps the body relax and digest is:

a. the sympathetic nervous system.
b. the parasympathetic nervous system.
c. the hypothalamus.
d. the somatic nervous system.

Mary is visiting the office of Dr. Alfredo Quinones-Hinojosa, a neuroscientist, physician, and neurosurgeon who is known affectionately by his patients as “Dr. Q”. Unfortunately, it is not a happy visit—Mary has been diagnosed with a glioma, a tumor caused by runaway cell division among the glial cells in her brain. Her first sign that something was wrong was a seizure, an episode of tremoring and muscle rigidity that left Mary exhausted and frightened. Now brain scans have revealed a glioma.

Mary is worried. Dr. Q patiently walks her through her prognosis, explaining how his team can conduct surgery to remove the glioma. “Will that stop the seizures?” Mary asks. “Maybe” says Dr. Q. But he warns that in almost 30% of cases, seizures persist

even after a glioma is removed. How can that be? Why would a tumor cause seizures in the first place? And if the tumor is removed, shouldn't the seizures go away? These are some of the medical mysteries Dr. Q's research team is trying to solve. In fact, Mary decides to donate tissue from her removed tumor to be studied, and with that tissue and samples from other patients Dr. Q's team uncover something remarkable: compared to glioma patients who do not suffer seizures, those with seizures show increased expression of the mRNA for a specific protein, VGLUT1 (Feyissa et al., 2021). VLGUT1 helps load the excitatory transmitter glutamate into vesicles to be released. This finding inspires Dr. Q's team to formulate a new hypothesis: that excess VGLUT1 causes runaway excitation, explaining why some gliomas lead to seizures. This hypothesis may not make complete sense to you yet, but stay tuned: we'll come back to it at the end of the chapter, and hopefully you'll be right with Dr. Q's team in understanding why this might be a breakthrough. What you can gain from this story for the moment is a glimpse into an important principle of neuroscience: The smooth functioning of neural circuits reflects an incredible ballet amongst protein machines working within each of our 86 billion neurons. The environment we live in can reshape which proteins are expressed and how, with profound implications for the functions of the brain.

In this chapter we'll explore neural communication. We'll see that neurons are constantly receiving messages from their partners and the outside world—messages that produce excitation, inhibition, or modulation. When a neuron is sufficiently excited, it generates an action potential—an electrical wave that spreads through the neuron, causing it to send its own chemical messages to all of its partners. In this way, neurons can form circuits, sending and integrating information to produce complex patterns of activity that muscles transform into behavior. How are neurons able to detect chemical signals, produce action potentials, and release transmitter? Through an amazing collection of protein machines: pumps that use energy to build up concentration gradients of electrically charged molecules, channels that monitor the neuron's environment and then switch open or closed to generate electrical currents, and a whole complex of machinery for both releasing transmitter to partner neurons and for detecting transmitter released from partner neurons. Let's dive in!

1.6.13.2: Neural Communication

Learning Objectives

By the end of this section, you should be able to

- 2.1.1 Describe the chemical communication that occurs between neurons, at synapses.
- 2.1.2 Describe the action potential, which moves information within a neuron.
- 2.1.3 Explain how neurons both synthesize information (by integrating inputs from many partners) and filter information (by having a threshold).

The 86 billion neurons in your brain differ dramatically in size, shape, and gene expression (Herculano-Houzel, 2012). What they all have in common is a specialization for communication, allowing them to form complex networks. All day long, neurons chatter away in your nervous system. A typical neuron in your central nervous system is in direct communication with about 7,000 synaptic partners and can send up to 400 messages per second (Pakkenberg et al., 2003; Testa-Silva et al., 2014). The quantity and complexity of communication occurring in your nervous system is staggering.

How do neurons communicate? It turns out they are bilingual (see Figure 2.2)—speaking in both chemical and electrical languages. Neurons speak to each other in an ancient chemical language, releasing chemical signals called neurotransmitters. These chemical messages are translated into an internal electrical language that influences the generation of action potentials, electrical waves that spread within a neuron at great speed. As they spread, action potentials are translated back into chemical messages that are released to partner neurons. Let's take a tour of these two signaling systems.

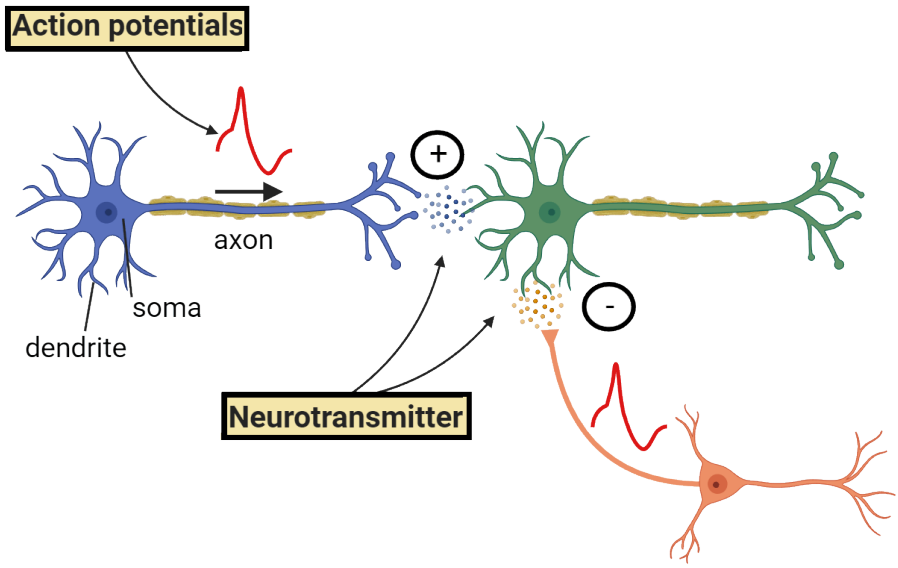

Figure 2.2 Neuronal languages Action potentials transfer information within a neuron. This electrical signal spreads through the neuron to trigger transmitter release to that neuron's synaptic partners. Neurotransmitter is released to transfer information between neurons. These signals excite or inhibit action potentials in the receiving neuron.

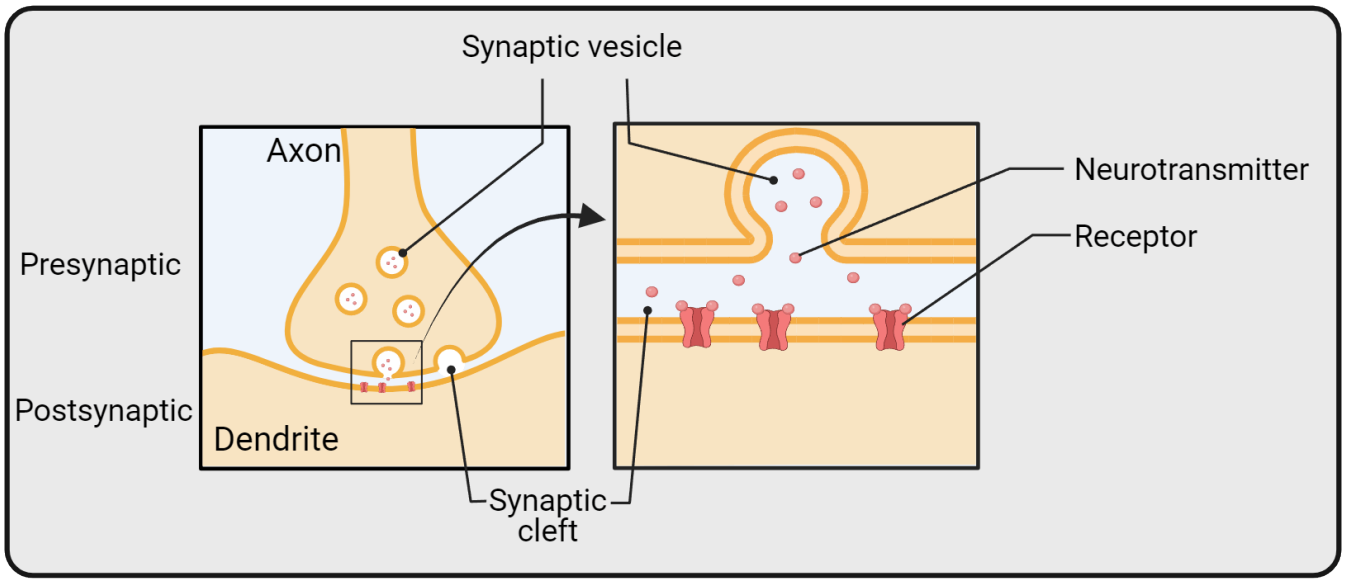

Figure 2.3 Closeup of chemical transmission

Communication between neurons happens chemically, at synapses

The chemical signaling that occurs between neurons happens primarily at chemical synapses (Figure 2.4), specialized communication structures where a broadcasting neuron and a receiving neuron draw very close to one another, separated only by a small pocket of extracellular space called a synaptic cleft. One neuron releases transmitter into the synaptic cleft—we call this the pre-synaptic neuron and say that it contains the pre-synaptic terminal. The presynaptic terminal stores neurotransmitter in small membrane-bound bubbles called vesicles (Step 1 in Figure 2.4). In response to an action potential within the neuron, these vesicles fuse with the pre-synaptic membrane and dump their neurotransmitter into the synaptic cleft (Step 2 in Figure 2.4). The other neuron is studded with specialized receptors that recognize the transmitter and respond to it—we call this the post-synaptic neuron and say that it contains the post-synaptic terminal. There are many different neurotransmitters and many different transmitter receptors. Despite this complexity, each chemical message received is translated by receptors into one of just three responses in the post-synaptic neuron (Step 3 in Figure 2.4):

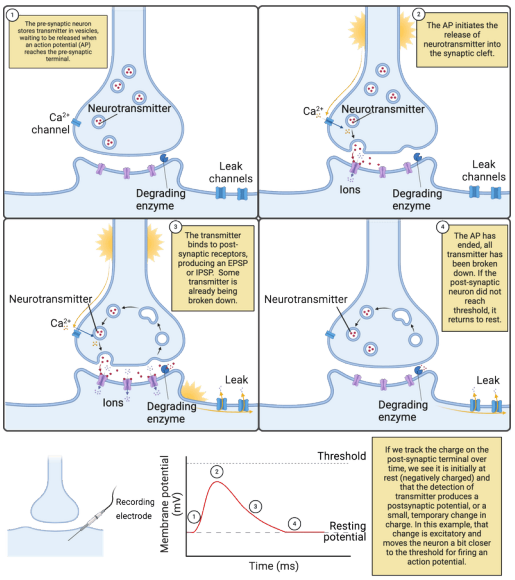

Figure 2.4 Chemical communication by neurons

- An Excitatory Post-Synaptic Potential (EPSP), a brief electrical change in the post-synaptic neuron that excites the neuron, pushing it towards firing an action potential.
- An Inhibitory Post-Synaptic Potential (IPSP), a brief electrical change in the post-synaptic neuron that inhibits the neuron,

pushing it away from firing an action potential.
- Neuromodulation, a change in intracellular signaling in the post-synaptic neuron that modulates that neuron, changing its patterns of growth, connectivity, or signaling.

Almost as soon as it is released, neurotransmitter is broken down and recycled, inactivating the receptors on the post-synaptic membrane (Step 4 in Figure 2.4). This ensures your synapses don't clog up with accumulated neurotransmitter over time. More importantly, it tunes neural communication to the here and now, making their messages to one another extremely transient (short-lived). Each EPSP and IPSP lasts only a few milliseconds (bottom of Figure 2.4). The one exception to this rule is modulation, which is usually short-lived, but which can also become long-lasting; more details on modulation are in Chapter 3 Basic Neurochemistry.

The chemical communication that occurs between neurons is a specialization of systems that appeared very early in the history of life. Even bacteria can secrete chemicals and have receptors that stick through their membranes to detect and respond to chemicals in their environment. Many of the neurotransmitters and transmitter receptors used in your nervous system have long evolutionary histories, so it is not uncommon to find similar chemicals and proteins both in other forms of life and in other parts of your body. For example, histamine is an important neurotransmitter, but is also produced in white blood cells as part of an immune response to injury. This is part of the reason why substances in the natural world can influence your nervous system (caffeine!) and why drugs developed to treat brain disorders often have unwanted side effects in other parts of the body.

Although chemical communication between neurons has ancient roots, it has become highly specialized in neurons. One key specialization is that chemical communication is precisely targeted. Neurons release neurotransmitter almost exclusively at synapses. The tiny volume of the synaptic cleft ensures the post-synaptic neuron will get the message, and that other neurons (for the most part) will not. The pre-synaptic terminal also has specialized protein machinery to maintain a steady supply of neurotransmitter for release, and the post-synaptic terminal is loaded with receptors as well as other proteins that anchor the receptors and help fine-tune their responses to synaptic signals.

Although most communication between neurons occurs via chemical synapses, neurons can also signal to each other through electrical synapses (Figure 2.5); At an electrical synapse, neurons express a specialized protein, called connexon, which forms a protein bridge called a gap junction between the neurons. This enables electrical signals to pass directly from one neuron to another. In addition, small molecules can pass through an electrical synapse, so they actually allow for both electrical and chemical communication.

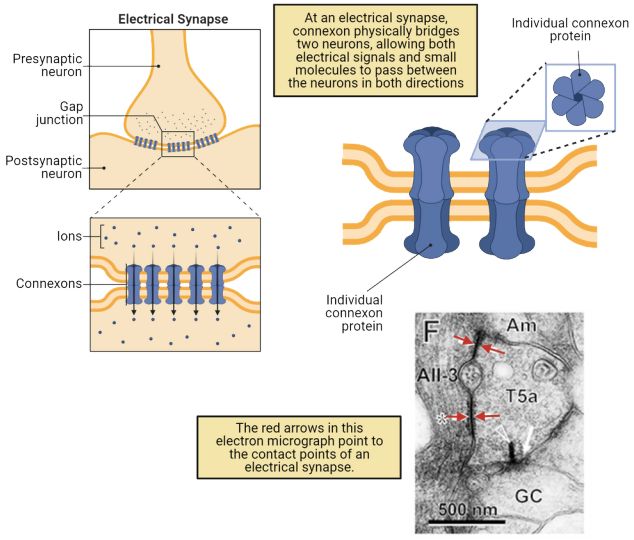

Figure 2.5 Electrical synapses Image credit: Tsukamoto Y and Omi N (2017) Classification of Mouse Retinal Bipolar Cells: Type-Specific Connectivity with Special Reference to Rod-Driven AII Amacrine Pathways. Front. Neuroanat. 11:92. doi: 10.3389/fnana.2017.00092. CC BY 4.0.

If you find communication between neurons fascinating, you're not alone and you're also in luck. When you get to Chapter 3 Basic Neurochemistry, you'll read more about chemical communication between neurons.

Information spreads within a neuron electrically

Neurons are specialized not only for communicating with each other, but also for generating internal electrical signals (Figure 2.6). Like almost all cells, neurons maintain an overall negative charge called a resting potential. In addition, neurons are electrically excitable, generating action potentials that sweep through a neuron at speeds up to 60 meters per second (134 miles per hour; Todnem et al., 1989). Each action potential is translated back into chemical messages released to partner neurons.

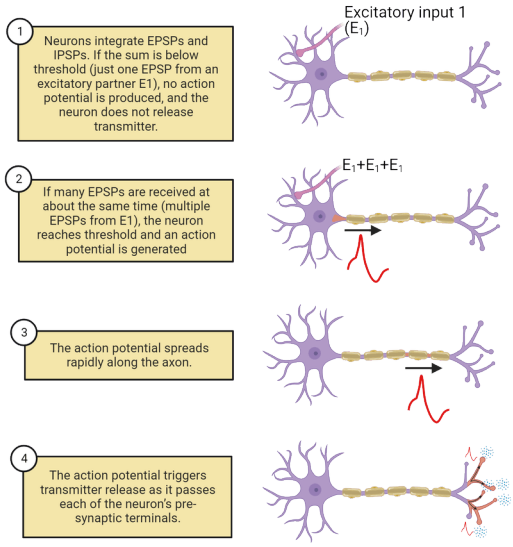

Figure 2.6 Action potential spread and neurotransmitter release

How does a neuron decide when to "fire" an action potential? Based, in part, on the constant barrage of chemical messages it is receiving on the post-synaptic side of its synaptic contacts. The EPSPs and IPSPs produced by these messages push a neuron above or below its threshold for generating an action potential (Step 1 in Figure 2.6). When the balance of excitation and inhibition being received is below a neuron's threshold, the neuron does not fire an action potential or release transmitter to its partner neurons. When the balance of excitation and inhibition rises above a neuron's threshold, it fires an action potential (Step 2 in Figure 2.6). The action potential spreads from the cell body along the length of the axon and all of its branches (Step 3 in Figure 2.6). As it spreads, the action potential is translated back into chemical messages, triggering the release of neurotransmitter from the pre-synaptic side of all the neuron's synaptic contacts (Step 4 in Figure 2.6). A neuron firing an action potential is said to be activated or excited, with each action potential producing a burst of chemical signals to its synaptic partners.

The more excitation a neuron receives, the more frequently it fires action potentials. But this doesn't make the action potential itself taller, stronger, or faster. Action potentials are 'all-or-nothing'—each action potential a neuron generates is basically just like every other. There can be, however, considerable diversity between neurons. For example, some neurons fire action potentials that spread very quickly; others fire action potentials that spread more slowly. In addition, neurons are highly dynamic. Experience, disease, and maturation can change a neuron's threshold, which synaptic partnerships it maintains, and more. For example, modulatory signaling in your nervous system is constantly fine-tuning action potential thresholds, lowering them to produce more activity during times of concentration and raising them to produce less activity during rest and sleep (more on this in Chapter 15 Biological Rhythms and Sleep).

Excitation and inhibition from partner neurons are not the only factors that determine when a neuron fires an action potential. Some neurons fire action potentials in response to changes in the outside world. We call these sensory neurons. In addition, most neurons in your nervous system generate action potentials spontaneously, meaning that they generate action potentials from time to time even without excitatory messages from partner neurons. For example, motor neurons, the neuron which release transmitter onto muscles, are often spontaneously active. This regular activity in your motor neurons maintains muscle tone (see Chapter 10 Motor Control). In spontaneously active neurons, EPSPs and IPSPs from partner neurons serve to speed up (when excited) or slow down (when inhibited) the rate at which action potentials are fired. In Figure 2.7 you can see an example of a sensory neuron (left) responding to the outside world and a spontaneously-active motor neuron (right) that changes its rate of firing to control muscle tension.

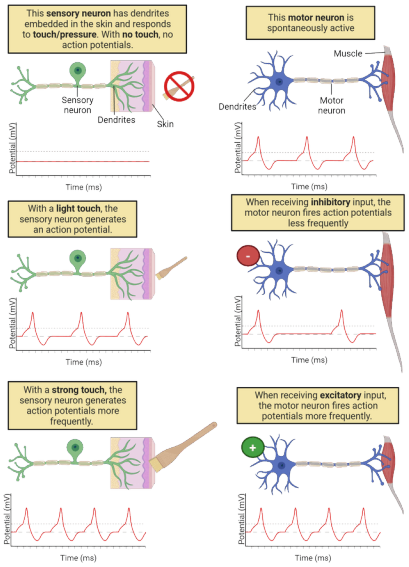

Figure 2.7 Internal and external triggers for action potentials

The electrical signaling system in neurons is relatively new in the history of life, emerging at the dawn of the Animal kingdom at least 500 million years ago (though with important precursors in other life forms; Anctil, 2015). Electrical signaling enables neurons to coordinate information throughout your body with speed and precision, something that would be difficult to do with chemical communication alone. For example, you have sensory neurons in your toe (Figure 2.8). The axons of these neurons ascend in your sciatic nerve to the base of your spine (depending on how tall you are, that can be a distance of up to 1 meter!). Pinch your big toe and you will trigger action potentials in your toe sensory neurons that spread to the spine within a couple of milliseconds, releasing transmitter onto partner neurons in the spine. Some of these partner neurons will send signals back down to the muscles of your leg and foot to cause muscle contractions to jerk your foot away from the pain. Other neurons will generate action potentials that spread rapidly to the brain, hopefully triggering you to question your life choices:

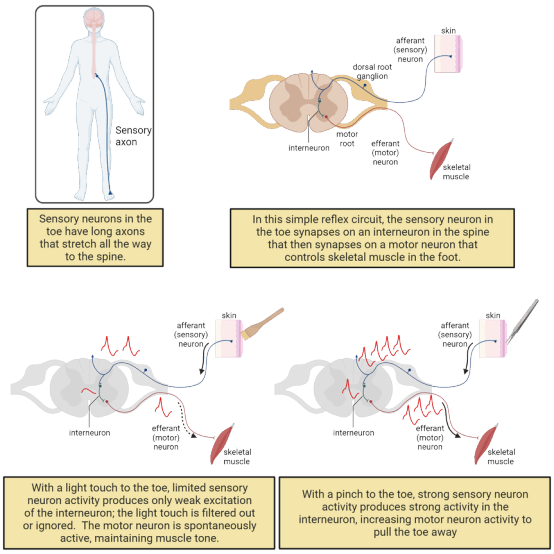

Figure 2.8 Simple reflex circuit

Why would you pinch your big toe? Just because your neuroscience textbook told you to? These circuits, showing neural circuit from sensory neuron to spinal interneuron to motor neuron, are diagrammed at the top of Figure 2.8.

Neurons don't just transfer information; they also process information. Each neuron synthesizes the excitation and inhibition received from thousands of synaptic partners, instantly tallying up these different influences to help determine when an action potential will be generated. In addition, the threshold for an action potential means that neurons filter information. Inputs that push a neuron above threshold produce action potentials, which then cause neurotransmitter release to partner neurons. Inputs

that do not reach threshold are essentially 'ignored' or filtered out. For example, recall again the toe-pinching experiment shown in Figure 2.8. The interneuron in that circuit filters out gentle stimuli, ensuring only painful stimuli produce a withdrawal. If your toe is only lightly touched (bottom left), there won't be very much sensory neuron activity, so the interneuron will receive some excitation but not quite enough to get to threshold. In that case, the interneuron does not fire an action potential, and the motor neuron never gets the message: the light touch is ignored. A strong pinch, though (Ow!), produces enough sensory activity to drive the interneuron to threshold (bottom right), and it passes along the message to the motor neuron, producing a behavior to get away from the painful stimulus. Thresholds give neural circuits the ability to ignore some events and respond to others, a key ability for using the body's energy wisely.

1.6.13.3: Neural Circuits

Learning Objectives

By the end of this section, you should be able to

- 2.2.1 Describe the rhythmic behavior produced by the simple swim circuit in *Tritonia diomedea*.
- 2.2.2 Define some of the key features of neural circuits: parallel processing, feedback, efficiency, and a careful balance between excitation and inhibition.
- 2.2.3 Describe the work of computational neuroscientists to build mathematical models of neurons and neural circuits.

As specialists in communication, neurons do not work on their own, but in interconnected groups, often called a neural circuit or a neural network. Even small numbers of neurons can generate remarkably complex behavior. To see this, let's examine a very simple neural circuit: the "swim" network in the sea slug *Tritonia diomedea*.

In the swim circuit of *Tritonia diomedea* a few neurons produce rhythmic behavior important for survival

Tritonia is a species of slimy mollusk that glides along the ocean floor off the west coast of the United States and Canada. The mortal enemy of a *Tritonia* is the Pacific sea star, a voracious predator that loves to dine on *Tritonia*. To avoid this fate, a *Tritonia* "swims" away if it feels the touch of a sea star. Well, actually the *Tritonia* kind of thrashes about, arching its back, then relaxing, then arching again, in a rhythmic motion that helps it move up into the ocean current. When the *Tritonia* stops swimming, it sinks back down to the ocean floor, hopefully far away from the hungry sea star. Check out a video of a *Tritonia* escaping a sea star here:

View this Interactive Content online

Researchers have found that *Tritonia* swim away from danger with the help of a relatively simple neural circuit (Willows and Hoyle, 1969; Getting, 1983), consisting of sensory neurons, motor neurons, a partner neuron, and an inhibitory neuron.

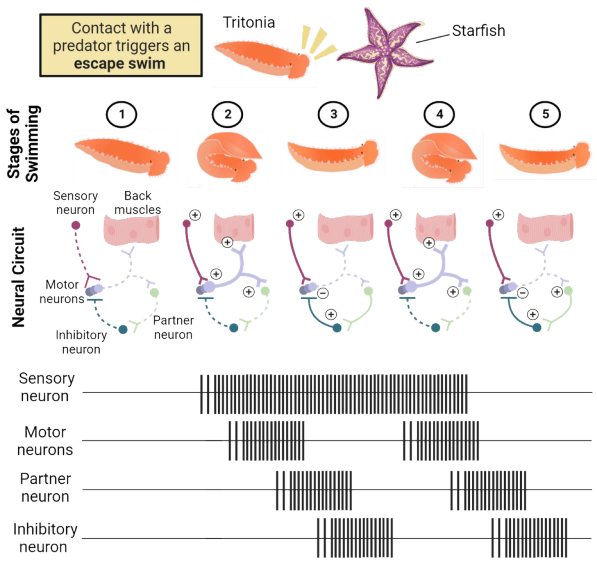

Figure 2.9 The swim circuit in *Tritonia diomedea* Image credit: Tamvacakis AN, Lillvis JL, Sakurai A and Katz PS (2022) The Consistency of Gastropod Identified Neurons Distinguishes Intra-Individual Plasticity From Inter-Individual Variability in Neural Circuits. Front. Behav. Neurosci. 16:855235. doi: 10.3389/fnbeh.2022.855235. CC BY 4.0

The sensory neurons in the skin are tuned to specific chemicals on the tentacles of the Pacific sea star. When these are detected, the sensory neurons become very excited, firing a long-lasting barrage of action potentials (Step 2 in Figure 2.9; each hash line represents an action potential). The sensory neurons release excitatory transmitter onto a set of 3 motor neurons which control the muscles of the back. When these motor neurons reach threshold they fire action potentials, contracting the back muscles to produce the arching movement that forms the first half of the 'swim' rhythm (a behavior that is cyclical or periodic).

This is not all the motor neurons do. They also release excitatory transmitter onto a partner neuron, which in turn excites an inhibitory neuron (Step 3 in Figure 2.9). This inhibitory neuron provides feedback to the circuit, inhibiting the motor neurons. When this happens, the inhibition overwhelms the excitatory input from the sensory neurons, and the motor neurons are pushed below threshold. With the motor neurons inactive, the back muscles relax and the *Tritonia* straightens out. At this point, it has arched back and then relaxed forward, completing a 'swim' rhythm.

Can you predict what will happen next? Stop and think about it for a moment. If you predicted that the whole cycle would begin again, you're spot on: with the motor neurons inactive, the partner neuron and, in turn, the inhibitory neuron are no longer being excited, so they stop firing action potentials and the motor neuron is released from inhibition. That means the long-lasting activity in the sensory neurons is again able to activate the motor neurons, producing another arching of the back (Step 4), followed by another round of inhibition that again relaxes the animal forward (Step 5 in Figure 2.9). The whole cycle repeats over and over again until the sensory neurons stop firing, which usually takes 10 to 30 seconds (far longer than the brief touch of the predator). Thus, just a few neurons in the *Tritonia* nervous system transform an outside event (a sea star touch) into a complex and long-lasting rhythm that 'swims' it away from danger.

The *Tritonia* swim network is not only rhythmic; it is also dynamic, changing based on the *Tritonia*'s experience. For example, if a *Tritonia* is injured, the sensory neurons become hyper-excitable, firing at a lower threshold and for longer times. This shifts the *Tritonia* to be more likely to swim and to swim more vigorously, hopefully protecting it from further injury (but also using precious energy). The swim network can also shift in the other direction. If a *Tritonia* is gently touched over and over again, the sensory neurons produce smaller and smaller EPSPs, and the network begins to ignore this gentle touch, learning that it does not pose a real danger (Brown, 1998; Hoppe, 1998). The dynamic nature of the swim network helps the *Tritonia* strategically allocate its energy based on its experiences—to swim away from real danger while also saving energy by ignoring events that are innocuous (meaning harmless or non-threatening).

Even though the *Tritonia* swim circuit is simple, it can still malfunction. If the connection to the inhibitory neuron is weakened, there will not be enough inhibition to pause activity in the circuit, and instead the circuit will produce constant activity that could lock up the back muscles, freezing the *Tritonia* in an arched position that will make it into an easy dinner. Too much inhibition is also problematic. If the inhibitory neuron releases too much neurotransmitter, the circuit would pause for too long, letting the animal drop back down to the ocean floor before it has managed to get away from the sea star. Generating the swim rhythm that keeps a *Tritonia* safe requires just the right balance between excitation and inhibition to keep the circuit moderately but not

excessively activated (Katz and Frost, 1997; Calin-Jageman et al., 2007).

Studying neural circuits reveals important principles about how nervous systems generate behavior

You probably never thought about the swimming behaviors of slimy mollusks before, but hopefully you found it exciting (pun intended!) to learn how just a few neurons can produce a life-saving behavior. One of the key goals of neuroscience is to uncover the secrets of more complex neural networks, such as the ones operating in your nervous system to produce language, emotions, and thought. There is still a lot we do not know, but even from the simple swim circuit of *Tritonia* we can glean a few key insights (Figure 2.10):

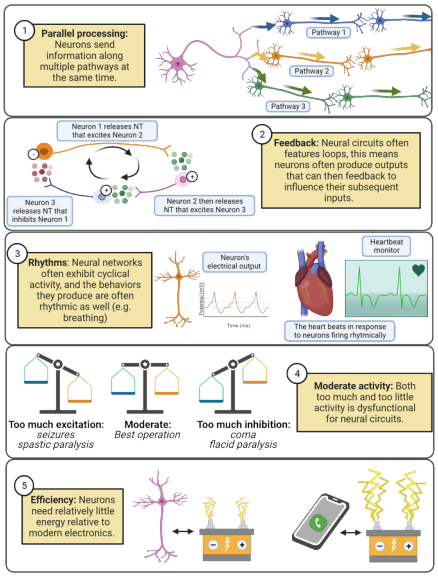

Figure 2.10 Five principles of neural networks

Neural networks feature parallel processing, meaning that information spreads along multiple pathways. In the *Tritonia* swim network, the motor neurons form synapses onto the muscles and onto a partner neuron that activates inhibition, sending messages along two distinct pathways at the same time.

Feedback, where a neuron influences the inputs it will later receive, makes even seemingly simple networks capable of producing complex patterns of activity.

Neural networks are often rhythmic or cyclical, exhibiting repeating patterns of activity and inactivity. This is reflected in the fact that many of our behaviors are also rhythmic: walking, sleep/wake cycles, breathing, and more. Chapter 15 Biological Rhythms and Sleep digs into detail on these fascinating cycles of neural activity.

Neural circuits can malfunction. They operate best at moderate levels of activity. They can easily be overwhelmed with excitation (which shows up in behavior as seizures or muscle spasticity) or inhibition (which shows up in behavior as torpor or muscle flaccidity). To work well, networks need both inhibition and excitation, and in the right balance.

Neural networks are highly efficient. *Tritonia* can swim away from danger with a network of less than a dozen neurons. Even with the large numbers of neurons in the mammalian nervous system, the efficiency of operation is incredible. Your entire brain uses about 20 watts of electrical power (Balasubramanian, 2021). For comparison, a modern Xbox or Playstation draws up to 160 watts of power. It is true that your brain uses a large fraction of your daily energy budget (about 500 kilocalories per day, or 25% of a typical 2,000 kilocalorie daily energy budget; Herculano-Houzel, 2012), but nervous systems are still remarkably efficient relative to the electronics around us.

What makes neural networks even more incredible is that they are self-assembled, following genetic and environmental signals to create and maintain the functioning of the network. How, exactly, this happens is still deeply mysterious. Chapter 5 Neurodevelopment explains some of what we've learned about how neural circuits assemble.

Scientists frequently express and check our understanding of natural phenomena by creating models and comparing our models to reality. This is the guiding principle for computational neuroscience, a diverse subfield of neuroscience dedicated to developing and exploring mathematical models of neurons and neural networks. Computational neuroscientists simulate neurons, meaning that they specify a set of mathematical rules to stand in for a real neuron, and then use computers to repeatedly apply those rules, producing data on how their models would perform under different conditions.

Some simulations use very simple models of neurons. For example, in an integrate-and-fire model, each "neuron" is represented in the computer as a set of inputs and a threshold, and there is just one simple rule: if the sum of a neuron's inputs is greater than its threshold it fires, sending a temporary input to its partners; otherwise, it stays silent. Even such simple simulations of neurons are capable of producing complex behaviors that can mimic the operation of real nervous systems, to some extent. Computational neuroscientists have also developed highly detailed models of neurons, where a complete 3-d reconstruction of a real neuron is simulated, sometimes even down to the level of individual molecules. Different levels of abstraction allow computational neuroscientists to test ideas about what aspects of neurons are especially important for different functions of the nervous system.

Many computational neuroscientists explore neural simulations simply to better understand the brain and to generate predictions which can then be tested experimentally. In addition, simulated neural networks have many practical applications. In fact, every time you ask Siri or Google to play some music, a simulated neural network is used to convert your spoken command into a text-based representation of your music choice that can then be played on your smartphone. Artificial neural networks have also become key technologies for processing images (that's how you can search for 'cute dogs' in your photostream) and are at the heart of AI technology like ChatGPT.

As computational neuroscientists become even more skilled at simulating neurons, they have begun exploring using their simulations to replace or repair parts of living nervous systems. For example, Rosa Chan at Hong Kong University is one member of a large team of collaborators who have been working to develop a neural prosthetic, a device that could replace or repair a part of the nervous system. In one set of studies, the researchers implanted a rat with electrodes to record some of the inputs and outputs to its hippocampus as it completed a memory task (Berger et al., 2011; Deadwyler et al., 2013). The researchers analyzed how the rat's real hippocampus works, and used these recordings to fine-tune a simulated hippocampus, tweaking it so that when given the real inputs from the rat their simulation generated similar outputs. This "simulated hippocampus" is diagrammed in the top of Figure 2.11.

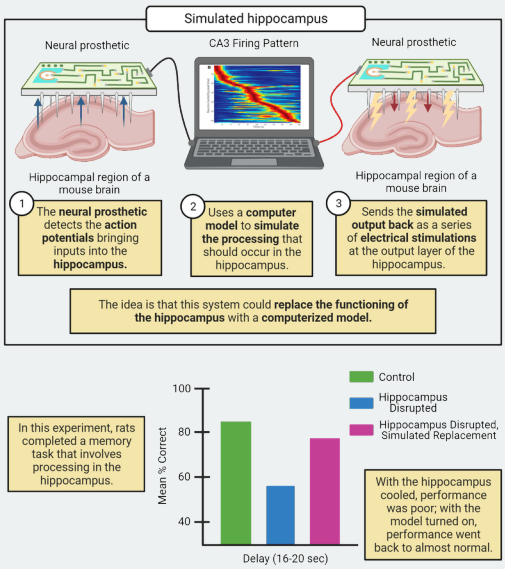

Figure 2.11 Simulated hippocampus and performance improvements Image credit: CA3 firing pattern image by Salz, D. M., Tiganj, Z., Khasnabish, S., Kohley, A., Sheehan, D., Howard, M. W., & Eichenbaum, H. (2016). Time cells in hippocampal area CA3. Journal of Neuroscience, 36(28), 7476–7484. https://doi.org/10.1523/jneurosci.0087-16.2016

To test the simulation, the researchers measured the rat's ability to complete a memory task that involves the hippocampus

(bottom of Figure 2.11). Under normal circumstances, the rats performed well (green bar in Figure 2.11). Next, the researchers temporarily shut down processing in the real hippocampus by cooling it, an intervention that disrupts activity in the hippocampus but not the inputs coming into it. When this happened, the rat began to fail the memory task (blue bar in Figure 2.11), as it no longer had help processing new memories from the hippocampus. Finally, the researchers "replaced" the rat's hippocampus with the simulation, feeding into it the inputs the real hippocampus should have been receiving and sending the simulation's outputs back into the rat's brain. Amazingly, the rat began to succeed at the memory task again (magenta bar in Figure 2.11), though not quite with the same accuracy as when its real hippocampus was available. Preliminary testing of this type of system is now underway with humans (Hampson et al., 2018). This incredible achievement takes us back to this foundational idea in computational modeling: the researcher's ability to simulate a hippocampus shows that they have understood something essential about what the hippocampus actually does. It's also an inspiring invitation into computational neuroscience: who knows what you could achieve or do by using computers to simulate the incredible power of neurons?

1.6.13.4: Principles of Bioelectricity

Learning Objectives

By the end of this section, you should be able to

- 2.3.1 Define fundamental concepts of electricity (current (I), conductance (G), and electrical potential (V)) and the inter-relationships between them defined by Ohm's law (I = GV).
- 2.3.2 List the 4 electrolytes in our cellular fluids (K^+, Na^+, Cl^-, and Ca^{2+}) that underlie most electrical currents in neurons and describe how the movement of each electrolyte is determined both by electrostatic force (opposites attract; likes repel) and diffusion (movement from high to low concentration).
- 2.3.3 Describe the major players controlling electrolyte movement: 1) the cell membrane, 2) ion pumps, and 3) ion channels.

In a chemistry lab at Harvard university, a team of researchers led by Adam Cohen is developing new ways to 'listen in' on the electrical signals in neurons (Kralj et al., 2012). One approach is the development of voltage-sensitive fluorescent proteins, genetically-engineered proteins that give off fluorescent light based on their electrical environment (Figure 2.12). When expressed in neurons, these proteins can translate the electrical signals in neurons into light that can be captured on a specialized camera. To test their work, the researchers carefully culture neurons, growing them in a dish where they can provide the nutrients the neurons need to survive plus the instructions for assembling the new voltage-sensitive proteins the lab has developed. One neuron is then placed under a fluorescent microscope equipped with a camera that can record 100,000 images per second. Adjusting the knobs on the microscope, the researchers bring a single neuron into focus. Then, they work intensely to keep the neuron healthy and the recording stable.

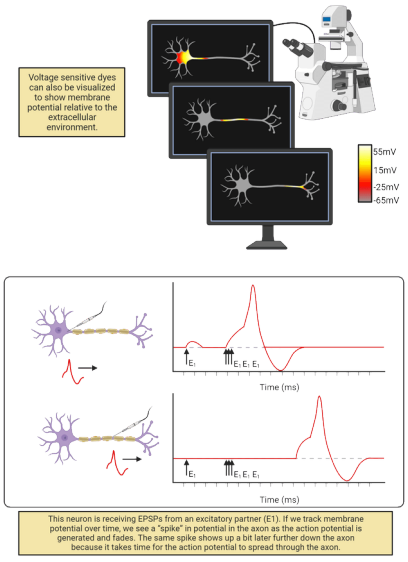

Figure 2.12

After several hours recording with the microscope (and several days processing all the data), the researchers assemble a remarkable video. Check it out here:

View this Interactive Content online

In the video, you can "see" the neuron generating action potentials. At first, there is no fluorescent signal in the neuron; it is at its negative resting potential and this does not activate the dye. Suddenly, though, we see a tiny glimmer of electrical change: the cell body has become positively charged! This region of positive charge then spreads out, traveling through every stem and branch of the neuron's complex axonal tree. As quickly as it spreads, the action potential also fades, so the whole neuron is quickly back to its normal negative resting potential. The video is slowed down, but the timer on the top-left of the screen shows that the rise-and-fall of the action potential occurs very quickly, in less than 1 millisecond. If we graph the intensity of the dye over time, we see that each branch of the axon experiences this rapid "spike" in voltage, flipping from negative to positive and back again (bottom of Figure 2.12).

Watching this video, you are witnessing action potential propagation, the spreading of an action potential that relays information from one end of a neuron to another at great speed. But, you may be wondering: what, exactly, am I seeing? What does it mean to say that an action potential is electrical? Is the electricity in a neuron the same as what is coursing through your cell phone? If so, how do neurons generate their own electricity? To answer these questions, we first need to get our footing with some fundamental concepts of electricity. Then we'll see how ion pumps and ion channels enable neurons to generate signals via the controlled movement of four electrolytes dissolved in your cellular fluids: sodium (Na^+), potassium (K^+), chloride (Cl^-), and calcium (Ca^{2+}).

As you read, you'll see that this section (and the next) throws a lot of numbers at you. Don't stress about memorizing these numbers. First, all the numbers in this chapter are approximate; the actual figures vary from neuron to neuron, and from species to species. More importantly, the numbers in this chapter are not for rote memorization but for thinking and building context. For example, in a section below you'll read that the peak of an action potential reaches an electrical potential of about 40 mV. When you read that number, don't waste time repeating it over and over again (you won't have to know that exact number for the exam, I promise). Instead, seek some points of comparison to build your understanding. For example, a AA battery has an electrical potential of 1,500 mV and a wall outlet in the U.S.A. has an electrical potential of 120,000 mV. From thinking about these numbers you quickly understand that action potentials are much weaker than the potentials that power our electronics. Putting numbers in context (rather than just memorizing them) produces nummarcy rather than stress. So read on, ready to be engaged by, rather than intimidated by, the quantities you are about to encounter.

Fundamentals of electricity: Charge, current, conductance, and potential

Electricity is the movement of charge. Charge is a fundamental property of sub-atomic particles: electrons have a negative charge; protons have a positive charge. For reasons even physicists don't completely understand, charges exert force on one another: opposites attract and likes repel (Figure 2.13).

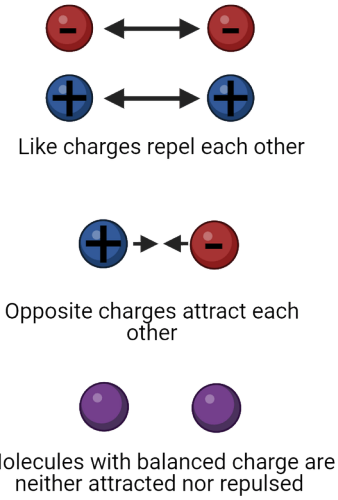

Figure 2.13 Electrochemical force

If a molecule has equal numbers of protons and electrons, then its net charge is 0 and the molecule is electrically neutral. When a molecule has an imbalance of protons and electrons, though, it is said to carry a charge, meaning that it has a net positive or negative charge that will exert electrostatic force on other charged particles. We call a charged particle an ion. In physics, charge is given the symbol Q and measured in coulombs.

Forces induce movement. Because of the electrostatic forces between them, ions move towards their opposites and away from their likes, if they can. The movement of ions is an electrical current. It is this movement of charge that we call electricity. Anywhere we see work being done by electricity there must be a current flowing: a light bulb glows as electrical current flows through its light-emitting diode, your laptop responds to your commands as electrical current surges through its transistors. In physics, the symbol for current is I. We measure electrical currents in amperes (often shortened to amps), which tells us about the rate at which charge is flowing (number of Coulombs of charge per second).

When an electrical current flows, the path it takes can impede the movement of the ions or it can allow an easy passage. We call this conductance. Physicists use the symbol G for conductance, which is measured in siemens. For example, water has a fairly high conductance, meaning that charged particles in water can rapidly respond to electrostatic forces, moving to disperse from their likes and to unite with their opposites. Cell membranes, on the other hand, have very low conductance, and act as insulator. (If you've had a physics class that discussed resistance rather than conductance, don't panic: these are the same idea but expressed from different perspectives. Conductance is a measure of how easy it is to move charge; resistance is a measure of how difficult it is to move charge. You can convert back and forth between conductance and resistance: $G = \frac{1}{R}$; $R = \frac{1}{G}$.)

By acting as an insulator, cell membranes can hold electrostatic forces "in check", holding ions in place even if electrostatic forces are pushing to move them. We call this pent-up energy electrical potential; it is a push or pressure just waiting to generate a current should a conductive pathway become available. In physics, the symbol for electrical potential is V, and it is measured in volts. You'll often hear electrical potential referred to as voltage. Technically, this mixes up the unit (volt) with the concept (electrical potential), but the term has become so popular that we can accept voltage as a synonym for electrical potential.

Current, conductance, and potential are inter-related: Math input error

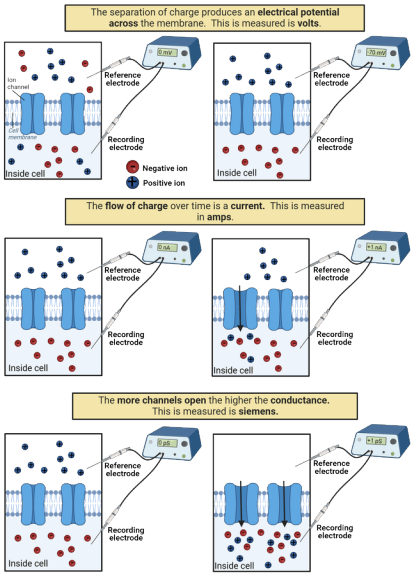

Figure 2.14 Ohm's law

This relationship is known as Ohm's law. This means the electrical current that flows in a system is determined by the product of the conductance (how easy it is for charge to move) and the potential (how much pressure there is for charge to move). You can use algebra to re-arrange Ohm's law to solve for different electrical concepts (for example, $V = I/G$ is also Ohm's law); this is because in all of its forms Ohm's law expresses the idea that potential, conductance, and current are inter-related in such a way that knowing any two of these values instantly tells you the third.

Electrical signaling in neurons involves changes in potential and can be measured with a voltmeter

Electrical signaling in neurons involves changes in current, conductance, and potential. The easiest of these to measure in neurons, though, is potential. Because of this, scientists first characterized and named the electrical signals in neurons in terms of electrical potential: the resting potential, excitatory and inhibitory post-synaptic potentials, and the action potential.

We can measure a neuron's membrane potential by connecting it to a voltmeter, a device for measuring electrical potential (Figure 2.15). All that is needed is a voltmeter and two wires, or electrodes. For neurons, this usually means placing one wire, called the recording electrode, inside the neuron, and a second wire, called a reference electrode, outside the neuron. The voltmeter measures the electrical potential between these two points, indicating the difference in charge across the neuron's membrane, its membrane potential. For neurons, this is usually reported in millivolts (mV). A negative membrane potential (as a neuron has at rest) indicates the inside of the neuron has a net negative charge relative to the outside of the neuron. A positive membrane potential (as a neuron has at the peak of an action potential) indicates the neuron has a net positive charge relative to the outside. A membrane potential of 0 volts would indicate no imbalance of charge: the neuron is electrically neutral relative to the reference electrode.

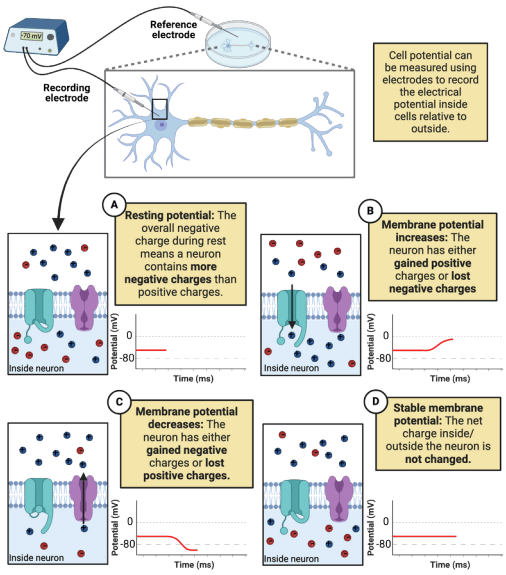

Figure 2.15 Measuring changes in neuronal membrane potential with a voltmeter

In some ways, neurophysiology, the recording of electrical signals from neurons, is no different than when a mechanic checks the charge on your car's battery. There are some huge technical difficulties, though, including the challenge of trying to place the tip of an electrode inside a microscopic neuron (!). The methods section in this book explains some of the specialized equipment that is used to make neurophysiology possible (see Chapter 2 Neurophysiology).

If you get your car battery checked at an auto shop, you will observe a stable potential (unless something has gone very wrong). In contrast, membrane potential in neurons is highly dynamic: it is negative at rest (Part A in Figure 2.15), becomes slightly more positive during an EPSP, becomes slightly more negative during an IPSP, and flips to positive and back to negative during action potentials. Because of this, we graph membrane potential as a function of time. When a neuron's membrane potential increases, it means a current has flowed that either brought positive charge into the neuron or that removed negative charge (Part B in Figure 2.15). When a neuron's membrane potential decreases, a current has flowed that either brought negative charge into the neuron or removed positive charge (Part C in Figure 2.15). When a neuron has a stable membrane potential, there is no net current, maintaining the neuron's current charge (Part D in Figure 2.15). The currents that flow in neurons are typically quite small and are usually reported in nanoAmps (nA).

Another complexity of neural electricity is that membrane potential varies over the length of a neuron's dendrites and axons. EPSPs and IPSPs alter membrane potential right at the synapse. Action potentials travel down the axon, with one segment flipping to a positive potential and then the next and then the next. Thus, we have to keep track of not only how membrane potential changes over time but also *where* membrane potential is changing.

Voltage-sensitive dyes enable us to measure potential along an entire neuron at once, so we can see the locations of different signals and how they spread (Figure 2.12). In contrast, a voltmeter can only measure membrane potential at the exact location of the recording electrode. Because of this, the first recordings of action potentials captured only the up and down of electrical potential at a single point, showing up as a "spike" in the membrane potential recording. The spread of an action potential had to be deduced from systematically moving the electrode along the length of the axon. When you see an action potential "spike" from a voltmeter, try to keep in mind that it is just a limited view of what is actually an electrical wave that spreads through the axon.

Electrical currents in neurons are the movement of four electrolytes dissolved in your cellular fluids: Na^+, K^+, Cl^-, and Ca^{2+}

What are the moving charges that generate electrical currents in neurons? They are trace minerals dissolved in your intracellular and extracellular fluids (Figure 2.16). Nearly all electrical signaling in neurons is due to the movement of just 4 minerals: sodium (chemical symbol Na^+), potassium (chemical symbol K^+), calcium (Ca^{2+}) and chloride (Cl^-). Notice the positive and negative symbols next to the chemical symbols. That is because each is not only a mineral but also an electrolyte, something that dissolves into water as an ion, a charge-carrying molecule. Because electrolytes dissolved in water carry a charge, their movement is an

electrical current. It is the movement of Na^+, K^+, Cl^-, and Ca^{2+} into and out of neurons that we observe as electrical signals in neurons.

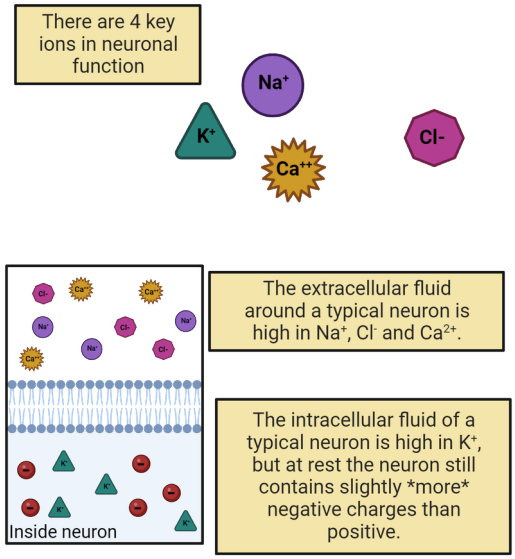

Figure 2.16 Key electrolytes for neuronal signaling

In the next section, we'll examine the pressures that drive this movement: electrostatic force and diffusion. Before we move on, you might be wondering: where do electrolytes come from? The K^+, Na^+, Cl^-, and Ca^{2+} dissolved in your cellular fluids come from your diet. For example, bananas are loaded with K^+. You lose electrolytes in your urine and in your sweat, so you need daily intake from your diet to keep the proper balance of electrolytes in your body. That's why sports drinks are always promising to "replenish your electrolytes"—they are selling you sugar water supplemented with a few milligrams of these basic minerals (though some leave out the calcium). Electrolytes are essential not only for generating neural electricity, but for nearly all cellular processes, including transcription and translation. This reflects the ancient origins of life in the Earth's oceans: the Na^+, K^+, Cl^-, and Ca^{2+} dissolved in your cellular fluids are the same trace minerals found in salt water and are ubiquitous (ever-present) in all cellular forms of life. At the dawn of the animal kingdom, new mechanisms evolved to harness electrolytes for a new function: neural signaling.

Electrolytes are moved by electrostatic force and diffusion but their movement is blocked by the cell membrane

What moves the molecules of electrolytes dissolved in your cellular fluids? Two things: electrostatic force and diffusion (Figure 2.17).

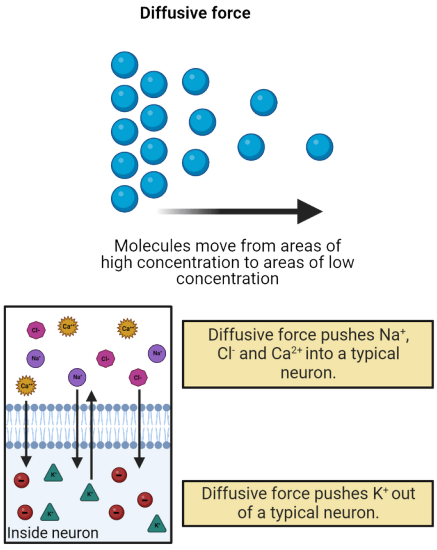

Figure 2.17 Diffusion

We've already discussed electrostatic force. Every molecule of Na^+, K^+, Ca^{2+}, and Cl^- dissolved in your cellular fluids carries a charge. Because of this, each is subject to electrostatic forces that push them towards their opposites and away from their likes.

Because they are dissolved in water, your electrolytes also diffuse, spreading out, as much as possible, towards equal concentration. The rules of diffusion are simple: when possible, solutes will always move down a concentration gradient, spreading from a region of high concentration to a region of low concentration, movement that would eventually produce equal concentrations. The steeper the concentration gradient (the more different the concentrations between regions) the stronger the push of diffusion.

Diffusion and electrostatic force sum and can produce strong pressure on ions to move. Water has a high conductance, so diffusion and electrostatic force easily move ions around inside your cellular fluids. The cell membrane, on the other hand, has a low conductance; ions cannot move directly through the cell membrane. Thus, a molecule of K^+ inside a neuron cannot directly leave the neuron, even if electrostatic force and diffusion are pushing it to do so. You could say that the cell membrane is the Gandalf of neural signaling ("You shall not pass!"), but being that corny could lose you friends.

If the membrane blocks electrolyte movement, how do they travel into and out of neurons, generating the currents that carry signals in neurons? All ion traffic occurs via transmembrane proteins—amino acid machines that stick through the membrane. In the next sections we'll discuss two families of proteins that control the movement of electrolytes: ion pumps and ion channels.

Ion pumps create concentration-gradient batteries, concentrating K^+ inside neurons and Na^+, Ca^{2+}, and Cl^- outside

For your cell phone to work, it needs a battery, something that can generate a steady electrical potential to push electrical currents through the circuits in your phone. Neurons also have batteries. They use ion pumps to create concentration gradients of the electrolytes found in your cellular fluids (Figure 2.18).

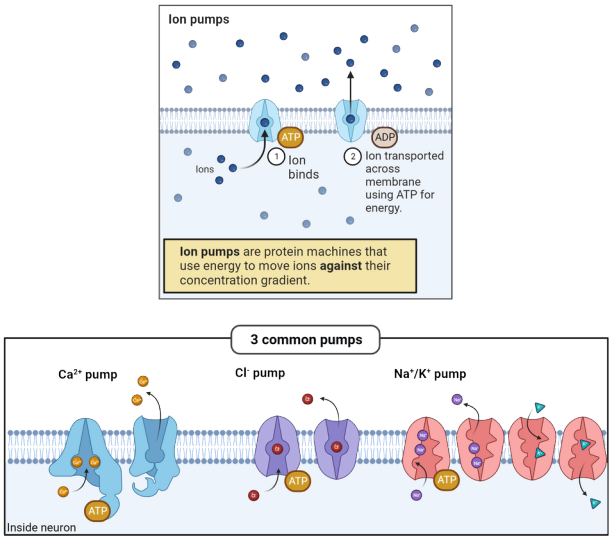

Figure 2.18 Ion pumps

All the cells in your body express ion pumps, specialized proteins that stick through the membrane. Pumps use the energy-molecule ATP to actively transport ions across the cell membrane, working against diffusion to concentrate ions inside or outside of the cell. These concentration gradients are chemical batteries, giving each ion a distinct "push" from diffusion. The bottom of Figure 2.18 shows several of the most prominent ion pumps that help maintain the concentration gradients for the 4 major electrolytes. For example, one type of pump pushes Ca^{2+} out of the cell. Once pushed outside the cell, Ca^{2+} cannot directly re-enter (because the cell membrane acts like Gandalf). Thus, pumps cause calcium to become much more concentrated in the extracellular fluid than in the intracellular fluid. The specific concentration gradient can vary in different tissues, but in your brain most neurons have about 10,000x the concentration of Ca^{2+} outside the cell membrane compared to inside (Erecińska and Silver, 1994). This represents a strong push of diffusion for Ca^{2+} to enter cells, a positive current.

Like Ca^{2+}, Cl^- and Na^+ are also pushed out by ion pumps. In neurons, Cl^- is usually 20x more concentrated outside the cell membrane compared to inside, and Na^+ typically about 7x more concentrated. Thus, both Na^+ and Cl^- have a pressure of diffusion to enter cells.

K^+ stands out as the only major electrolyte pumped into cells. In neurons K^+ is usually ~25 times more concentrated in the intracellular fluid than in the extracellular fluid. This means that there is a constant pressure of diffusion for K^+ to leave cells, a negative current. Table 2.1 summarizes the concentration gradients pumps create for each of the electrolytes that play a key role in neural signaling.

Name	Symbol	Typical intracellular concentration	Typical extracellular concentration	Typical concentration gradient (outside to in)	Equilibrium potential	Pressure of diffusion
Sodium	Na^+	26	182	7 to 1	+52 mV	Pressure for Na^+ to enter, a positive current
Calcium	Ca^{2+}	0.0001	1	10,000 to 1	+124 mV	Pressure for Ca^{2+} to enter, a positive current
Chloride	Cl^-	7.45	149	20 to 1	-81 mV	Pressure for Cl^- to enter, a negative current

Name	Symbol	Typical intracellular concentration	Typical extracellular concentration	Typical concentration gradient (outside to in)	Equilibrium potential	Pressure of diffusion
Potassium	K^+	85	3.4	1 to 25	–87 mV	Pressure for K^+ to leave, a negative current

Table 2.1

Notice an interesting balancing act in the actions of the pumps. They import K^+ into the neuron, filling the neuron with positive charge. This is mostly offset, however, by the fact that the pumps expel Na^+ and Ca^{2+} from the neuron, removing those positive charges. In fact, if we tally up all the Na^+ and Ca^{2+} and Cl^- outside the neuron against all the K^+ inside we end up very close to an even balance sheet in terms of both concentration and charge (though not quite even, as we'll discuss in the section on the resting potential). Thus, pumps, on the whole, do not directly charge the membrane, and they do not upset the important balance of net electrolyte concentrations that all cells must maintain.

What pumps do achieve is the build-up and maintenance of strong concentration pressures that the cell membrane can then hold in place: Na^+ and Ca^{2+} are just raring to charge the neuron to a positive potential, K^+ and Cl^- stand ready to charge the neuron to a negative potential. Note that K^+ and Cl^- are both on "team negative" despite having different charges; this is because K^+ has a pressure to leave but Cl^- has a concentration gradient to enter.

Ion channels are selective but passive conductors; some ion channels are gated

Look inside a laptop and you'll see a tangle of wires, pathways of high conductance that allow electrical currents to flow. What are the 'wires' that carry electrical currents into and out of a neuron? It's not the cell membrane, which has a low conductance. Instead, neurons (and all other cells) express ion channels (Figure 2.19). Ion channels are proteins that stick through the membrane. Each has a water-filled central pore through which specific ions can flow with high conductance. Ion channels allow currents of electrolytes to flow into and out of neurons.

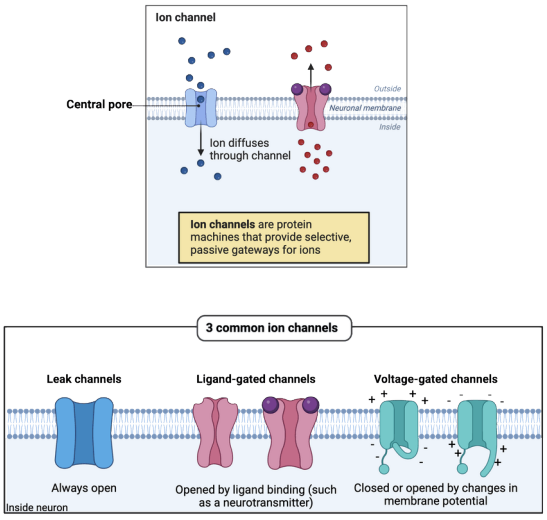

Figure 2.19 Ion channels

Unlike pumps, ion channels are passive. Any ion that fits through an ion channel is "free" to move through it in either direction. The channel does not add any "push" or use energy to direct the flow of ions. Instead, ion movement through channels is determined purely by the pressures operating on that ion (diffusion and electrostatic force). Table 2.2 gives a summary comparison between pumps and channels.

	Ion Pump	Ion Channel
Biomolecule	Protein	Protein
Selective	Yes, each type of pump binds to and moves only specific electrolytes	Yes, each type of channel has a selectivity filter that allows only specific electrolytes to pass
Uses ATP	Yes	No
Central pore	No	Yes
Ion movement	Active transport— moves ions against their concentration gradient	Passive channel— central pore allows ions to move based on the electrostatic pressure and diffusion

Table 2.2

Although ion channels are passive they are nevertheless selective. Some channels are conductive only to Na^+; they are called Na^+ channels. Other channels are only conductive to K^+; they're called K^+ channels. As you can probably already guess, there are also Ca^{2+} channels and Cl^- channels.

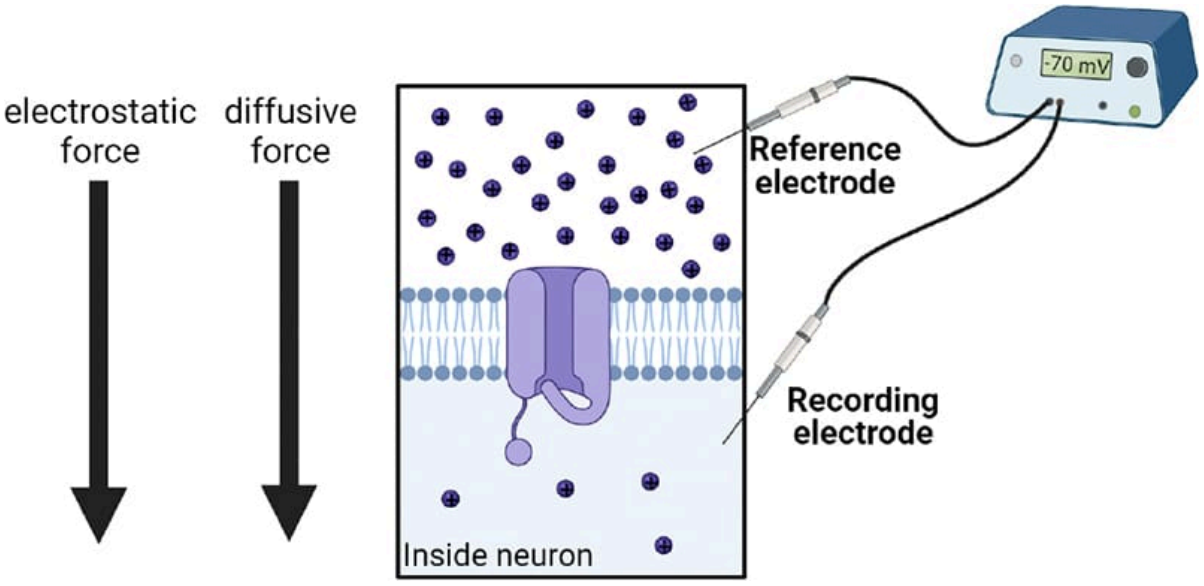

Figure 2.19 shows 3 common types of channels in the bottom panel. Some ion channels, called leak channels, are simply a pore with a selectivity filter—they provide a constant selective conductance. Other ion channels are gated, meaning that they can switch from open (a conformation with a high conductance) to closed (a conformation with a low conductance).

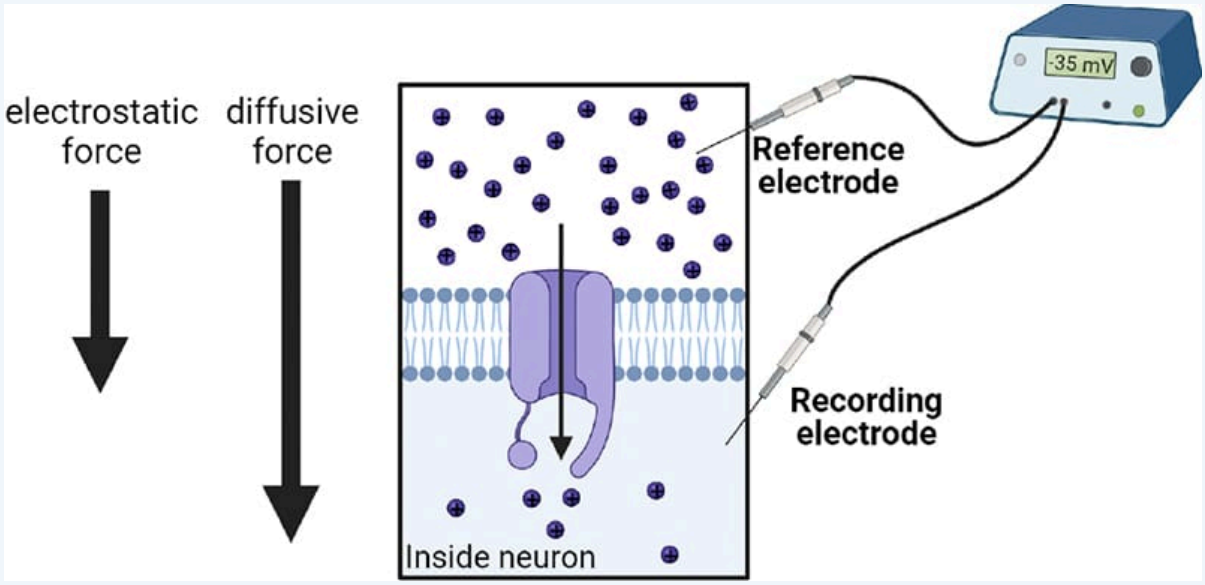
Gated channels don't just open and close willy-nilly —they have sensors, specialized sections of their protein structure that determine when they open and when they close. For example, ligand-gated ion channels have sensors that bind to specific neurotransmitters, opening the channel only when the right transmitter is present. Voltage-gated ion channels have sensors that detect electrical events in a neuron, opening the channel only when the neuron reaches a specific membrane potential. This is just the tip of the iceberg. Other chapters will introduce you to channels that respond to many different events from the outside world (light, physical pressure, chemicals, and more). For this chapter, we'll focus in on 3 families of ion channels that are critical for neural signaling: 1) leak K^+ channels that produce the resting potential, 2) ligand-gated channels that produce EPSPs and IPSPs, and 2) voltage gated Na^+ and K^+ channels that produce the action potential.



Ionic Currents and Equilibrium Potentials

Pumps create concentration gradients that act like chemical batteries, storing up pressures of diffusion for Na^+, Ca^{2+}, and Cl^- to enter neurons and K^+ to leave. What happens when an ion channel is open, providing a pathway to release that pressure? We get a current, the flow of ions into or out of a neuron. This current charges the neuron, changing its membrane potential.

Let's think about this in detail (Table 2.3).

At rest, Na^+ is high outside the neuron. Both electrostatic and diffusive forces pull Na^+ in but it cannot flow with no channels open.

Na^+ channels open. Electrostatic and diffusive forces pull Na^+ in the cell rapidly. This increases the membrane potential, weakening the elctrostatic attraction for Na^+.

	As the neuron's potential becomes more positive, electrostatic repulsion starts to push Na^+ out of the cell. At +52 mV, diffusion pushing Na^+ in the cell is equally opposed by electrostatic repulsion pushing Na^+ out.

Table 2.3

Imagine a neuron at rest (top of Table 2.3). Its membrane potential is negative, around -70mV, meaning that it has an excess of unpaired negative charges in the intracellular fluid. Pumps have concentrated Na^+ outside the neuron, but it cannot re-enter directly through the membrane. What happens if Na^+ channels now open? Na^+ will come flowing in: it is pulled in both by the pressure of diffusion (going from the high concentration outside the neuron to the lower concentration inside) and by electrostatic force (positive Na^+ is attracted to the negative charge in the neuron). Each molecule of Na^+ that enters, though, offsets some of the neuron's negative charge, so the membrane potential begins to rise (middle of Table 2.3). If Na^+ channels stay open, the neuron will eventually become neutral (its membrane potential will rise to 0mV); this occurs when enough Na^+ has entered to fully offset all the negative charges that had given the neuron a negative resting potential. At this point, there is no longer any electrostatic pull for Na^+ to enter, but there is still a strong pressure of diffusion, so Na^+ will continue to enter, charging the neuron up to a positive potential. Will this continue forever? No: as the neuron becomes more positive it becomes increasingly repulsive to Na^+ (likes repel), and eventually this electrostatic force will be able to stand up to the pressure of diffusion, preventing any further increase in Na^+ (bottom of Table 2.3). We call this the equilibrium potential. An ion's equilibrium potential depends (mostly) on the concentration difference created by the pumps: the bigger the concentration difference the more charged the neuron has to become before electrostatic force can stand up to it. For Na^+ in a typical neuron, the equilibrium potential is about +52mV. That is: when Na^+ channels open in a resting neuron, Na^+ will rush in and keep rushing in until the neuron is charged up to +52mV, but at that point it will stop further charging the neuron even if the Na^+ channels remain open.

When Na^+ enters the neuron through a Na^+ channel, is all the hard work of the pumps undone? To some extent, yes, but not by much. Amazingly, only a few thousand Na^+ molecules have to enter a neuron to charge it from rest to +52mV, a small fraction of all the Na^+ the pumps have pushed out of the neuron. This is because the neuron is small and the membrane is very thin: each ion inside a neuron has little space to spread out and is held tantalizingly close to opposite charges on the other side of the membrane. So, when Na^+ channels open, Na^+ rushes in to charge the neuron to the Na^+ equilibrium potential (around +52mV) but this "spends" relatively little of the concentration gradient pumps have worked so hard to create.

What happens when there is a K^+ channel open? The pressure of diffusion is for K^+ to leave a neuron, and this departure is a negative current that builds a negative charge for the neuron. As the neuron becomes more and more negative, though, there is an increasing electrostatic attraction for K^+ to come back in (opposites attract), and eventually this electrostatic charge can stand up to the pressure of diffusion for K^+ to leave. In a typical neuron, the equilibrium potential for K^+ is around -87mV, meaning that when K^+ channels are open K^+ brings the neuron's charge to a very negative potential. Again, though, only a small fraction of all

the K^+ in the neuron has to leave to charge a neuron to this point.

Table 2.1 lists the equilibrium potential for all 4 of the important electrolytes in neural signaling. These numbers are not there to memorize but to help you build some context and understanding. Focus especially on the last column: Na^+ and Ca^{2+} generate currents that pull a neuron up to positive potentials while Cl^- and K^+ generate currents that pull a neuron down towards negative potentials. Keeping those general trends in mind is key for understanding how resting, post-synaptic, and action potentials are generated.

1.6.13.5: Mechanisms of Neural Signaling

Learning Objectives

By the end of this section, you should be able to

- 2.4.1 Explain how the resting potential is generated and defended primarily by leak K^+ channels, which allow a constant but slow K^+ current to pull the neuron towards the negative equilibrium potential for K^+.
- 2.4.2 Understand the role of ligand-gated ion channels in producing EPSPs and IPSPs, the small, transient, changes in membrane potential that represent the receipt of transmitter from partner neurons.
- 2.4.3 Describe how the action potential is generated by the sequential opening of voltage-gated inactivating Na^+ channels (allowing Na^+ in to produce the rising phase, but which then clog) and voltage-gated K^+ channels (which allows K^+ to depart, accelerating the falling phase and producing the undershoot).

Before we took our deep dive into bioelectricity, we marveled at a video that used voltage-sensitive dyes to let us “see” action potentials spreading rapidly through a neuron. We’re now ready to unravel this fascinating signal, to learn about the incredible interplay of pumps, channels, and ions that allow each of your 86 billion neurons to generate the constant barrage of electrical signals that make you who you are. We’ll start by exploring the resting potential, then we’ll examine how this rest is perturbed by EPSPs and IPSPs imposed by synaptic partners. Finally, we’ll dissect the action potential and its rapid spread throughout the axon to produce transmitter release.

Table 2.4 gives a bird’s eye view of everything we’ll cover, breaking down the properties of the resting potential, post-synaptic potentials, and the action potential. Take a look at the table now if you want an overview to guide your reading, or dig into the details first and come back to the table to organize your thoughts at the end.

Electrical signals in neurons	Description	Magnitude	Where	Key channels
Resting potential	Overall negative membrane potential maintained throughout a neuron when it is not receiving signals or generating an action potential	Around –60 to –80 mV, depending on the neuron	Global: the whole neuron maintains a negative potential	Leak K^+ channels and Leak Na^+ channels
EPSP	Brief, transient local increase in membrane potential due to detection of transmitter from a partner neuron	a 1-2 mV **increase** in membrane potential	Local: occurs right at the synapse	Transmitter-gated Na^+ channels
IPSP	Brief, transient local decrease in membrane potential due to a detection of transmitter from a partner neuron	a 1-2 mV **decrease** in membrane potential	Local: occurs right at the synapse	Transmitter-gated Cl^- channels
Action potential	Rapid flip in membrane potential from negative to positive and back that spreads rapidly through a neuron, triggering transmitter release at each of the neuron's synapses as it passes	Rapid increase in membrane potential to about +40mV (Rising Phase), then rapid decline to rest (Falling Phase) and even temporarily 5-10 mV **below** typical rest (Undershoot)	Traveling: usually initiated at the first segment of the axon then travels through all branches of the axon	Inactivating voltage-gated Na^+ channels and non-inactivating voltage-gated K^+ channels

Table 2.4

The resting potential is produced by leak channels and concentration gradients

The resting potential is an overall negative charge maintained by a neuron, typically around -65mV (though the exact value varies from neuron to neuron and can change). Neurons are sometimes said to “defend” their resting potential, meaning that after any stimulation they have a strong tendency to return quickly to rest. Neurons are not alone in having a resting potential—most of the cells in your body also maintain an overall weak negative charge.

The resting membrane potential is primarily due to the concentration-gradient for K^+ (more inside than out) and special ion channels called leak K^+ channels. As their name suggests, leak K^+ channels are selective for K^+ and always open (Figure 2.20).

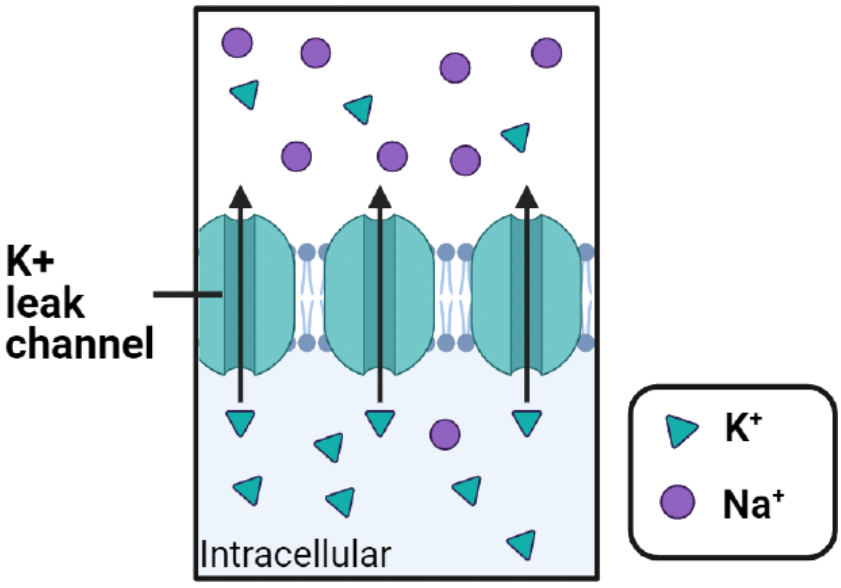

Figure 2.20 Neurons weakly express leak K^+ channels; these provide a constant but weak conductance for K^+ currents to charge the neuron to a negative potential.

Recall that pumps concentrate K^+ inside a neuron. On its own, this might seem like it would make the neuron positive: after all, it’s full of K^+! But remember that the pumps also expel Na^+ and Ca^{2+}, so from the pumps alone the neuron ends up close to neutral (equal numbers of charges inside and out). But then the leak K^+ channels come into play: they provide a constant conductance to release part of the pressure of diffusion the pumps have created for K^+. Currents through the leak channels allow some K^+ to leave, charging the neuron towards the negative equilibrium potential for K^+. Not all of the K^+ leaves, though, because as the neuron gets more and more negative, that negativity creates a pull back into the neuron, creating an equilibrium (no net movement). That’s why neurons are negative at rest: from a starting point of relative balance, a small number of K^+ ions have left through leak channels, giving the neuron an overall negative charge. The number of K^+ ions that leaves is so small, though, that K^+ remains much more concentrated inside that out.

Not only do leak K^+ channels allow K^+ to produce a negative charge on a neuron, they allow the neuron to keep returning to that negative charge. Figure 2.21 shows how this works.

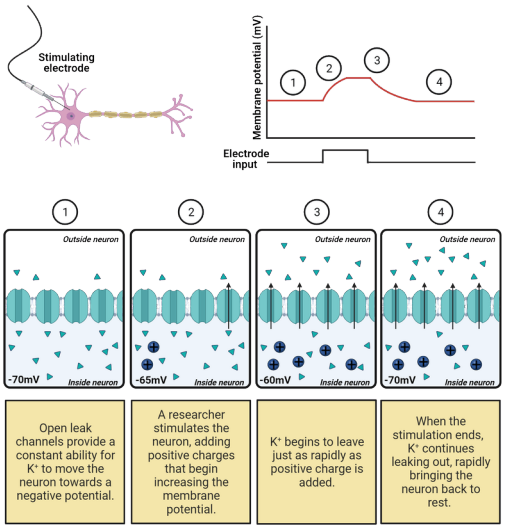

Figure 2.21 Leak channels defend the resting potential

For a neuron at rest (step 1), the K^+ leak channels have allowed a few molecules of K^+ to leave the neuron, leaving the inside of a neuron with a negative charge. Imagine we now make the neuron more positive by using an electrode to inject some positive charges (step 2). This upsets the balancing act between diffusion and electrostatic force for K^+; the electrical pull into the neuron is now weaker (because the neuron is not as negative) so the push of diffusion to eject K^+ temporarily "wins", expelling a few more molecules of K^+. Thus, the leak channels allow K^+ to work against the positive current we are injecting and limit the degree we can charge the neuron (step 3). When we stop injecting current (step 4), K^+ continues to depart until it pulls the neuron right back down to its normal resting potential. This is what we observe as the "defense" of the resting potential: the leak K^+ channels provide a constant conductance that always allows K^+ to pull the neuron's membrane potential back towards the negative equilibrium potential for K^+.

If leak K^+ channels allow K^+ to work against changes to a neuron's membrane potential, how can there still be EPSPs, IPSPs, and action potentials? Shouldn't K^+ flow through leak channels to instantly cancel out any change in a neuron's charge? The answer is that leak K^+ channels are only weakly expressed in neurons; there are relatively few of them embedded in each neuron's membrane. This low conductance keeps the flow of K^+ fairly slow, so it does work against changes in membrane potential, but not instantly.Interestingly, neurons can change their excitability by changing how many leak K^+ channels they have: the more leak channels expressed the more rapidly a neuron returns to rest and the harder it is to get it to threshold; the less leak channels a neuron has the easier it is for the neuron to reach threshold and fire action potentials.

Post-synaptic potentials are produced by ligand-gated channels

At the beginning of the chapter we found that neurons don't just rest; they chatter away, firing action potentials that release chemical messages that excite (EPSP) or inhibit (IPSP) their partners (see 2.1 Neural Communication). Each EPSP and IPSP is a small, temporary change in the membrane potential that is produced because neurotransmitter has been released by a synaptic partner. EPSPs and IPSPs are like "Yes" and "No" votes that determine if a neuron will get to threshold and fire an action potential. We'll get to the action potential in the next section. For now we consider: how do chemical messages from a partner neuron get translated into the electrical "votes" we observe as EPSPs and IPSPs?

EPSPs and IPSPs are produced by ligand-gated ion channels (Figure 2.22).

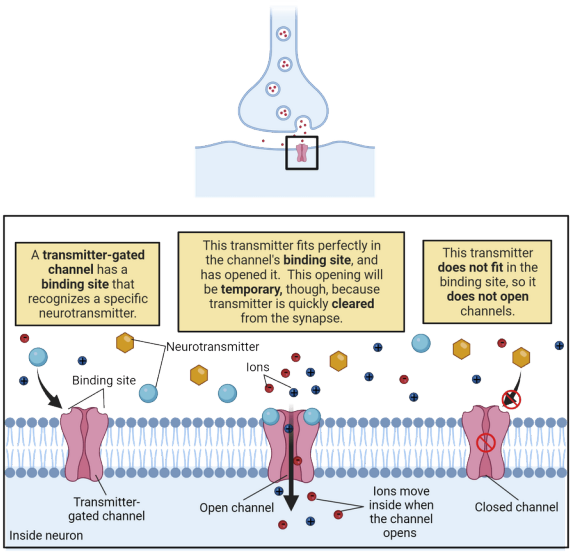

Figure 2.22 Ligand-gated channels

These are transmembrane proteins with a central pore. Each has an external binding site that recognizes a specific neurotransmitter. When a molecule of neurotransmitter fits into the binding site the channel is pulled open; when no transmitter is present, the channel stays closed. The post-synaptic side of each synapse is studded with hundreds of ligand-gated ion channels, so each burst of transmitter release from the pre-synaptic neuron produces a temporary but substantial opening of channels on the post-synaptic membrane, translating the chemical transmitter signal into a sharp change in conductance that allows current to flow.

There is tremendous diversity in ligand-gated ion channels, with the human genome containing genes encoding several hundred ligand-gated ion channels (Viscardi et al., 2021). Part of this diversity is due to differences in binding sites, with different receptors specialized for detecting different neurotransmitters. Chapter 3 Basic Neurochemistry will discuss the different classes of neurotransmitters and their receptors in more detail.

What happens when a ligand-gated ion channel opens? That depends on its selectivity. If the channel is selective for Cl^-, the channel produces IPSPs (top of Figure 2.23).

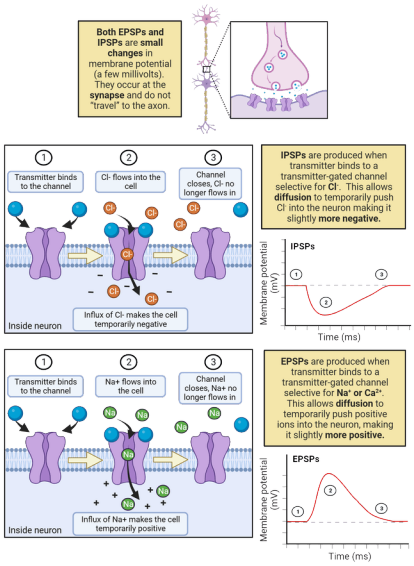

Figure 2.23 EPSPs and IPSPs

That is because in a neuron at rest there is pressure for Cl^- to enter the neuron (see Table 2.1). The higher outside concentration

of Cl^- enables diffusion to push Cl^- through the open ligand-gated channels, producing a negative current that decreases the neuron's membrane potential, moving it further away from the threshold for generating an action potential.

If the channel is selective for Na^+ or Ca^{2+}, the channel produces EPSPs (bottom of Figure 2.23). That is because both Na^+ and Ca^{2+} carry a positive charge and are more concentrated outside the neuron than in, giving them a strong pressure to enter a neuron at rest. Therefore, an increase in conductance for these ions provides an opportunity for diffusion to produce a positive current that moves the neuron's membrane potential towards threshold.

As you'll have noticed, there are multiple steps for an EPSP or IPSP to be produced: transmitter has to be expelled from the pre-synaptic neuron, diffuse across the synaptic cleft, and then bind to a ligand-gated channel (Figure 2.4). Only then does the post-synaptic neuron begin to get the influx of Na^+, Ca^{2+}, or Cl^- that creates an EPSP or IPSP. This multi-step process creates a "synaptic delay", a gap of up to 5 ms between the partner neuron firing the action potential and the post-synaptic neuron exhibiting the EPSP or IPSP. This time penalty for converting from electrical message (action potential) to chemical message (neurotransmitter) and back again (EPSP or IPSP) is one of the key factors limiting how quickly we can respond to outside events.

Once an EPSP or IPSP finally gets started, it very rapidly ends, usually within just 1ms. The transient (short-lived) nature of EPSPs and IPSPs is due, in part, to the fact that the neurotransmitter released by partner neurons is rapidly inactivated and recycled. As neurotransmitter is cleared from the synapse, the ligand-gated channels close. A second limiting factor are the K^+ leak channels: almost as quickly as Na^+ or Cl^- can enter to produce an EPSP or IPSP, leak channels allow K^+ to undo that work and pull the neuron back towards the neuron's normal resting potential. Thus, each message from a partner is processed but quickly cleared; this keeps neurons tuned to the here and now (though neuromodulation and neuroplasticity enables long-term changes in the nervous system). Each synaptic message leaves the neuron with a few ions "out of place" (e.g. some extra Cl^- inside with each IPSP). Pumps work continuously to put things back to normal. The constant need for pumps to reset ion concentrations is why they consume a large portion (about 28%) of your brain's energy budget (Lennie, 2003).

Another notable feature of EPSPs and IPSPs is that they are usually quite small relative to a neuron's threshold. For example, in a human cortical neuron, a single EPSP is estimated to increase the membrane potential at the soma by only 0.3 mV, whereas the threshold for generating an action potential usually requires about a 30mV increase in potential (Eyal et al., 2018).

If each partner message is so small, how does a neuron ever reach threshold? The answer is that EPSPs and IPSPs summate over space and over time. Figure 2.24 shows how summation works.

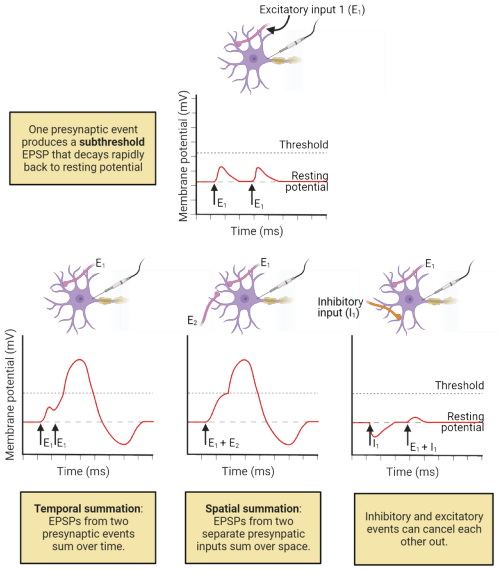

Figure 2.24 Temporal and spatial summation

At the top of the figure we see a neuron receive an EPSP from a partner neuron (E1) that is subthreshold, meaning it is too small to take it to threshold. This partner neuron can try again later (second arrow labeled E1), but the result is the same: poor E1 is being ignored by its synaptic partner! Things change, though, if E1 fires action potentials more rapidly (bottom left of Figure 2.24), delivering the second EPSP before the first one has fully faded. In this case, a second round of Na^+ or Ca^{2+} can enter before

the postsynaptic neuron has returned to rest from the first EPSP, and this overlap brings the neuron much closer to threshold. We call this temporal summation because it adds up EPSPs from the same partner that occur close together in time. Neurons can only fire so fast, though. A far more effective way to get a partner neuron to threshold is to team up with its other inputs. As shown in the middle part of Figure 2.24, if a neuron receives EPSPs from two different partners (E1 and E2) at the same time this creates a bigger EPSP than either could produce on its own. We call this spatial summation because it sums inputs from multiple locations across a neuron's dendritic tree. Of course, neurons aren't just tallying the "yes" votes of EPSPs: IPSPs also factor in, summing with ongoing EPSPs to pull the neuron away from threshold (bottom right of Figure 2.24). Synaptic summation is just the simple addition and subtraction of charges, and yet it is what underlies the incredible ability of neurons to synthesize and integrate information.

The key point for synaptic summation is the axon hillock (also called the initial segment). The hillock is the very first part of the axon where action potentials are initiated, so this is where the sum of current EPSPs and IPSPs can tip a neuron past threshold. It's worth reflecting again that most EPSPs and IPSPs make a very small impact on the axon hillock relative to its threshold: it is estimated that it would typically require the summation of about 100 EPSPs to trigger an action potential in a resting human cortical neuron (Eyal et al., 2018). That sounds like a lot, but keep in mind that a typical cortical neuron has about 7,000 synaptic contacts! Thus, receiving 100 excitatory messages at about the same time is a fairly common occurrence, though not so common that your cortical neurons are relentlessly activated.

The action potential is produced by sequential opening of voltage-gated Na^+ and K^+ channels.

The action potential is a rapid up-and-down of electrical potential that spreads through a neuron to trigger transmitter release. Figure 2.25 diagrams each step of the action potential.

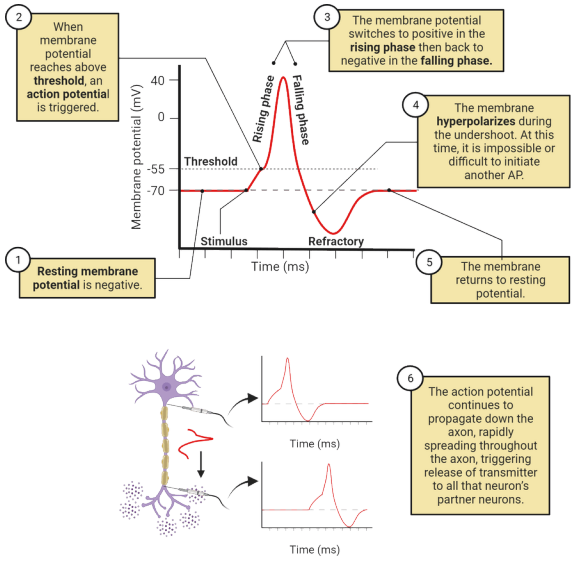

Figure 2.25

We start with a neuron at its typical negative resting potential (step 1) that then receives excitation strong enough to bring the neuron to threshold (step 2). Once at threshold, the action potential is initiated, starting in the cell body or right where an axon branches off from the cell body, a point called the initial segment or axon hillock (these terms are interchangeable). We observe the action potential as a rapid and dramatic rise and fall of electrical potential (step 3). During the rising phase (step 3), the neuron's membrane potential flips from negative all the way up to a positive potential of around 40mV (though this varies from neuron to neuron). In a typical cortical neuron this upward climb in potential takes only about 0.5ms. This is followed immediately by the falling phase, when the neuron's membrane potential descends just as quickly, falling back down to a negative potential and becoming even more negative than during the typical resting potential, often reaching about -85mV. The descent "below" rest is called the undershoot (step 4), and it takes a typical cortical neuron about 4-5 ms to gradually return to the typical resting potential (step 5). Critically, this same rise, fall, and undershoot then occurs a bit further down the axon, then even further down, and so on. As the action potential propagates down the axon, it triggers transmitter release at each presynaptic membrane it passes.

The action potential is due to the operation of two specialized ion channels that are relatively unique to neurons: inactivating voltage-gated Na^+ channels and non-inactivating voltage-gated K^+ channels.

Inactivating voltage-gated Na^+ ion channels are highly expressed in neurons, and are often inserted in the cell membrane specifically within the initial-segment and axon. Scientists classify these channels as voltage-gated because they have a sensor that holds them closed when a neuron is near its negative resting potential, but that pulls them open when a neuron's membrane potential rises to threshold. A better name, though, would be excitation-sensing because it is excitation (EPSPs) from partner neurons that makes a neuron's membrane potential positive enough to begin opening these channels. This gating of the voltage-gated Na^+ channels is what we observe as the threshold for an action potential.

Figure 2.26 shows how the inactivating voltage-gated Na^+ channels produce the rising phase and propagation of the action potential.

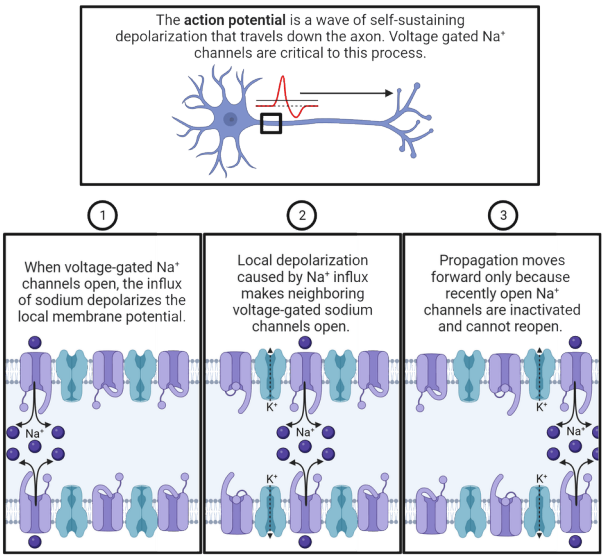

Figure 2.26 Action potential propagation

When threshold is reached, these channels open (step 1), producing a sharp increase in conductance for Na^+: there are now many pathways available for diffusion to push Na^+ into a neuron (recall that pumps have concentrated Na^+ outside the neuron, so the pressure of diffusion is for Na^+ to enter, see Table 2.1). The result is a rapid influx of Na^+ that quickly pulls the neuron's membrane potential all the way up to a positive membrane potential. This is what we observe as the rising phase of an action potential.

The rising phase of the action potential propagates down the axons because the opening of one voltage-gated Na^+ channel produces a chain reaction (step 2 in Figure 2.26). The first voltage-gated Na^+ channel to open allows Na^+ to enter, causing an increase in membrane potential—the very thing that can trigger the opening of more voltage-gated Na^+ channels! This positive-feedback loop, where each Na^+ channel that opens can help trigger additional openings causes the action potential to propagate down the axons, triggering transmitter release at all that neuron's pre-synaptic terminals along the way.

Although the rising phase on an action potential propagates through the axon, it is very brief, followed very quickly by a plunge back down to a negative potential. One factor limiting the rising phase is the inactivation of the voltage-gated Na^+ channels. Each channel has a "tail" of positively charged amino acids on the intracellular side of the membrane. When these channels open and drive a neuron to a positive potential, the tail is repelled, and this repulsion actually pushes it into the channel, clogging it! Even though the voltage-sensor is still pulling the channel open (because the neuron has a positive membrane potential), the inactivating tails temporarily eliminates the Na^+ conductance through these channels (step 3 of Figure 2.26).

The clogging of the inactivating voltage-gated Na^+ channels is reversible. When a neuron returns to a negative resting potential, that negative charge attracts the positive charges in the inactivating tails, pulling them out of the Na^+ channels so that they can work again. This amazing system helps prevent excessive activity in the nervous system: once a neuron generates an action

potential, it cannot generate another until it returns to rest and the majority of its voltage-gated Na^+ channels are unclogged. We observe this as a brief refractory period that occurs immediately after each action potential (recall, again, step 4 of Figure 2.25).

Figure 2.27 recaps these steps in the action potential, showing how a neuron goes from rest (step 1) to the rising phase (step 2) as the inactivating voltage-gated Na^+ channels open, but then clog (step 3). With the clogging of the voltage-gated Na^+ channels, Na^+ can no longer enter the neuron. This means the leak K^+ channels can now begin restoring the resting potential, allowing K^+ to leave (it is more concentrated outside than in, and during the rising phase is also repulsed by the neuron) to bring the membrane potential back down to a negative potential. We observe this as the falling phase of the action potential.

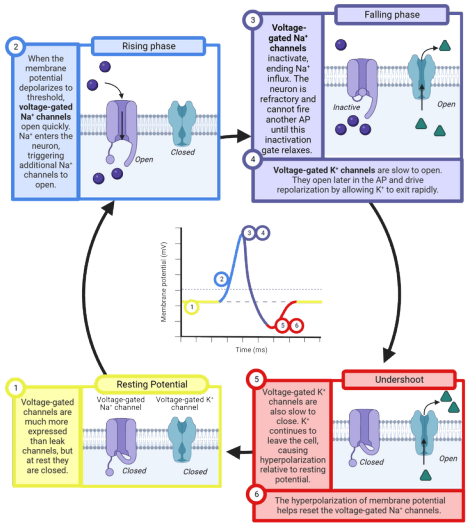

Figure 2.27 Action potential generation

The falling phase is “turbo charged” by voltage-gated K^+ channels. These channels are somewhat similar to the voltage-gated Na^+ channels: they have a sensor that detects increases in the membrane potential, swiveling them open when there is sufficient excitation. When these channels are open, they provide additional conductance for K^+ above and beyond what is provided by the leak K^+ channels. This allows K^+ to be more rapidly pushed out of the neuron by diffusion, accelerating the falling phase (step 4 of Figure 2.27). You can think of K^+ as soccer fans trying to leave a stadium after a match. Everyone could be anxious to leave, but if there are only a few exits it will take a long time for the stadium to empty. The opening of the voltage-gated K^+ channels is like adding a bunch of new exits to the stadium, allowing a much more rapid departure of the crowd. Without the voltage-gated K^+ channels, it would take a typical neuron about 2-3 times as long to return to rest after an action potential, and that would greatly limit the frequency at which neurons can send messages.

Although the voltage-gated K^+ channels respond to excitation in the same way that Na^+ channels do, they are different in two key ways. First, the K^+ channels do not inactivate—they stay open as long as the neuron has a positive charge, working continuously to allow K^+ to depart to drive the neuron back down to its negative resting potential. A second distinctive feature is that the voltage-gated K^+ channels are slow—their voltage sensor takes longer to open and to close the channels than the sensor on the voltage-gated Na^+ channels. This “tardiness” is important, causing the K^+ channels to only begin opening just as the Na^+ channels are beginning to clog. This remarkable feat of timing makes the action potential extremely efficient, limiting the overlap between the increases in Na^+ and K^+ conductance that happen during the rising and falling phases. If the K^+ channels opened earlier, K^+ would be able to diffuse out of the neuron as quickly as the voltage-gated Na^+ channels were allowing Na^+ to diffuse in, an offsetting current that would produce no signal in the membrane potential!

A second consequence of the slow operation of the voltage-gated K^+ channels is the undershoot (step 5 of Figure 2.27). Even after the neuron begins to return to a negative charge, it takes a few milliseconds for the K^+ channels to swivel closed. During this time, K^+ continues to be able to leave the neuron, making the neuron temporarily more negative than usual. This is what we observe as the undershoot phase (step 6). The enhanced negative charge of the undershoot phase helps to unclog the voltage-

gated Na^+ channels, ending the refractory period (step 6). Ending the refractory period means the neuron is now capable of firing another action potential (the voltage-gated Na^+ channels have been reset), and yet the undershoot makes this a bit less likely than usual by keeping the neuron a bit further from threshold for a few milliseconds. Thus, the undershoot both prepares the neuron for sending the next message while also helping to ensure the neuron isn't hyper-active. What a clever system!

Table 2.5 provides another way of organizing all this information, providing an overview table of what is happening in each phase of the action potential.

Channel	Expression	Resting potential	Beginning of EPSP	Rising phase	Falling phase	Back to resting potential
Channels						
Leak K^+ channels	Weakly expressed throughout neuron	Open	Open	Open	Open	Open
Transmitter-gated Na^+ channels	Only expressed at synapses	Closed	Open	Closing	Closed	Closed
Inactivating voltage-gated Na^+ channels	Strongly expressed through axon	Closed	Closed	Opening	Inactivated	Closed
Non-inactivating voltage-gated K^+ channels	Strongly expressed through axon	Closed	Closed	Opening	Open	Closed
Membrane potential						
Membrane potential		Around –65 mV	Rises several mV, triggering voltage-gated Na^+ channels	Rises to around +40 mV	Falls, even more negative than rest	Around –65 mV

Table 2.5

We see that each action potential is a sequential opening of voltage-gated Na^+ channels and voltage-gated K^+ channels, progressing down an axon and into all its synaptic terminals. The rapid opening of the voltage-gated Na^+ channels allows the pressure of diffusion to rapidly push Na^+ into the neuron, driving it from its negative resting potential all the way up to a positive potential that then opens the next voltage-gated Na^+ channel and the next and the next, all the way down the axon. The voltage-gated Na^+ channels clog, however, stopping the rising phase, and just as this happens the voltage-gated K^+ channels finally open, allowing the pressure of diffusion to push K^+ out of the neuron, a negative current that rapidly brings the neuron back down to its negative resting potential and even temporarily making the neuron more negative than usual. Each action potential, then, lets a bit of Na^+ into the neuron and a bit of K^+ out, undoing some of the hard work of the ion pumps. It's a surprisingly small amount of Na^+ and K^+ that actually shuffles around, producing only a fractional change in concentrations. Still, ion pumps have to continuously operate to undo the Na^+ entry and K^+ departure that occurs with each action potential, otherwise the pressures of diffusion would gradually dissolve away and action potentials could no longer be generated (see 2.5 Our Deep but Still Incomplete Understanding of Neural Signaling for an interesting example of how this can happen).

Action potential propagation is sped up by myelin

When you connect a battery to a wire, it pushes current directly through the circuit. As long as the wire is properly insulated, almost no current leaks out as it travels, so you don't need additional batteries along the length of the wire, and current covers the distance of the circuit at very close to the speed of light. That's why flipping a light switch instantly turns on your lights, even though the power station might be located several miles away.

As we have seen, that's not exactly how an action potential propagates. Instead, neuronal axons are "leaky", expressing leak K^+ channels. This means that when the first segment of an axon experiences the rising phase, the Na^+ that rushes in can quickly be offset by K^+ rushing out. Due to this leak, the action potential is regenerated down the length of the axon, with each segment undergoing the precise opening and closing of voltage-gated channels that triggers the next segment, and so on. This takes time, and it means that the action potential does not travel down the axon at anything near the speed of light.

Many animals, including all mammals, have evolved ways to speed up action potential propagation by having support cells wrap axons in myelin, a fatty substance that insulates the axon, greatly limiting the operation of the leak channels (Figure 2.28).

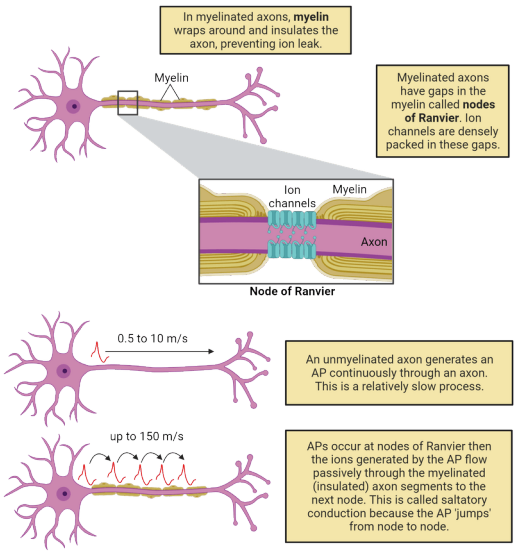

Figure 2.28 Saltatory conduction

A segment of axon wrapped in myelin works more like the wires we're used to dealing with in electronics: a current applied to one end can spread rapidly, at almost the speed of light, with fairly little leakage. That's a great speedup in the spread of an action potential. Unfortunately, myelin isn't perfect, and there is still some leakage, so it can only effectively deliver currents over relatively short distances, around 1mm. Because of this, myelin is wrapped around axons in bands and between these bands are nodes of Ranvier, bare patches of axon crowded with voltage-gated channels that can regenerate the action potential and push current through the next band of myelin. The mix of relatively slow regeneration (at each node of Ranvier) and exceptionally fast current spread (through each segment of myelin) is called saltatory conduction, and it lets action potentials travel fast, at speeds of up to 150 meters per second (333 miles per hour). That's very slow compared to the currents in your cell phone, which approach the speed of light (almost 300 million meters per second or 670 million miles per hour). But it's still much faster than action potentials can travel in bare, unmyelinated neurons, which typically ranges between 0.5 to 10 meters per second (1 to 22 miles per hour).

Wrapping axons in myelin requires support cells and energy, so not all axons in the CNS are myelinated. But most tracts, where axons from many neurons carry information over long distances feature almost exclusively myelinated axons. The high density of fatty myelin in these tracts is what gives white matter its distinctive appearance (see Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy).

1.6.13.6: Our Deep but Still Incomplete Understanding of Neural Signaling

Learning Objectives

By the end of this section, you should be able to

- 2.5.1 Give examples of how our understanding of neural signaling has helped us understand specific medical conditions.
- 2.5.2 Describe some of the ways neural signaling is complex and still mysterious.

This is a long and difficult chapter. That's because neuroscientists have succeeded in unraveling some of the important principles of neural communication. Moreover, what we covered was complex. Our understanding of neural signaling now ties together multiple levels of understanding, from physics (potential, current, and conductance), to chemistry (Na^+, K^+, Ca^{2+}, and Cl^-), to biology (pumps, channels, membranes), providing a detailed and rich understanding of how neurons and their circuits process information. Whew!

In this section, we'll tackle three topics. First, we'll examine the power of understanding neural signaling, looking at examples of how that understanding has helped unravel long-standing medical mysteries. The last two sections provide some humble pie: first, by noting some of the additional complexity to neural signaling that was not discussed in this chapter, then by describing some of the many mysteries of neural signaling that still remain to be explored. Hopefully, this chapter will leave you with a sense of pride in your hard-won understanding of neural signaling and also with a sense of wonder for all there is left to learn.

Neuroscience helps us understand dysfunctions of the nervous system

Although getting your head around neural signaling can be exhausting, it is also rewarding, providing us with a powerful framework for understanding the function and dysfunction of the nervous system.

Think back to the beginning of this chapter, to Dr. Q and his work to understand how a cancerous glioma can leave a patient with epilepsy even after the glioma is removed. Dr. Q's team has found that the uncontrolled growth of the glioma provokes surrounding neurons to increase their production of VGLUT1, a protein that helps load excitatory transmitter into synaptic vesicles. If you've made it through this chapter, you can now understand the excitement Dr. Q's team felt when they made this discovery, and why they think it might explain the previously mysterious link between gliomas and seizures. If neurons make more VGLUT1, we should expect more excitatory transmitter loaded into each synaptic vesicle. That would mean more transmitter released for each action potential. That should produce more activation of the ligand-gated Na^+ channels that produce EPSPs, and that should mean larger EPSPs, letting each of the affected neurons be more likely to drive their partner neurons to fire action potentials, perhaps past the tipping point towards a seizure. That's still just a theory that will require much more exploration, but you can see how our understanding of neural signaling gives us a foothold for understanding (and possibly treating) dysfunctions of the nervous system.

Here are four more examples of how our understanding of neural signaling helps us better understand dysfunctions of the nervous system.

Pumps and the Resting Membrane Potential. The "Poison Arrow Plant" (*Acokanthera schimperi*) found in eastern Africa contains a powerful toxin, ouabain, which causes heart arrhythmia, seizures, and, in strong enough doses, death (Figure 2.29).

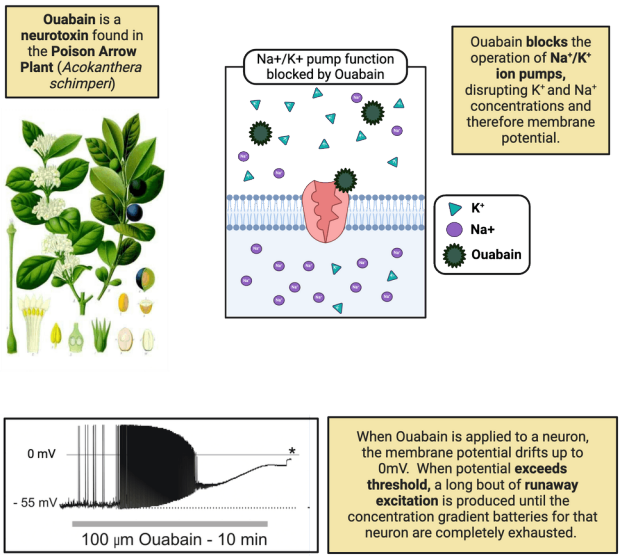

Figure 2.29 Ouabain blocks Na^+-K^+ ion pumps Image credits: Image of plant By Franz Eugen Köhler, Köhler's Medizinal-Pflanzen - List of Koehler Images, Public Domain, https://commons.wikimedia.org/w/inde...p?curid=255485; Image of trace by Brisson CD, Lukewich MK, Andrew RD (2013) A Distinct Boundary between the Higher Brain's Susceptibility to Ischemia and the Lower Brain's Resistance. PLoS ONE 8(11): e79589. https://doi.org/10.1371/journal.pone.0079589. CC BY 4.0

The plant seems to produce this toxin as an adaptation to prevent animals from eating it. As the name of the plant suggests, though, the plant gained traditional uses making poison-tipped arrows, and there is even a species of African rat that anoints itself with the plant to protect itself! What makes ouabain so deadly? It turns out that it can bind to and stop ion pumps, especially those that maintain the high concentration of K^+ inside a neuron. With the pumps stopped, the K^+ concentration battery becomes progressively depleted. It is this concentration gradient in conjunction with the leak K^+ channels that produces the resting potential, so as the concentration gradient for K^+ fades, the resting potential becomes less and less negative, meaning that neurons are now "resting" ever closer to threshold (Miura and Rosen, 1978). As you might imagine, this breakdown of the resting potential leads to the runaway excitation that manifests itself in seizures, and erratic heart rate, and spastic paralysis (paralysis due to muscles locking up).

Ligand Gated Ion Channels and Post-Synaptic Potentials. Childhood absence epilepsy is a form of epilepsy that emerges early in life (4-8 years) and is associated with frequent staring spells (Figure 2.30).

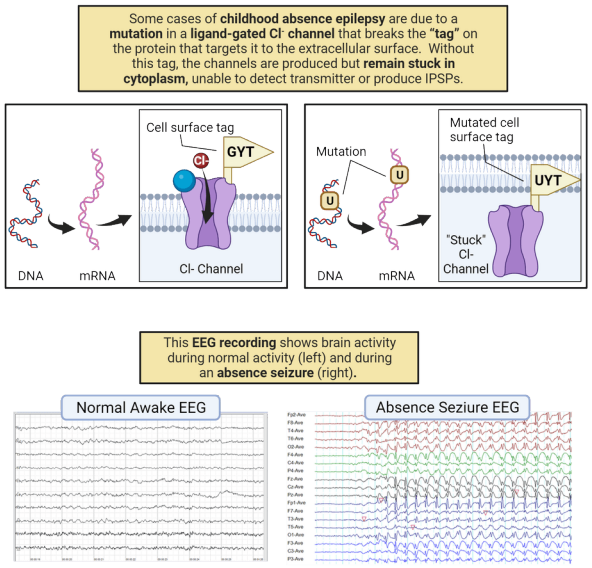

Figure 2.30 Childhood absence epilepsy and mutations in ligand-gated Cl^- channels Image credits: Absence seizure EEG Image by Seneviratne, U., Cook, M. J., & D'Souza, W. J. (2017). Electroencephalography in the diagnosis of genetic generalized epilepsy syndromes. Frontiers in Neurology, 8. https://doi.org/10.3389/fneur.2017.00499 CC BY 4.0; Normal EEG image By Andrii Cherninskyi, CC BY-SA 4.0, https://commons.wikimedia.org/w/inde...curid=44035072

While this frequent "absence" from paying attention or responding to the outside world was once blamed on the child, each staring spell is actually a small-scale seizure. Genetic sequencing has shown that childhood absence epilepsy is often related to genetic mutations in one of the genes coding for a ligand-gated Cl^- channel, a type of channel that normally helps produce IPSPs (Hirose, 2014). The most common disease-causing mutation is one that alters a special "tag" that helps target the channel to the neuronal membrane. With the mutated tag, the channels are manufactured by ribosomes, but remain in the cytoplasm, where they cannot detect transmitter from partner neurons and cannot generate IPSPs. It is this impairment of inhibition that likely leads to the runaway excitation that manifests as seizures.While childhood absence epilepsy can usually be treated with drugs that boost inhibition, most children grow out of this condition over time, a happy reminder that nervous systems can often adapt to maintain a proper balance of inhibition and excitation.

The Inactivating Voltage-gated Na^+ Channels and the Action Potential. Puffer fish (fish from the family *Tetraodontidae*) are adorable, but most are highly toxic (Figure 2.31).

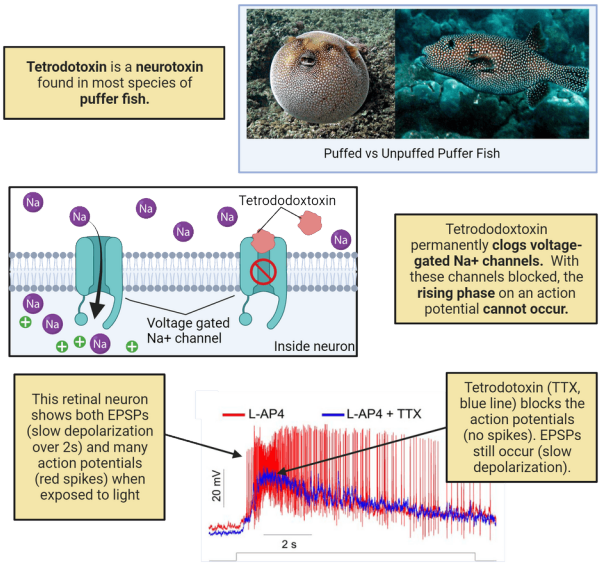

Figure 2.31 Puffer fish poison Image credits: unpuffed pufferfish image By NPS photo - Bryan Harry - www.nps.gov/archive/npsa/NPSA...n/puffer02.htm, Public Domain, https://commons.wikimedia.org/w/inde...?curid=1352381; puffed pufferfish image by By NPS photo - Bill Eichenlaub - www.nps.gov/archive/npsa/NPSA...n/puffer04.htm, Public Domain, https://commons.wikimedia.org/w/inde...?curid=1352380; tetrodotoxin action potentials image by Prigge, C. L., Yeh, P.-T., Liou, N.-F., Lee, C.-C., You, S.-F., Liu, L.-L., McNeill, D. S., Chew, K. S., Hattar, S., Chen, S.-K., & Zhang, D.-Q. (2016). M1 ipRGCs influence visual function through retrograde signaling in the retina. Journal of Neuroscience, 36(27), 7184–7197. https://doi.org/10.1523/jneurosci.3500-15.2016. CC BY 4.0

Why? Because of a symbiotic relationship puffer fish have evolved with special strains of bacteria in the *Aremonas* family (Noguchi, 2008). Through a pathway that remains mysterious, puffer fish collaborate with these bacteria to produce tetrodotoxin (TTX), a neurotoxin that clogs the inactivating voltage-gated Na^+ channels responsible for the rising phase of an action potential. In humans, ingestion of TTX causes tingling sensations as it initially shuts down signals from peripheral touch and pain receptors; it then shuts down motor neurons, causing flaccid paralysis (loss of muscle tone), coma, and the cessation of breathing function. Although deadly, TTX does not easily cross the blood-brain barrier, so those affected can remain lucid and aware even as the poison shuts down their body functions (!). Puffer fish are not the only animals who have evolved uses for TTX: it is the toxin injected by the bite of the dangerous blue-ringed octopus and it is also secreted in the skin of several species of poisonous amphibians. In fact, TTX is common enough in the animal kingdom that some predators have evolved counter-measures. For example, garter snakes have inactivating voltage-gated Na^+ channels that are not clogged by TTX, allowing them to dine on poisonous newts and frogs with impunity. For humans, though, TTX is one of the most toxic substances known, with even a milligram dose sufficient to cause death. Despite this, pufferfish is considered a delicacy in Japan, Korea, and parts of China where it is prepared by chefs specially trained in the removal of the toxic organs from the fish. While this special preparation is usually successful in removing almost all the TTX, rare cases of poisoning do occur. With no antidote available, the consumption of puffer fish can be considered a sort of culinary roulette; the real but low-probability danger is thought to heighten the dining experience.

Myelin and Action Potential Propagation. Multiple sclerosis (MS) is an autoimmune disorder affecting several million people worldwide (Figure 2.32), especially women (who develop MS at a rate twice as high as men).

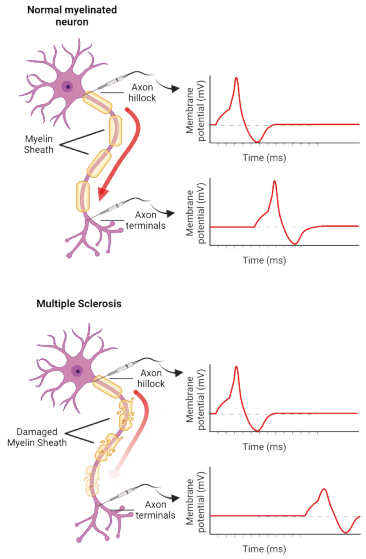

Figure 2.32 Multiple sclerosis

The most common symptoms are episodes of muscle weakness, blurred vision, and/or changes in the sense of touch, including numbness, pins and needles, and tingling. The severity of MS varies among patients and can be fatal. We now know that MS is caused, in part, by the immune system attacking and destroying myelin. This causes inflammation of myelinated axons, loss of myelin, and even neuronal death, leaving behind lesions in the white matter of the nervous system (these lesions, called sclerae, formed the basis for naming the disease). We still don't understand why the immune system mis-recognizes myelin as something to attack in MS patients, nor why this comes and goes in distinctive episodes. But knowing that MS affects myelin explains a lot about its symptoms, since the most prominent white-matter tracts in the CNS are the cortico-spinal tract that sends motor commands from the cortex down to motor neurons in the spine (see Chapter 10 Motor Control).

Neural signaling is complex

While we can feel triumph at the way neuroscience is helping to illuminate medical mysteries, it is important to note that this chapter only scratches the surface of what neuroscientists have discovered about neural signaling. For both space and clarity, some topics have been greatly simplified. That's fine: we needed to start somewhere, and this chapter was already quite long and complicated, right? But it's worth at least a peak behind the curtain at some of the additional complexities of neural signaling:

- **Chemical synapses are not only one-way.** In this chapter we've emphasized communication from the pre-synaptic to the post-synaptic neuron, noting that the pre-synaptic terminal is loaded with vesicles of transmitter to send messages and the post-synaptic terminal is studded with receptors to receive messages. It turns out this is only part of the story. The pre-synaptic terminal also has receptors (often called autoreceptors) and the post-synaptic terminal releases messages back to the post-synaptic neuron (these are often called retrograde messengers). So while there are clear specializations for communication from pre- to post, it is more accurate to think of chemical synapses as a point of interaction between neurons. This will be discussed more in Chapter 3 Basic Neurochemistry
- **Action potentials aren't always one-way either!** In this chapter we emphasized that action potentials are initiated at the initial segment of the axon and are then propagated down the axon. This is also just part of the story! In some neurons, action potentials also backpropagate, meaning that when they reach the end of the axon they then propagate back up the axon to the cell body and sometimes also into the dendritic tree. In some experiments, blocking back-propagation has impaired plasticity, suggesting an important role in fine-tuning connectivity (Stuart et al., 1997).
- **Synaptic messages are often quite complex.** We've explained how neurons release transmitter to partners to produce EPSPs (when binding to a ligand-gated Na^+ channel), IPSPs (when binding to a ligand-gated Cl^- channel), or neuromodulation (explained in Chapter 3 Basic Neurochemistry). These are, indeed, the fundamental types of messages that can be communicated at chemical synapses. Things become more complex, however, when we realize that a pre-synaptic neuron can actually release multiple transmitters (called co-transmitters) and that the post-synaptic neuron can express multiple types of receptors. This means that what one neuron "says" to another at a chemical synapse can be very complex, often involving a blend of excitation, inhibition, and modulation!
- **It's not just neural signaling taking place in the nervous system; glia are involved, too.** Glia have long been

considered mere support cells in the nervous system, but there is increasing evidence that they play important roles in nervous system communication as well (Allen and Lyons, 2018). Glia express many different types of receptors, they can both absorb and release transmitters, and they exchange signals with neurons that seem to play important roles in determining which synapses a neuron forms and maintains. We will learn much more about microglia specifically in Chapter 17 Neuroimmunology.

Neurons are astonishingly diverse. This chapter has tried to describe signaling in a "typical" neuron. This leaves out the tremendous diversity of neurons. First, there is incredible variety across species. Not all species have myelin. Not all species have a clear distinction between dendrites and axons. In fact, some species even lack inactivating voltage-gated Na^+ channels and instead have Ca^{2+}-based action potentials! Even within a species, there is incredible variety in size, shape, and signaling (Figure 2.33).

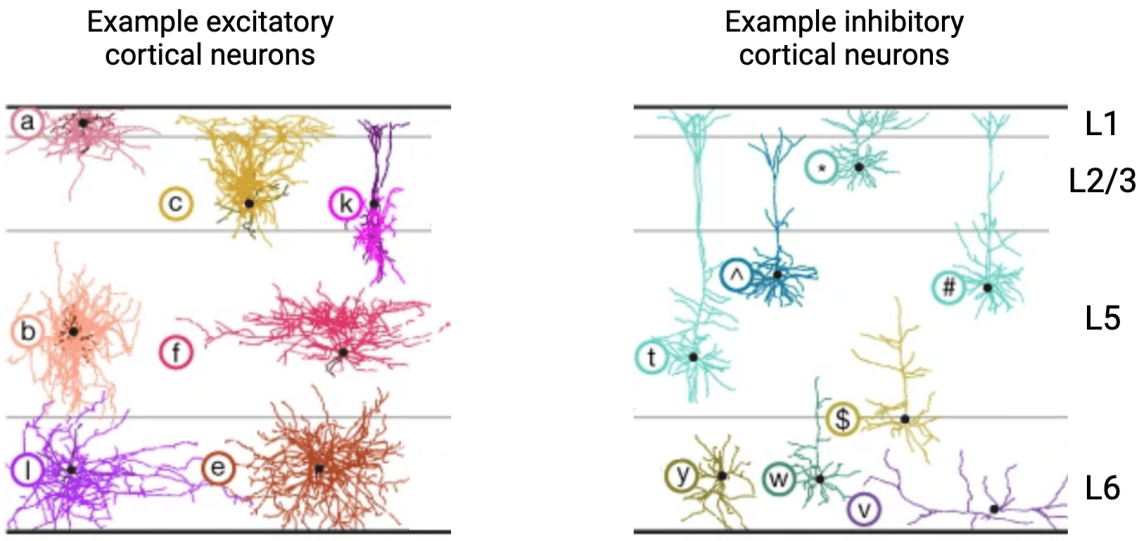

Figure 2.33 Diversity of neurons Neurons are extremely diverse. The diversity in branching and complexity is astonishing, and within each of these neurons is additional diversity in terms of gene expression and electrical signaling. Image credit: Neuron shapes adapted from: BRAIN Initiative Cell Census Network (BICCN). A multimodal cell census and atlas of the mammalian primary motor cortex. There is still so much to learn about neural signaling

We shouldn't leave this chapter with the impression that neuroscientists have figured it all out. There is still so much about neural signaling that we don't know, and there is still tremendous promise for applying the bits we do know to improve our lives. So, let's end this chapter by highlighting just a few of the many mysteries still to be resolved. That way we can close inspired by the possibility of helping to solve these mysteries, and with dreams of the better world we might build with that knowledge.

- **How do neuronal circuits maintain their function despite changing circumstances?** Most humans learn to walk early in life, at about 1 year of age. By adulthood, however, you are about twice as tall as when you learned to walk. That means the walking circuits in your spine have had to adapt throughout your lifetime. As you grew, the axons and dendrites in your walking circuits had to be extended over longer and longer distances. As your mass and center of gravity changed, inputs and outputs had to be adjusted to adapt the muscle commands for walking. Through it all, you experienced no major disruptions: you just kept on being able to walk! This is just one example of homeostasis in neural circuits: their ability to maintain the same function despite tremendous change (Marder and Goaillard, 2006). We don't fully understand how this works (does each neuron have an 'ideal' level of activity it is striving for?) or why some changes are easy for a neural circuit to cope with while others cause dysfunction.
- **How do neuronal circuits self-organize?** Each of your neurons carries your entire genome, about 6.4 billion base-pairs of DNA. That's an impressive amount of DNA, but it is simply not enough DNA to provide a complete wiring diagram for each of the 86 billion neurons in your brain. And yet, most human brains end up with striking and recognizable similarities in organization, with axons of sensory neurons finding their way to the thalamus, axons of the primary motor cortex descending down to the lumbar spine, etc. How does the human brain self-assemble? And is the assembly program fixed or does it incorporate feedback from the developmental environment? Chapter 5 Neurodevelopment discusses in more depth what we

know and don't know about the self-organization of neural circuits.

- **How many types of neurons are in the human brain?** Neuroscientists have long sought to create a classification system for neurons: to develop a complete list of the different types of neurons in the human brain (Bakken et al., 2021). While some differences seem clear (compare some of the different neuronal shapes in Figure 2.33), it has proven remarkably difficult to come up with a clear and consistent classification system. Molecular analysis has shown that two neurons that look alike might express markedly different channels and transmitters. Meanwhile, neurons that look different can serve very similar functions. As an added layer of complication, neurons are constantly adapting to new circumstances, so what seems like one type of neuron might adapt over time in ways that make it very difficult to classify. Maybe we're not thinking about neuron identity correctly? Or maybe we just need to crunch more data to see the patterns? Or, perhaps, neurons are so adaptable that detailed typologies aren't possible. This is a sobering gap in our knowledge: despite all we do know about the human brain we still don't have a master parts list! There really is so much more to learn.

View this Interactive Content online

Neurons are bilingual, using two inter-related but distinct signaling systems. Communication between neurons primarily uses the ancient language of chemical and receptor that all your cells use, though with adaptations for highly targeted and reliable communication. Grafted onto this ancient system is an electrical signaling system that transfers information within a neuron with a level of speed and precision that is relatively unique to the animal kingdom. An engineer probably wouldn't have designed such a complex system. Instead, the hybrid nature of neural signaling reflects the piecemeal adaptation of nervous system functioning through a long evolutionary history. From this complexity emerges neural processing. The back-and-forth-and back-again transformation from chemical to electrical to chemical signaling enables neurons to synthesize, filter, and transform information in complex and fascinating ways.

2.2 Neural Circuits

Communication between neurons allows them to form circuits that can generate complex rhythms and behaviors. In the *Tritonia* swim network, attack from a predator activates sensory neurons as well as inhibitory feedback that generates cycles of contraction and relaxation that "swim" the animal away from danger. This example typifies some of the key properties of neural networks: they are highly efficient, operate in parallel, feature extensive and complex forms of feedback, but are susceptible to malfunction from either too much or too little activity. The field of computational neuroscience explores mathematical models of neurons that can be simulated on a computer; this field is succeeding in producing artificial networks that can mimic many of the remarkable behaviors produced by animal nervous systems.

2.3 Principles of Bioelectricity

This section was a crash course in the physics of neural signaling. If you made it through, you've seen that pumps are protein machines that use energy to build up concentration gradients of 4 key electrolytes, pushing K^+ into neurons and Na^+, Cl^-, and Ca^{2+} out of neurons. The concentration gradients produced by pumps function as chemical batteries: they provide a "push" for K^+ to and Cl^- to charge the neuron towards negative potentials and for Na^+ and Ca^{2+} to charge the neuron towards positive potentials. The cell membrane holds back this push of diffusion. Ion channels, on the other hand, can open to allow the pressure for a specific ion to be partly released, producing currents that charge the neuron to that ion's equilibrium potential. Ca^+ and Na^+ produce currents that charge a neuron to a positive potential. K^+ and Cl^- produce currents that charge a neuron to a negative potential. While ion currents can produce big changes in a neuron's potential, they usually involve only a fraction of the ions the pumps have stored in or out of the neuron. The physics of neural electricity can be a bit daunting, but it provides a foundation from which we have built a detailed and powerful understanding of neural signaling.

2.4 Mechanisms of Neural Signaling

Neural signaling represents an incredible ballet of electrolytes, pumps, and ion channels. The resting potential in neurons occurs

due to the expression of leak K^+ neurons. Because pumps concentrate K^+ inside the neuron (along with balancing negative charges), leak channels allow diffusion to push some K^+ out of the neuron, a departure of positive charge that pulls the neuron towards a negative resting potential. Chemical messages from partner neurons disturb this rest, binding to ligand-gated channels to produce post-synaptic potentials: small, transient local changes in membrane potential that push a neuron towards threshold (EPSP, due to Na^+ or Ca^{2+} conductance) or away from threshold (IPSP, due to Cl^- conductance). When threshold is reached, an action potential is generated by a precisely timed sequence of Na^+ entering through inactivating voltage-gated Na^+ channels followed by K^+ departure through voltage-gated K^+ channels. This produces a rising phase (from Na^+ entry) that propagates down the axon followed by the falling phase and undershoot (from K^+ departure) that helps reset the neuron for the next action potential while also helping to prevent over-excitation. Myelin can speed up action potential propagation by preventing the leak of current over short sections of axon. Return to Table 2.4, which organizes the different types of electrical signals in neurons and their mechanisms.

2.5 Our Deep but Still Incomplete Understanding of Neural Signaling

Neuroscientists have developed a rich and detailed understanding of neural signaling that is helping us better understand and treat disorders of the nervous system. While this progress is encouraging, there is a daunting level of complexity to nervous system function and many important mysteries left to unravel.

1.6.13.8: Key Terms

2.1 Neural Communication

Neurotransmitters, Action potentials, Chemical synapses, Synaptic cleft, Pre-synaptic, Pre-synaptic terminal, Post-synaptic, Post-synaptic terminal, Excitatory Post-Synaptic Potential (EPSP), Inhibitory Post-Synaptic Potential (IPSP), Electrical Synapse, Connexon, Resting Potential, Threshold, Sensory Neuron, Motor Neuron

2.2 Neural Circuits

Rhythm, Feedback, Parallel processing, Model, Computational neuroscience, Simulation, Abstraction, Neural prosthetic

2.3 Principles of Bioelectricity

Voltage-sensitive fluorescent protein, Propagation, Ion pumps, Ion channels, Electrolytes, Charge, Electrostatic force, Ion, Current, Conductance, Insulator, Electrical potential, Ohm's law, Membrane potential, Electrode (recording electrode, reference electrode), Neurophysiology, Solute, Diffusion, Concentration gradient, Battery, Ion channel, Selectivity filter, Ligand-gated ion channel, Voltage-gated ion channel, Equilibrium potential

2.4 Mechanisms of Neural Signaling

Resting potential, Leak K^+ channels, Leak Na^+ channels, Ligand-gated channel (aka Neurotransmitter-gated channel), Action potential, Initial segment, Propagation, Rising phase, Falling phase, Undershoot, Inactivating voltage-gated Na^+ channel, Voltage-gated K^+ channel, Threshold, Subthreshold, Positive feedback, Refractory period

2.5 Our Deep but Still Incomplete Understanding of Neural Signaling

Autoimmune disorder, Autoreceptors, Backpropagate, Flaccid paralysis, Homeostasis, Retrograde messengers, Spastic paralysis

This page titled 1.6.13.8: Key Terms is shared under a CC BY-NC 4.0 license and was authored, remixed, and/or curated by Ivette Merced via source content that was edited to the style and standards of the LibreTexts platform.

1.6.13.10: Multiple Choice IVETTE KEEP OR DELETE?

2.1 Neural Communication

1.
All of the following are involved with synaptic transmission at chemical synapses except:

a. postsynaptic neurons.
b. presynaptic neurons.
c. gap junctions.
d. neurotransmitters.

2 .
Chemical messages released at synapses lead to different types of responses in postsynaptic neurons. Which type of response changes the patterns of growth, connectivity, or signaling for the post-synaptic neuron?

a. Excitatory postsynaptic potentials
b. Inhibitory postsynaptic potentials
c. Neuromodulation
d. None of the above

3.
Which is a brief electrical change in the postsynaptic neuron that excites the neuron and pushes it towards threshold?

a. EPSP
b. IPSP
c. Action potential
d. Resting potential

4 .
Which event occurs last in the process of chemical synaptic transmission?

a. Released neurotransmitter is broken down or removed from the cleft
b. The presynaptic neuron stores transmitter in vesicles
c. The released neurotransmitter binds to postsynaptic receptors
d. An action potential arrives at the presynaptic terminal leading to release of neurotransmitter

5.
All of the following are involved with synaptic transmission at electrical synapses except:

a. gap junctions.
b. synaptic vesicles.
c. presynaptic neurons.
d. postsynaptic neurons.

2.2 Neural Circuits

6 .
Imagine a sensory neuron that does not fire unless stimulated. With light touch the neuron generates an action potential. What would happen with strong touch?

a. Action potentials would occur more frequently
b. Action potentials would not occur
c. There would be no change in the frequency of action potentials, but the magnitude of each spike would increase
d. Action potential frequency and magnitude would increase

7.
If neural networks use parallel processing it means that:

a. they display rhythmic or cyclical activity.
b. information spreads along multiple pathways at the same time.
c. they are highly efficient.
d. a neuron influences the activity it will later receive.

8 .
Which subfield of neuroscience is involved with developing mathematical models of neurons and neural networks?

a. Cognitive neuroscience
b. Systems neuroscience
c. Computational neuroscience
d. Cellular and molecular neuroscience

9.
Researchers have developed devices that have the potential to replace or repair a part of the nervous system using a computer model that can simulate the processing in that brain region. This is an example of:

a. neurofeedback.
b. optogenetics.
c. deep brain stimulation.
d. a neural prosthetic.

2.3 Principles of Bioelectricity

10 .
What determines the movement of ions?

a. Forces from both diffusion and electrical charge
b. Forces from both the sun and the wind
c. Forces from both ATP and GTP
d. Forces from both dynein and kinesin

11.
In diffusion, molecules move:

a. down a concentration gradient.
b. up a concentration gradient.
c. down a voltage gradient.
d. up a voltage gradient.

12 .
Which is the best definition for electrical potential?

a. The flow of charge
b. The ease with which charge flows
c. The pressure for charge to flow
d. All of the above

13.
Which is the best description for conductance?

a. The flow of charge
b. The ease with which charge flows
c. The pressure for charge to flow
d. None of the above

2.4 Mechanisms of Neural Signaling

14 .
What is a resting potential?

a. A wave of positive electrical potential that sweeps through a neuron
b. An overall positive electrical potential neurons maintain while at rest
c. An overall negative electrical potential neurons maintain while at rest
d. A small, local change in potential caused when transmitter is received from a partner neuron

15.
Why do neurons have a resting potential?

a. Because they have leak K+ channels that allow K+ to pull the neuron towards a negative potential
b. Because they have leak K+ channels that allow K+ to pull the neuron towards a positive potential
c. Because they have leak Na+ channels that allow K+ to pull the neuron towards a negative potential
d. Because they have leak Na+ channels that allow K+ to pull the neuron towards a positive potential

16 .
An action potential is due to:

a. a departure of organic ions.
b. an entrance of Cl-.
c. a departure of Na+ followed by the influx of K+.
d. an influx of Na+ followed by the departure of K+.

17.
During an action potential, what happens when K+ channels open?

a. K+ rushes out making the neuron more negative
b. K+ rushes in making the neuron more negative
c. K+ rushes out making the neuron more positive
d. K+ rushes in making the neuron more positive

18 .
When a neuron is at rest, which of these could be Vm?

a. 0 mV
b. +60 mV
c. -60 mV
d. None of the above

19.
At the peak of the rising phase, which of these could be Vm?

a. -60 V
b. +60 V
c. +60 mV
d. -60 mV

20 .
Compared to an actional potential, which is true about graded potentials?

a. Larger
b. Faster
c. Local
d. Release more neurotransmitter

21.
An EPSP is generated when:

a. a neurotransmitter binds to a ligand-gated Na+ channel.
b. a neurotransmitter binds to a ligand-gated Ka+ channel.
c. K+ binds to a ligand-gated Na+ channel.
d. Ca2+ binds to a ligand-gated Cl- channel.

22 .
Why are graded potentials so short-lived?

a. Transmitter is broken down or reabsorbed
b. K+ leak channels
c. Ion pumps
d. All of the above

23.
Ion channels and ion pumps are similar in that:

a. both are proteins.
b. both use energy.
c. both move ions against their gradient.
d. both move ions down their gradient.

24 .
Which is not a property of voltage-gated K+ channels?

a. Slow to open and close
b. Transition between open, closed, and inactivated states
c. Open at depolarizing voltages
d. Permeable to a single ion

1.6.13.11: Fill in the Blank

2.1 Neural Communication

1.
The small pocket of extracellular space between presynaptic and postsynaptic neurons is called the _____.
2 .
Neurons maintain a negative _____ as a result of the concentration gradient for K+ and K+ leak channels.

2.2 Neural Circuits

3.
Neural circuits often feature loops, meaning that neurons often produce outputs that can _____ onto and influence their inputs.

2.3 Principles of Bioelectricity

4 .
The movement of charged particles is called electrical _____.

2.4 Mechanisms of Neural Signaling

5.
_____ potentials are a rapid flip in the membrane potential that can spread quickly through a neuron and trigger the release of neurotransmitter.
6 .
EPSPs and IPSPs are generated by _____ -gated ion channels.

1.7: NEURONAL COMMUNICATION

By the end of this section, you will be able to:

- Explain the events that occur during the conduction of nerve impulses
- Differentiate the nerve impulse propagation in saltatory and continuous conduction
- Describe the components of synapses and compare electrical and chemical synapses

Having looked at the components of nervous tissue, and the basic anatomy of the nervous system, next comes an understanding of how nervous tissue is capable of communicating within the nervous system. Neurons communicate with other neurons, muscles or glands through the generation and conduction of nerve impulses. These nerve impulses represent changes in the electrical properties of the neuronal cell membrane. All cells have an electrical charge associated with their membrane. However, neurons and other cells are able to change their electrical charge by moving ions across the membrane. In this section, you will look at the basics of neuronal communication, mainly focusing on the conduction of the nerve impulse.

Conduction of Nerve Impulses

Neurons possess electrical excitability, which is the ability to respond to a stimulus by generating a nerve impulse. In the majority of cases, the dendrites of a neuron are the place where local changes in the membrane electrical properties happen through synapses. Dendrites receive stimuli from the external environment (e.g. somatic sensory neurons) or internal environment (e.g. visceral sensory neurons, motor neurons or interneurons). The amount of change in the membrane electrical charge is determined by the strength of the stimulus that causes it. For example, a needle pricking a fingertip will result in a bigger stimulus compared to a blunt object touching the same fingertip. Once a stimulus (or multiple stimuli) produces a significant change in the membrane electrical properties of a dendrite and reaches a predetermined **threshold**, then a nerve impulse (also called action potential) occurs. An **action potential** is generated at the axon hillock of a neuron and progresses rapidly along the axon's plasma membrane to reach the targets (a second neuron, a muscle or a gland). This movement of an action potential along the axon is called **propagation**. While the stimuli can be weak or strong, the action potential follows a **All-or-None Law** by which it always has the same strength (referred to as amplitude) independently of the stimulus. This minimizes the possibility that information will be lost along the way. The only way to modulate the response is through the frequency of action potentials - how many action potentials reach the target in a set amount of time. A bigger stimulus will produce a series (or train) of action potentials that are close together, while a weak stimulus will produce sparse action potentials.

The speed of an action potential is influenced by the diameter of the axon and by its myelination. The larger the diameter of the axon, the faster the action potential will be conducted. Myelinated axons are able to carry action potentials faster than unmyelinated axons. As discussed in the previous section, myelinating cells (oligodendrocytes in the CNS and Schwann cells in the PNS) wrap around axons forming the myelin. Nodes of Ranvier are gaps between segments of myelin. The electrical charges of the action potential can "jump" from one gap to another one, thus allowing a faster speed of the action potential. This progression of a nerve impulse is called **saltatory conduction**. However, in unmyelinated axons, one side of the axon is not covered by myelin and the electrical charges move along the entire axonal membrane, thus taking longer to reach their target. This progression of a nerve impulse is called **continuous conduction**. Once the action potential reaches the axon terminal, it is either transported as electrical charge into the next cell or transformed into a chemical signal, depending on the type of synapse that the synaptic end bulb is forming with its target.

Neurons and their targets form synapses. The neuron that generates and conducts the action potential to the target is called a **presynaptic cell**. The target cell receiving the action potential is called a **postsynaptic cell**. While the presynaptic cell is always a neuron (because only neurons have axons and can form a synapse), the postsynaptic cell can be a neuron or another type of cell such as skeletal, cardiac or smooth muscle cells, or glands. In Figure 1.7.1, a presynaptic neuron forms synapses with two postsynaptic neurons. The nerve impulse (or signal) travels from a presynaptic neuron to a postsynaptic cell. If the postsynaptic cell is a neuron, a new action potential might be generated in the postsynaptic neuron and reach its postsynaptic targets.

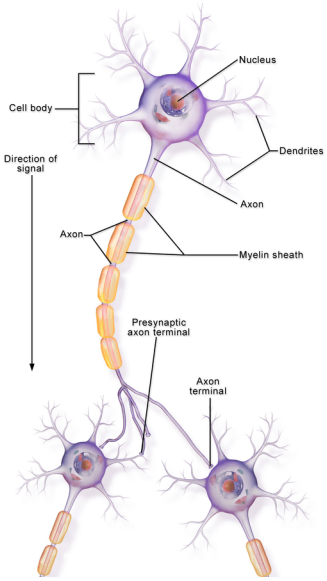

Figure 1.7.1: Presynaptic and postsynaptic neurons. A presynaptic neuron on top forms synapses with two postsynaptic neurons at the bottom. The parts of the presynaptic neuron are labeled as cell body, nucleus, dendrites and axon covered in a myelin sheath. The direction of signal shows that the electrical signal (action potential) travels from the axon of the presynaptic neuron to the axon terminals of the presynaptic neuron that are in contact with the dendrites and cell body of the postsynaptic neurons. (Image credit: "Neuron Part 1" by BruceBlaus is licensed under CC BY-SA 4.0)

Synapses

There are two types of connections between electrically active cells: electrical synapses and chemical synapses. In an **electrical synapse**, there is a direct connection between the presynaptic and postsynaptic cells and the connection is formed by gap junctions. Thus, the electrical charges of an action potential can pass directly from one cell to the next. If one cell delivers an action potential in an electrical synapse, the joined cell will also generate an action potential because the electrical charges will pass between the cells (Figure 1.7.2). Although representing the minority of synapses, electrical synapses are found throughout the nervous system. These synapses also occur between excitable cells other than neurons, for example between smooth muscle cells in the intestines and cardiac muscle cells in the heart.

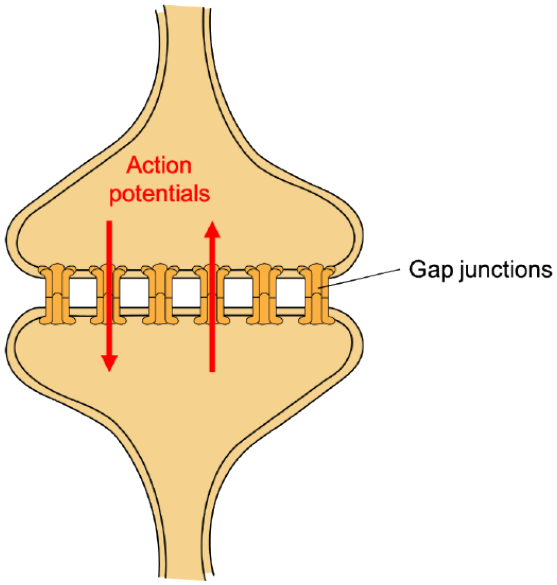

Figure 1.7.2: Electrical Synapse. Two synaptic end bulbs form an electrical synapse where gap junctions allow the passage of action potentials from one cytoplasm to the other, and viceversa. (Image credit: "Electrical Synapse" by Chiara Mazzasette is a derivative from the original work of Daniel Donnelly and is licensed by CC BY 4.0)

Chemical synapses involve the transmission of chemical information from one cell to the next and they represent the majority of the synapses found within the nervous system. In a **chemical synapse**, a chemical signal called a **neurotransmitter**, is released from the presynaptic cell and it affects the postsynaptic cell. There are many different types of neurotransmitters, for example acetylcholine, serotonin, dopamine, adrenaline, glutamate, etc. Each neurotransmitter has its own specific receptor on the postsynaptic membrane. Chemical synapses can then be classified based on the neurotransmitter that the cells use to communicate (for example glutamatergic synapses use glutamate). Different neurotransmitters and different receptors will determine the overall response to the stimulus. All chemical synapses have common characteristics, which can be summarized in this list and are shown in Figure 1.7.3:

- synaptic end bulb of presynaptic neuron
- neurotransmitter (packaged in vesicles)
- synaptic cleft
- receptors for neurotransmitter
- postsynaptic membrane of postsynaptic neuron

The synaptic end bulbs of chemical synapses are filled with vesicles containing one type of neurotransmitter. When an action potential reaches the axon terminals, the vesicles merge with the cell membrane at the synaptic end bulb, releasing the neurotransmitter through exocytosis into the small gap between the cells, known as the **synaptic cleft**. Once in the synaptic cleft, the neurotransmitter diffuses the short distance to the postsynaptic membrane and can interact with neurotransmitter receptors. Receptors are specific for the neurotransmitter, and the two fit together like a key and lock. One neurotransmitter binds to its receptor and will not bind to receptors for other neurotransmitters, making the binding a specific chemical event. The binding of the neurotransmitter to its receptor causes a brief electrical change across the postsynaptic membrane. The change depends on the type of neurotransmitter receptor. Changes in the postsynaptic cell membrane can cause a nerve impulse to begin in the postsynaptic cell or inhibit the generation of an action potential. The flow of information is unidirectional: from the presynaptic cell to the postsynaptic cell. After its release in a chemical synapse, neurotransmitters need to be removed from the synaptic cleft to ensure the propagation of new synaptic signals.

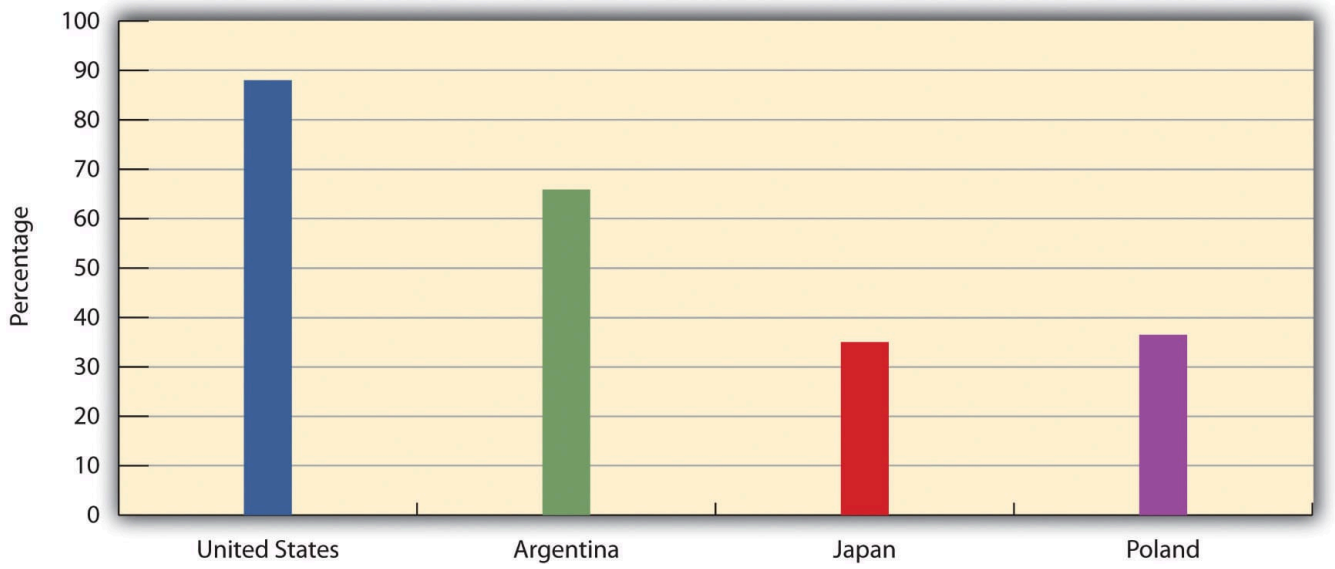

Figure 1.7.3: Chemical Synapse. The axon of the presynaptic neuron terminates at the axon terminal in a synaptic end bulb where the action potential arrives. The arrival of action potential causes the synaptic vesicles containing neurotransmitters to fuse with the membrane and release the neurotransmitters. The neurotransmitters diffuse across the synaptic cleft to bind to its receptor, in this case ligand-gated channels. Neurotransmitters will eventually be cleared from the synapse. (Image credit: "Chemical Synapse" by Young, KA., Wise, JA., DeSaix, P., Kruse, DH., Poe, B., Johnson, E., Johnson, JE., Korol, O., Betts, JG., & Womble, M. is licensed under CC BY 4.0)

DISORDERS OF THE...

Nervous System: Alzheimer's and Parkinson's Disease

The underlying cause of some neurodegenerative diseases, such as Alzheimer's and Parkinson's, appears to be related to proteins—specifically, to proteins behaving badly. One of the strongest theories of what causes Alzheimer's disease is based on the accumulation of beta-amyloid plaques, dense conglomerations of a protein that is not functioning correctly. Parkinson's disease is linked to an increase in a protein known as alpha-synuclein that is toxic to the cells of the substantia nigra nucleus in the midbrain.

For proteins to function correctly, they are dependent on their three-dimensional shape. The linear sequence of amino acids folds into a three-dimensional shape that is based on the interactions between and among those amino acids. When the folding is disturbed, and proteins take on a different shape, they stop functioning correctly. But the disease is not necessarily the result of functional loss of these proteins; rather, these altered proteins start to accumulate and may become toxic. For example, in Alzheimer's, the hallmark of the disease is the accumulation of these amyloid plaques in the cerebral cortex. The term coined to describe this sort of disease is "proteopathy" and it includes other diseases. Creutzfeld-Jacob disease, the human variant of the prion disease known as mad cow disease in the bovine, also involves the accumulation of amyloid plaques, similar to Alzheimer's. Diseases of other organ systems can fall into this group as well, such as cystic fibrosis or type 2 diabetes. Recognizing the relationship between these diseases has suggested new therapeutic possibilities. Interfering with the accumulation of the proteins, and possibly as early as their original production within the cell, may unlock new ways to alleviate these devastating diseases.

CAREER CONNECTIONS

Neurophysiologist

Understanding how the nervous system works could be a driving force in your career. Studying neurophysiology is a very rewarding path to follow. It means that there is a lot of work to do, but the rewards are worth the effort.

The career path of a research scientist can be straightforward: college, graduate school, postdoctoral research, academic research position at a university. A Bachelor's degree in science will get you started, and for neurophysiology that might be in biology, psychology, computer science, engineering, or neuroscience. But the real specialization comes in graduate school. There are many different programs out there to study the nervous system, not just neuroscience itself. Most graduate programs are doctoral, meaning that a Master's degree is not part of the work. These are usually considered five-year programs, with the first two years dedicated to course work and finding a research mentor, and the last three years dedicated to finding a research topic and pursuing that with a near single-mindedness. The research will usually result in a few publications in scientific journals, which will make up the bulk of a doctoral dissertation. After graduating with a Ph.D., researchers will go on to find specialized work called a postdoctoral fellowship within established labs. In this position, a researcher starts to establish their own research career with the hopes of finding an academic position at a research university.

Other options are available if you are interested in how the nervous system works. Especially for neurophysiology, a medical degree might be more suitable so you can learn about the clinical applications of neurophysiology and possibly work with human subjects. An academic career is not a necessity. Biotechnology firms are eager to find motivated scientists ready to tackle the tough questions about how the nervous system works so that therapeutic chemicals can be tested on some of the most challenging disorders such as Alzheimer's disease or Parkinson's disease, or spinal cord injury.

Others with a medical degree and a specialization in neuroscience go on to work directly with patients, diagnosing and treating mental disorders. You can do this as a psychiatrist, a neuropsychologist, a neuroscience nurse, or a neurodiagnostic technician, among other possible career paths.

Concept Review

The basis of the electrical signal within a neuron is the action potential that propagates down the axon. For a neuron to generate an action potential, it needs to receive input from another source, either another neuron or a sensory stimulus. That input will result in a change in the electrical properties of the cell membrane, based on the strength of the stimulus. Once the stimulus is strong enough, it will generate an action potential that travels along the axon to the synaptic end bulb.

The diameter of the axon and the presence or absence of myelin determines how fast the action potential is conducted down the axon. A larger diameter and the presence of a myelin sheath will ensure a fast propagation of the action potential.

Synapses are the contacts between neurons, which can either be chemical or electrical in nature. Chemical synapses are far more common. At a chemical synapse, neurotransmitter is released from the presynaptic element and diffuses across the synaptic cleft. The neurotransmitter binds to a receptor protein and causes a change in the postsynaptic membrane (the PSP). The neurotransmitter must diffuse, be inactivated or removed from the synaptic cleft so that the stimulus is limited in time.

Review Questions

Q. At an electrical synapse, what do the presynaptic and postsynaptic cells communicate through?

A. neurotransmitters

B. neurotransmitter receptors

C. nodes of Ranvier

D. gap junctions

Answer

Answer: D

Q. Which of the following axons would propagate an action potential faster than the others?

A. myelinated, large diameter, axons

B. myelinated, small diameter, axons

C. unmyelinated, large diameter, axons

D. unmyelinated, small diameter, axons

Answer

Answer: A

Glossary

action potential
change in the electrical properties of a cell membrane in response to a stimulus that results in transmission of an electrical signal; unique to neurons and muscle fibers

All-or-None Law
the principle that the strength by which a neuron responds to a stimulus is not dependent on the strength of the stimulus;

chemical synapse
connection between two neurons, or between a neuron and its target, where a neurotransmitter diffuses across a very short distance

continuous conduction
slower propagation of the action potential along an unmyelinated axon

electrical synapse
connection between two neurons, or any two electrically active cells, where an action potential can flow across gap junctions into the adjacent cell

neurotransmitter
chemical signal that is released from the synaptic end bulb of a neuron to cause a change in the target cell

postsynaptic cell
cell receiving a synapse from another cell

presynaptic cell
cell forming a synapse with another cell

propagation
movement of an action potential along the length of an axon

saltatory conduction
faster propagation of the action potential in a myelinated axon, from one node of Ranvier to the following node

synaptic cleft
small gap between cells in a chemical synapse where neurotransmitter diffuses from the presynaptic element to the postsynaptic element

threshold
membrane voltage at which an action potential is initiated

1.7.1: Neurons and their Basic Functions

Learning Objectives

1. Describe the anatomy of neurons and the function of each of the three major parts of a neuron
2. Describe neurotransmitters, synapse, synaptic vesicles, resting potential, EPSP, IPSP, and action potential
3. Explain saltatory conduction and why it is important to communication within the nervous system; include description of the myelin sheath and nodes of Ranvier
4. Describe the role of post-synaptic receptor sites in communication between neurons
5. Describe neurons classified by shape and by their functions

Overview

In this section, we continue our exploration of neurons, the building blocks of the nervous system. We examine how they generate electrochemical signals, and how the billions of neurons in the nervous system communicate with one another, a process known as synaptic transmission. Before tackling these topics, we review and expand the basic anatomy and functioning of neurons covered in part in Chapter 4. A sound grasp of these facts provides the groundwork for understanding how neuron potentials are generated within neurons and how they combine to trigger synaptic transmission. As you read, remember that the voltages and chemical events we discuss in this section, operating in large populations of brain cells, somehow generate our perceptions, thoughts, emotions, and the entirety of our mental experience. To date, how this happens, how patterns of neuron potentials in brain circuits become conscious minds, remains the greatest mystery of all facing modern science.

Introduction to Neuron Anatomy, Neuron Potentials, and Synaptic Transmission

The nervous system of vertebrates like us is comprised of the **central nervous system**, made up of the brain and spinal cord, and the **peripheral nervous system**, which consists of all the nerves outside the brain and spinal cord.

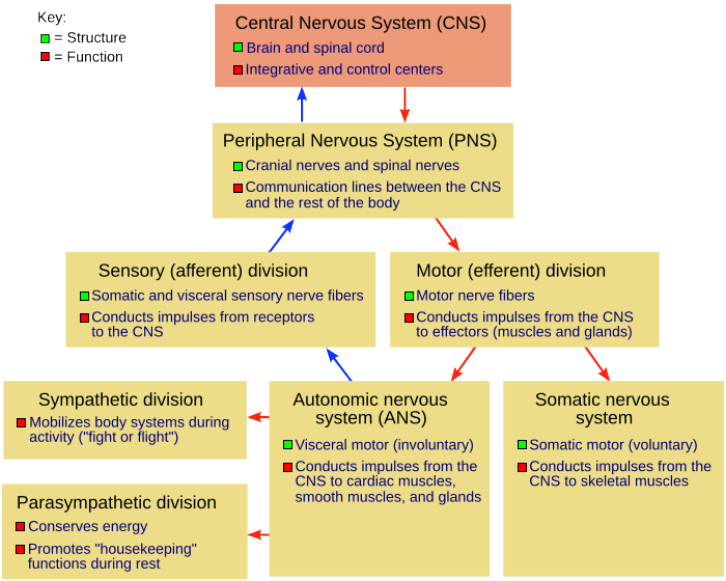

Figure 1.7.1.1: The human nervous system and its major divisions. All components consist of neurons--nerve cells. (NSdiagram NGB colors fixed.png adapted by Naomi Bahm (colors boxed and fixed) from File:NSdiagram.svg; https://commons.wikimedia.org/wiki/File:NSdiagram.svg; by Fuzzform via Wikimedia Commons; Permission is granted to copy, distribute and/or modify this document under the terms of the **GNU Free Documentation License**, Version 1.2 or any later version published by the Free

Software Foundation; with no Invariant Sections, no Front-Cover Texts, and no Back-Cover Texts. A copy of the license is included in the section entitled *GNU Free Documentation License*. Subject to disclaimers).

The peripheral nervous system is composed of the **somatic sensory nerves** (input nerves such as the auditory nerve, the optic nerve, spinal sensory nerves mediating skin sensations, etc.) and **somatic motor nerves** (output nerves, serving the skeletal muscles, activating or inhibiting them) as well as the **autonomic sensory and motor nerves** (serving the internal body organs such as the heart, lungs, blood vessels, digestive system, adrenal glands, etc.). These autonomic motor nerves, which either activate or inhibit the internal body organs, are of two types: the **sympathetic** (activate heart, lungs, constrict blood vessels, etc. to prepare the body for "fight or flight") and **parasympathetic** (conserve the body's resources during non-emergency, non-threatening situations) motor autonomic nerves. All of these parts of the nervous system, including the brain, spinal cord, and the peripheral nervous system, are made up of nerve cells, technically known as **neurons**. The **human brain** is estimated to have somewhere between **80 and 100 billion neurons**. Recall from Chapter 4 that neurons have three major parts: the soma or cell body, the dendrites which receive inputs from other neurons, and the axon, which carries the output of neurons, nerve impulses (action potentials), to other neurons, to muscles, or to glands.

You have probably seen photographs or drawings of neurons previously in your introductory psychology course. The images below show small sections of cerebral cortex in a human adult and a human infant. Note the density of neurons and connections in each brain slice. The complexity of interconnections among neurons is evident in the image at the far right which is based on use of Golgi stain.

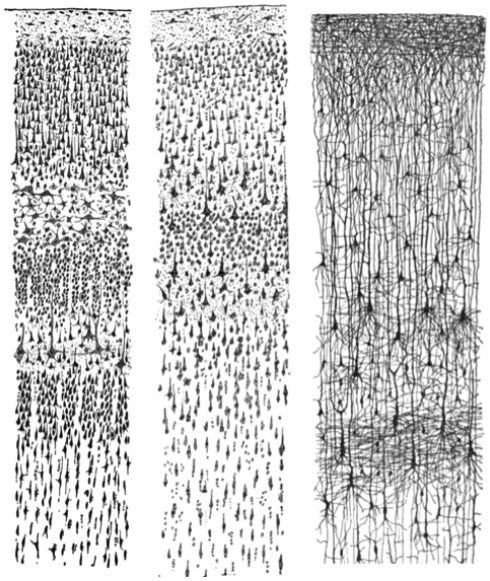

Figure 1.7.1.2: Small sections of tissue from the brain of a human infant and a human adult. The image at the far right using Golgi stain highlights cell bodies and extensive branching of dendrites. Left: Nissl-stained visual cortex of a human adult. Middle: Nissl-stained motor cortex of a human adult. Right: Golgi-stained cortex of a 1 1/2 month old infant. [Image: Santiago Ramon y Cajal, https://goo.gl/zOb2l1, CC0 Public Domain, https://goo.gl/m25gce]

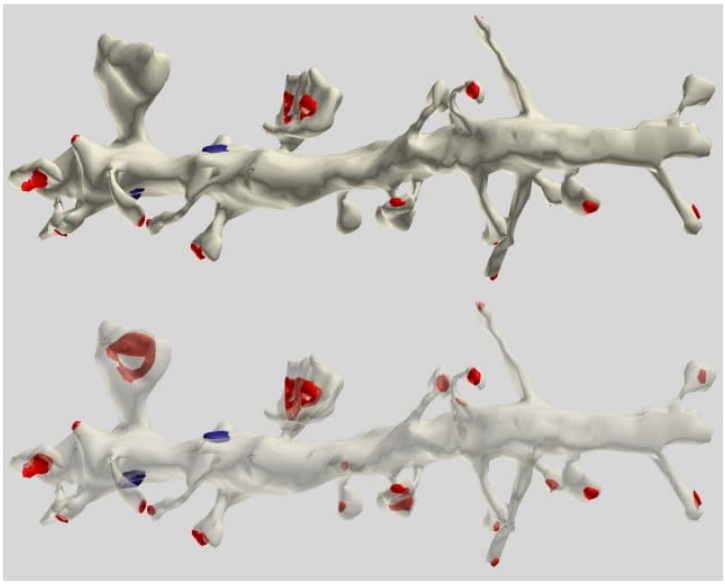
Nissl and Golgi Stains



Note that different chemicals were used to stain the neurons in the figure above so that they could be seen under the microscope. Nissl stain labels only the main part of the cell (i.e., the cell body; see left and middle panels of Figure 5.1.2). However, by contrast, a Golgi stain fills the cell body and all the processes that extend outward from the cell body (see right panel of Figure 5.1.2). A more notable characteristic of a Golgi stain is that it only stains approximately 1–2% of neurons (Pasternak & Woolsey, 1975; Smit & Colon, 1969), permitting the observer to distinguish one cell from another. These qualities of the Golgi stain allowed the pioneering neuroanatomist Santiago Ramon y Cajal to examine the full anatomical structure of individual neurons for the first time. This significantly enhanced our appreciation of the intricate networks their processes form. Based on his observation of Golgi-stained tissue, Cajal suggested neurons were distinguishable processing units rather than part of a continuous network of nerves, as had been previously believed. Cajal and Golgi shared the Nobel Prize for Medicine in 1906 for their combined contribution to the advancement of science and our understanding of the structure of the nervous system.

Neuron Anatomy and Basic Functions

To understand neuron function, it is important to be familiar with the anatomy involved. As noted above, neurons have three major structural parts - - the **soma** or cell body, the **axon** (carries the neuron's output), and the **dendrites** (the "receivers" of the neuron). The entire neuron is bounded by a **cell membrane**, the neural membrane. The cell membrane of a neuron has **channels or "doors" for ions** (electrically charged atoms) which can pass through the membrane when specific channels are opened for specific ions. Figure 5.1.4 shows this basic neuron anatomy. Various types of neurons are discussed below.

The soma or cell body contains organelles, common to all types of cells in the body. These are involved in the basic metabolism of the cell. The soma also contains the nucleus, where the genes and chromosomes (containing DNA) are located.

The second main part of the neuron is the **dendrites**, the receivers of the neuron. Dendrites in some neurons can branch profusely (large numbers of dendritic branches off the main shaft of a dendrite with their own branches are often collectively called **dendritic trees**), expanding the region of the neuron that can receive inputs from other neurons. The **receptor sites** (or more technically, **postsynaptic receptor sites** because of their location on the receiving or postsynaptic neuron) which receive molecules of **neurotransmitter** are located on the dendrites (and, to a lesser degree, on the soma) of the receiving neuron. On the dendrites are small **dendritic spines** which are associated with the connections between neurons (the **synapses**) and can change shape rapidly when learning occurs (see Chapter 10 for more detail). Note that the spines are not the same thing as dendritic branches. In Figure 5.1.3, a dendritic branch with dendritic spines is shown on the left in microscopic detail, and on the right, are dendritic trees of two types of neuron found in the retina. Spines are not visible in the images of dendritic trees on the right because the dendritic spines are too small, while dendritic branches comprising the dendritic trees can easily be seen (see caption for Figure 5.1.3).

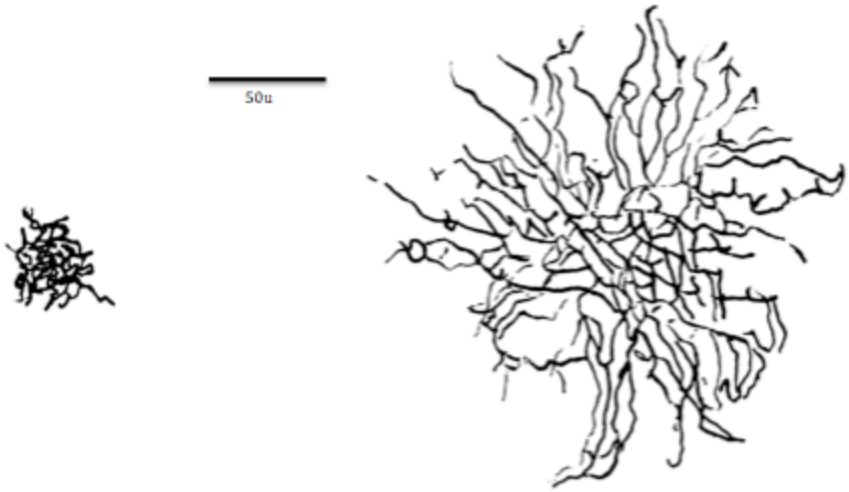


Figure 1.7.1.3: (Left) A segment of pyramidal cell dendrite from stratum radiatum (CA1) of the hippocampus with thin, stubby, and mushroom-shaped spines. Spine synapses are colored in red, stem (or shaft) synapses are colored in blue. The dendrite was made transparent in the lower image to enable visualization of all synapses. (Right) A size comparison between midget and parasol cell dendritic trees. Dendritic spines are too small to be visible in the two images on the right. Parasol and midget neurons are found in the ganglion cell layer of the retina. (On left, Pyramidal cell dendrite and spines: Image and caption from Wikimedia Commons; File:A segment of pyramidal cell dendrite from stratum radiatum (CA1).jpg; https://commons.wikimedia.org/wiki/F...atum_(CA1).jpg; by Synapse Web, Kristen M. Harris, PI, http://synapses.clm.utexas.edu/; licensed under Creative Commons Attribution 2.0 Generic license. On right, Midget and parasol cell dendritic trees: Image and one line caption from Wikimedia Commons; File:Midget vs Parasol cell.png; https://commons.wikimedia.org/wiki/F...rasol_cell.png; by Stromdabomb; licensed under the Creative Commons Attribution-Share Alike 4.0 International license; two sentence explanation by Kenneth A. Koenigshofer, PhD).

The third major part of the neuron is the **axon**, coming out of the soma like a hose. The axon carries the output messages of a neuron (nerve impulses) along its length to its axon terminal buttons (axon endings). There is only one axon per neuron, although it can branch into multiple axon terminal buttons. In a typical neuron, the root end of the axon emerges out of the soma at a small swelling called the **axon hillock**. Between the axon hillock and the first segment of the axon is where the nerve impulse is first generated (see discussion of the action potential, the nerve impulse, that follows below).

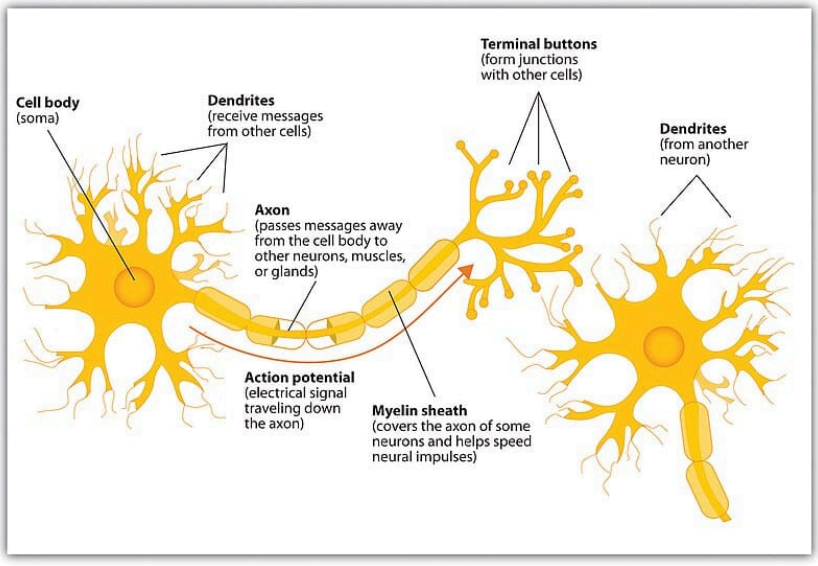

Figure 1.7.1.4: Basic structure of a neuron (Image from Wikimedia Commons; File:Components of neuron.jpg; https://commons.wikimedia.org/wiki/F..._of_neuron.jpg; by Jennifer Walinga; licensed under the Creative Commons Attribution-

Share Alike 4.0 International license).

Myelinated Axons and Saltatory Conduction

Some axons have a glial cell covering (glials are non-neural cells in the nervous system, see Chapter 4.1) known as the **myelin sheath**. This fatty, insulating, myelin sheath has gaps in it, revealing the bare axon, at regular intervals along the axon's length. These bare spots along the length of a **myelinated axon** are called nodes, or **nodes of Ranvier**, after their discoverer.

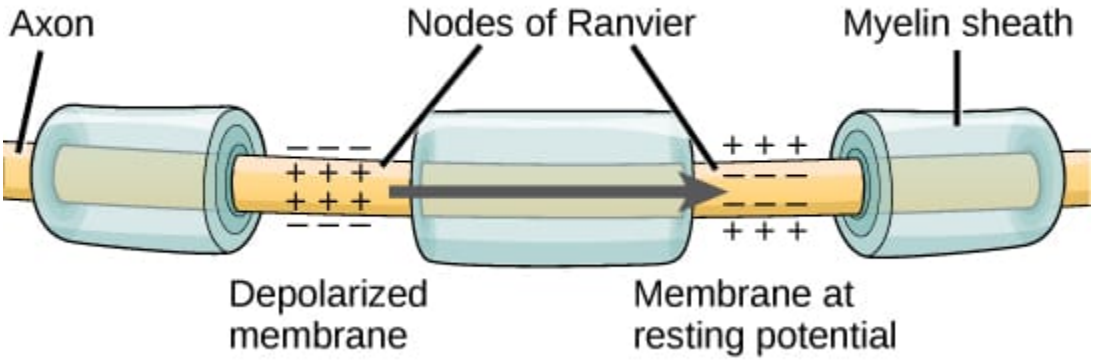

Figure 1.7.1.5: **Nodes of Ranvier.** Nodes of Ranvier are gaps in the myelin sheath which covers myelinated axons. Nodes contain voltage-gated potassium (K+) and sodium (Na+) channels. Action potentials travel down the axon by "jumping"from one node to the next, speeding conduction of the action potential down the length of the axon toward the axon ending, also known as the axon bouton, axon button, or axon terminal.

The function of the myelin sheath and the nodes is to speed up the rate at which nerve impulses travel down the length of the axon toward their destination, the axon ending (axon bouton). In myelinated axons, the impulses sort of "jump" from node to node allowing the action potential to move more rapidly down the axon. This leaping of the nerve impulse (action potential) from node to node is called **saltatory conduction,** from the Latin "saltatore" which means to dance. Imagine the romantic image of the impulse dancing from node to node.

A node of Ranvier is a natural gap in the myelin sheath along the axon. These unmyelinated spaces are about one micrometer long and contain voltage-gated (i.e., opened by voltage) sodium (Na^+) and potassium (K^+) ion channels (ions are electrically charged atoms). The flow of ions through these channels, particularly the Na^+ channels, regenerates the action potential over and over again along the axon at each successive node of Ranvier. As noted above, the action potential “jumps” from one node to the next in saltatory conduction. If nodes of Ranvier are not present along an axon (as is the case in unmyelinated axons; see below), the action potential propagates much more slowly; ion movement through Na^+ and K^+ channels continuously regenerates new action potentials at every successive point along the axon, using extra time to do so. In effect, conduction of the action potential along an axon involves voltage-gated channels (channels that respond to voltage, rather than to neurotransmitter), on the axon, responding to voltage arising from an electrical field which spreads from the action potential in the previous segment of the axon. In a myelinated axon, because the action potential jumps from node to node, it does not have to be regenerated at every successive point along the axon, but only at the nodes, skipping across myelinated segments of the axon between nodes. Because the action potential in a myelinated axon must be regenerated fewer times to move any particular distance along the length of the axon, it reaches its destination faster, compared to the speed of conduction in an unmyelinated axon.

Nodes of Ranvier also save energy for the neuron since the ion channels only need to be present and opened and closed at the nodes and not along the entire axon. It is extraordinary that the nodes are placed along the axon's length at just the right spatial intervals to make impulse conduction down the axon the most efficient and speedy as possible. One can only wonder at the incredible precision with which natural selection operated on this feature of myelinated axons over the long course of animal evolution to create this optimal spacing of the nodes.

Neural Conduction in Unmyelinated Axons

Not all axons are myelinated. **Unmyelinated axons** tend to be older in evolution and to be the smaller diameter axons (classified as C fibers based on their small diameters; large diameter myelinated axons are called A fibers). In unmyelinated axons, in

order to move, the nerve impulse must be regenerated at every successive point along the axon. This takes time and slows the conduction of the nerve impulse (the action potential) down the length of the axon. Therefore, conduction of the action potential down the length of an unmyelinated axon is relatively slow. An example of unmyelinated C fibers are axons that are part of slow pain pathways. These pathways mediate the slower aching pain that follows tissue damage. The quick, sharp pain from an injury is mediated by larger diameter A fibers (axons).

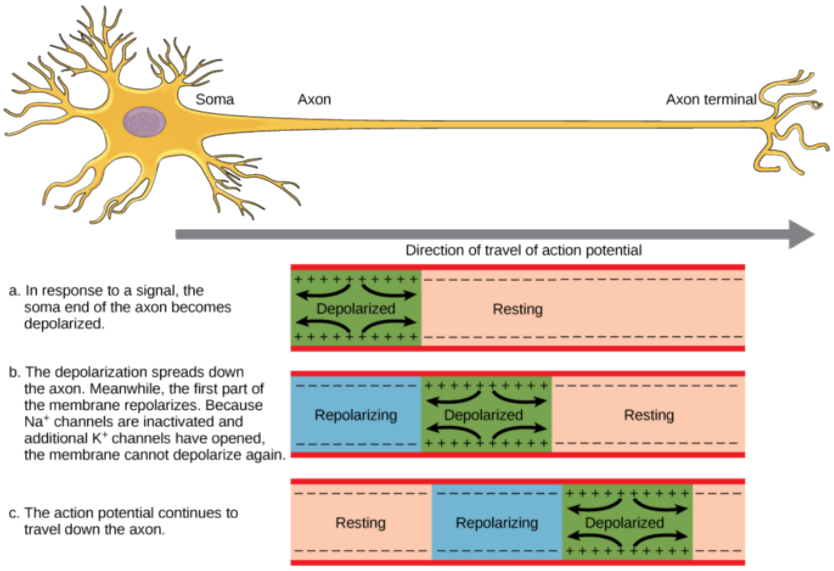

Figure 1.7.1.6: Action potential traveling along an unmyelinated neuronal axon. The action potential is conducted down the axon as the axon membrane depolarizes, then repolarizes. Because of these dynamics, the action potential can only be conducted in one direction, away from the cell body. Image: figure-35-02-04_NGB_added_resting.png adapted by Naomi Bahm (resting added to part a) from https://s3-us-west-2.amazonaws.com/c...e-35-02-04.png

The ion channels along the length of the unmyelinated axon are called voltage-gated channels because the voltage generated by the action potential in the prior segment of the axon triggers opening of these channels in the next segment. This leads to regeneration of the action potential. As this process is repeated over and over along the length of the unmyelinated axon, the action potential is conducted along the length of the axon away from the cell body toward the axon endings of the neuron. Figure 1.7.1.7 shows the channels opening and closing and the ions moving across the cell membrane generating an action potential in successive segments of the axon. This causes movement of the action potential, its conduction, along the axon away from the cell body (from right to left in the figure, as the arrow shows).

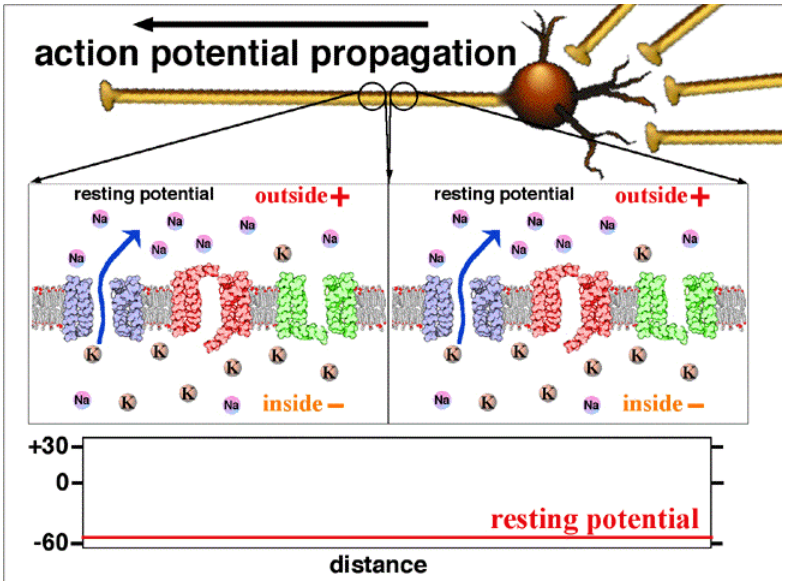

Figure 1.7.1.7: Another depiction of propagation of the nerve impulse (the axon potential) along an axon. This animation illustrates action potential propagation in an axon. Three types of ion channel are shown: potassium "leak" channels (blue), voltage-gated sodium channels (red) and voltage-gated potassium channels (green). The movement of positively-charged sodium and potassium ions through these ion channels controls the membrane potential of the axon. Action potentials are initiated in the axon's initial segment after neurotransmitter activates excitatory receptors in the neuron's dendrites and cell body. This depolarizes the axon initial segment to the threshold voltage for opening of voltage-gated sodium channels. Sodium ions entering through the sodium channels shift the membrane potential to positive-inside. The positive-inside voltage during the action potential in the initial segment causes the adjacent part of the axon membrane to reach threshold voltage. When positive-inside membrane potentials are reached, voltage-gated potassium channels open and voltage-gate sodium channels close. Potassium ions leaving the axon through voltage-gated potassium channels return the membrane potential to negative-inside values. When the voltage-gated potassium channels gate shut, the membrane potential returns to the resting potential. (Image and caption from Wkimedia Commons; File:Action potential propagation animation.gif; https://commons.wikimedia.org/wiki/F..._animation.gif; by John Schmidt; licensed under the Creative Commons Attribution-Share Alike 4.0 International, 3.0 Unported, 2.5 Generic, 2.0 Generic and 1.0 Generic license).

By contrast, as described above, in myelinated axons, the impulse gets regenerated only at the bare spots on the axon, the nodes of Ranvier. Because the action potential gets regenerated fewer times in order to travel a given distance, than is the case for unmyelinated axons, neural conduction is faster with the insulating myelin sheath. Myelinated axons tend to be large diameter (A and B fibers) and found in neural pathways mediating rapid behavioral response, such as the Pyramidal tract that runs from motor cortex to spinal cord motor neurons which generate voluntary action.

Synapses

The axon splits many times, so that it can communicate, or synapse, with several other neurons (see Figure 5.1.4). At the end of the axon, the **axon terminal button** (also called the axon ending, the terminal bouton, or the axon terminal) forms synapses with the dendritic **spines**, small protrusions mentioned above, on the dendrites of receiving neurons (postsynaptic neurons). Synapses form between the axon terminal button of the ***presynaptic neuron*** (neuron sending the signal) and the ***postsynaptic*** membrane (membrane of the neuron receiving the signal; see Figure 5.1.4). Here we will focus specifically on synapses between the axon terminal button of an axon and a dendritic spine; however, synapses can also form between the axon terminal button of the presynaptic neuron and the postsynaptic neuron's soma, dendritic shaft directly, or the axon of another neuron.

A very small space called a **synaptic gap** or a synaptic cleft exists between the pre-synaptic axon's terminal button and the post-synaptic neuron's dendritic spine. To give you an idea of the size of the synaptic gap, a dime is 1.35 mm (millimeter) thick. There are 1,350,000 nm (nanometers) in the thickness of a dime. The synaptic gap is only about 5 nm wide. In the pre-synaptic terminal button, there are **synaptic vesicles** that package together groups of chemicals, **neurotransmitters** (see Figure 5.1.4). Neurotransmitters are released from the pre-synaptic axon's terminal button or axon ending into the synaptic gap; molecules of neurotransmitter then travel across the synaptic gap, and open ion channels on the post-synaptic spine by binding to *receptor sites* there. We will discuss the role of these receptors in more detail later in section 5.2.

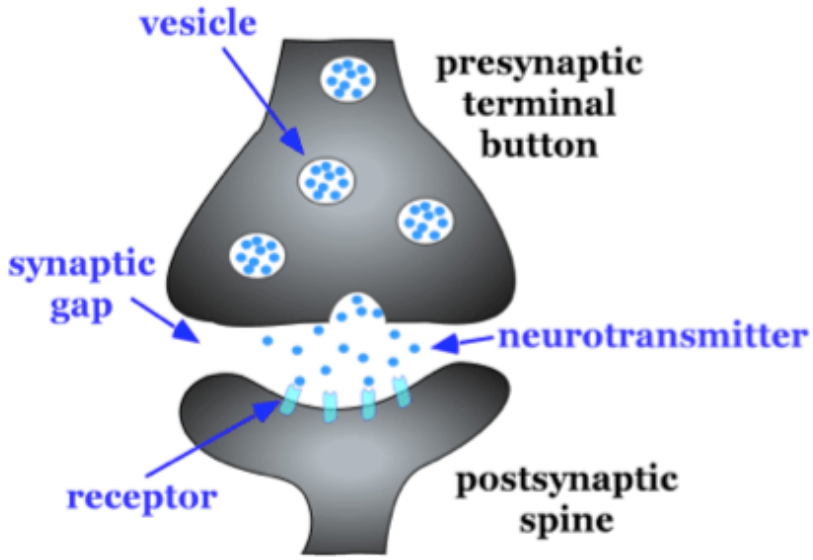

Figure 1.7.1.8: Basic characteristics of a typical synapse. Enlargement of the synapse between one of the axon terminal buttons (labeled presynaptic terminal button) and one of the dendrites of the second neuron shown (on the right) in Figure 5.1.4 above.

Axon Terminal Buttons, Synaptic Vesicles, PSPs, and Synaptic Transmission

Recall that the end of an axon or axon branch is called the axon terminal button (or terminal, or simply the axon ending). Within the axon terminal button are structures called **synaptic vesicles**, which contain neurotransmitter chemicals (which have been manufactured in the soma and transported to the axon ending and stored there in the synaptic vesicles, ready for release). When neurons communicate with one another across the synaptic gap which separates them, it is the **neurotransmitter**, released from the synaptic vesicles in the axon terminal button of the "sender" neuron (the presynaptic neuron) that transmits the neural message across the synaptic gap (the space between the membrane of the axon terminal button of the pre-synaptic neuron and the membrane of the dendrite or soma of the postsynaptic neuron). The **event that triggers release of neurotransmitter** from the synaptic vesicles in the axon terminal button is the **arrival of an action potential at the axon terminal button** of the sender neuron. The nerve cell releasing the neurotransmitter, the sender neuron, is known technically as the **presynaptic neuron**. The neuron receiving the neurotransmitter, the receiver cell, is called the **postsynaptic neuron**.

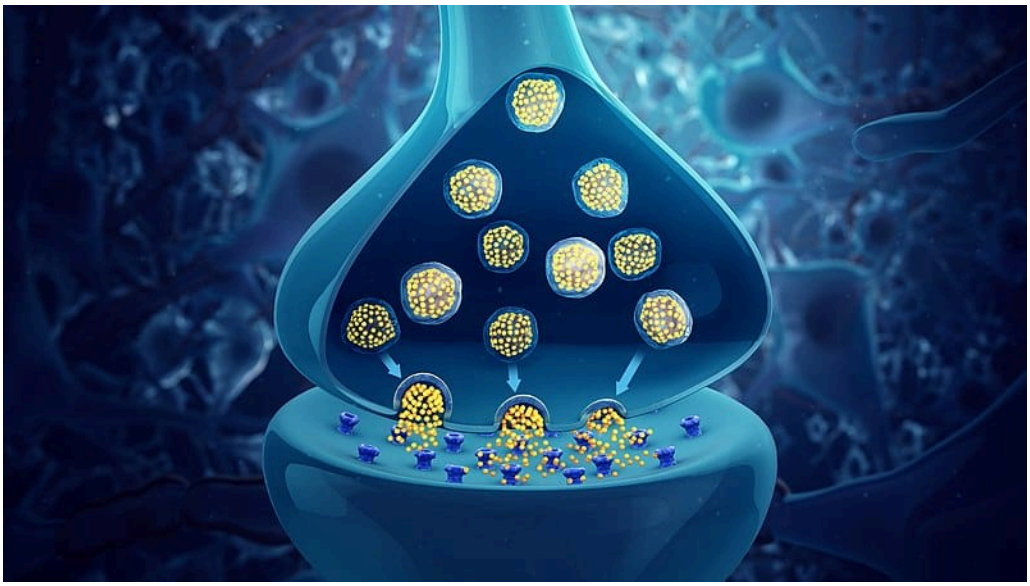

Figure 1.7.1.9: A synapse. Synaptic vesicles release neurotransmitters (small yellow balls) which bind to the receptors (blue peg-like structures) on the postsynaptic membrane. Synaptic vesicles inside a presynaptic axon terminal button (axon ending) releasing neurotransmitter molecules onto receptors on a dendrite of a receiving (post-synaptic) neuron. (Image from Wikimedia Commons; File:Neurotransmitters.jpg; https://commons.wikimedia.org/wiki/F...ansmitters.jpg; by https://www.scientificanimations.com/; by https://www.scientificanimations.com/; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

The neurotransmitter molecules attach to special sites on the membrane of the postsynaptic neuron. These special sites are called **receptor sites or postsynaptic receptor sites** and are typically located on the dendrites and dendritic spines of the receiving neuron, but can also be on its soma. Their molecular shapes match the shapes of the neurotransmitter molecules they receive, a kind of "lock and key" fit, which opens chemically-gated ion channels allowing ions with their electrical charges to move across the cell membrane creating voltage shifts called **postsynaptic potentials** (PSPs; additional details follow in Section 5.2).

These events from release of transmitter to generation of post-synaptic potentials comprise **synaptic transmission**. Many **psychoactive drugs** (drugs that alter mind and/or behavior) such as amphetamines, LSD, "magic mushrooms," etc. produce their effects by **blocking or activating specific receptor sites** (other psychoactives produce their effects by other mechanisms which affect synaptic transmission, some of which are discussed below and in Chapter 6 of this textbook).

As mentioned above, the cell membrane of a neuron has **channels or "doors" for ions** (electrically charged atoms) which can pass through the membrane when specific channels are opened for specific ions. Normally the channels are closed until acted upon by the attachment of neurotransmitter molecules to receptors sites on the membrane of the receiving neuron (the post-synaptic neuron). The **attachment of the molecules of transmitter to the receptors sites**, like a key into a lock, **opens the**

"doors" (ion channels) to specific ions which pass through the cell membrane carrying with them their electrical charge. This results in a change in the electrical state of the neuron, a post-synaptic potential (i.e. a voltage shift in the post-synaptic neuron)--if a positive shift in voltage occurs, it is called an **EPSP**, an excitatory post-synaptic potential; if a negative shift in voltage occurs in the post-synaptic neuron, then it is called an **IPSP**, an inhibitory post-synaptic potential. **EPSPs are caused by excitatory neurotransmitters** (e.g. glutamate; acetylcholine; histamine; epinephrine), **IPSPs by inhibitory transmitters** (e.g. GABA, gamma amino butyric acid; serotonin, also known by its chemical name, 5-hydroxytryptamine, abbreviated 5-HT).

These **PSPs**, whether excitatory or inhibitory, are called **graded potentials** because they are **not of a fixed voltage, but instead vary in voltage** depending on the amount of neurotransmitter (and other factors) that has been released onto the receptor sites on the postsynaptic neuron's dendrite. This is in contrast to the **action potential** (the nerve impulse) which is of a **fixed voltage and is "all or none"** which means that if it occurs, it occurs at its full strength or not at all. Think of a gun firing. If you pull the trigger of the gun with sufficient force (a kind of "trigger threshold" of force), then the gun fires a bullet with its full strength. But if trigger threshold is not reached, the gun doesn't fire at all. You don't get half a shot or one-eighth of a shot if you pull with less force, you can only get an "all or none" result--the gun fires, or it doesn't. Either the force on the trigger reaches threshold and the gun fires at its full "strength," or if the force is insufficient, the gun does not fire a bullet. The same is true of the action potential; if an action potential occurs, it occurs "all or none," at its full strength (voltage), or not at all, and, like the gun, the neuron "fires" only if its trigger threshold or **firing threshold** (in voltage, **about -55 millivolts for most neurons**) is reached. Graded potentials (EPSPs and IPSPs) are akin to **analog** signals (of different voltages), whereas action potentials aresimilar to **digital** signals (fixed voltage).

Types of Neurons

Not all neurons are created equal! There are neurons that receive information about the world around us, ***sensory* neurons**. There are ***motor* neurons** that allow us to initiate movement and behavior, ultimately allowing us to interact with the world around us. Finally, there are ***interneurons***, which process the sensory input from our environment into meaningful representations, plan the appropriate behavioral response, and connect to the motor neurons to execute these behavioral plans.

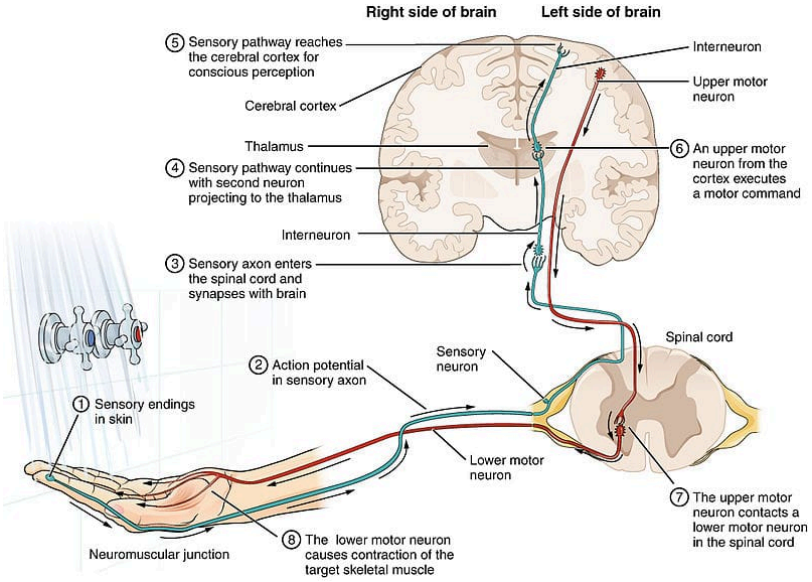

Figure 1.7.1.10: Sensory neurons carry information towards the CNS. Motor neurons carry information from the CNS. Interneurons carry information between sensory and motor neurons.

In addition to this general functional categorization of neurons (sensory, motor, and interneurons), neurons may also be classified by structure (e.g. unipolar, bipolar, multipolar), shape, or other characteristics. See Chapter 4.1 for an overview of these classifications. Since the shape of the neuron relates to its role in communication, this categorization is explored in greater depth below.

Categorizing Neurons by Shape

Neurons can also be classified by their shape. For example, Cajal used such names as basket, stellate, moss, pyramidal, etc. to describe various types of neurons he observed. However, this classification is anatomical and does not reflect whether the cell is, for example, a motor neuron or an interneuron. Nevertheless, the shape of neurons may reflect aspects of their function and their role in information processing in the nervous system. For example, **pyramidal neurons** (Figure 1.7.1.11) are "a common class of neuron found in the cerebral cortex of virtually every mammal, as well as in birds, fish and reptiles. Pyramidal neurons are also common in subcortical structures such as the hippocampus and the amygdala. They are named for their shape: typically they have a soma (cell body) that is shaped like a teardrop or rounded pyramid. They also tend to have a conical spray of longer dendrites that emerge from the pointy end of the soma (apical dendrites) and a cluster of shorter dendrites that emerge from the rounded end. . . They comprise about two-thirds of all neurons in the mammalian cerebral cortex . . . they are 'projection neurons' — they often send their axons for long distances, sometimes out of the brain altogether. For example, pyramidal neurons in layer 5 of the motor cortex send their axons down the spinal cord to drive muscles" (Bekkers, 2011). They are the primary excitatory neurons in the motor cortex and the pre-frontal cortex. Table 1.7.1.1 summarizes features of pyramidal neurons.

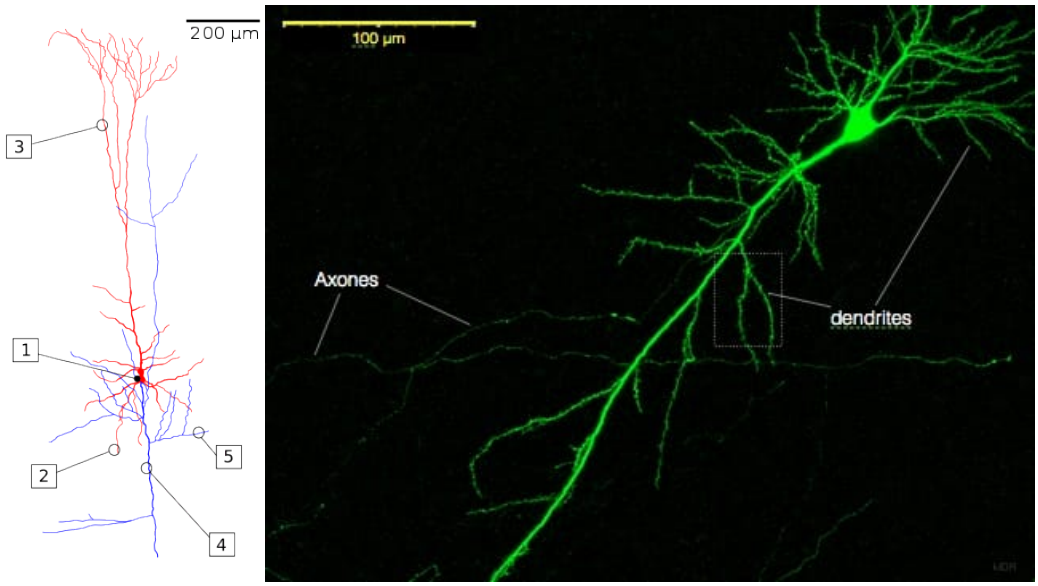

Figure 1.7.1.11: (left) A reconstruction of a pyramidal cell. Soma and dendrites are labeled in red, axon arbor in blue. (1) Soma, (2) Basal dendrite, (3) Apical dendrite, (4) Axon, (5) Collateral axon. (right) Pyramidal neuron of a rat hippocampal organic culture. Axons shown (axones, in Spanish) are from another neuron most of which is not shown (Image on left, Wikipedia, The Pyramidal Cell, retrieved 8/30/21. Image on right from Wikimedia Commons, File:Neurone pyramidal.jpg; https://commons.wikimedia.org/wiki/F..._pyramidal.jpg; by Mathias De Roo; licensed under the Creative Commons Attribution-Share Alike 3.0 Unported license.).

Table 1.7.1.1. Features of pyramidal neurons. (adapted from John Bekkars; Pyramindal Neurons; Current Biology).

Location	Common in cerebral cortex of mammals, especially Layers III and V (cerebral cortex in mammals has six cell layers); also found in hippocampus, and amygdala. Also found in other vertebrates
Shape and numbers	Multipolar Pyramidal, but some variations among species and location in brain; about 2/3 of all neurons in the mammalian cerebral cortex
Function	Excitatory projection neurons with long axons carrying action potentials long distances, sometimes completely out of the brain; e.g. pyramidal neurons in layer 5 of motor cortex go all the way to spinal motor neurons; others that remain in the cortex interconnecting distant areas of cortex are critically important in many cognitive functions
Neurotransmitter	Glutamate, the most abundant excitatory transmitter in the vertebrate nervous system

By contrast, **stellate neurons** have a star-like shape by virtue of the dendrites which radiate out from the stellate neuron's cell body (see Figure 5.1.12(b)). Spiny stellate neurons, like pyramidal neurons, have large numbers of dendritic spines, but they lack

the long apical dendrite characteristic of pyramidal neurons. Like pyramidal neurons, spiny stellate neurons in the cerebral cortex are excitatory and use glutamate as transmitter. Van Essen and Kelly (1973) reported different functions for visual cortical neurons depending upon whether they were pyramidal or stellate neurons. After pyramidal neurons, stellate neurons are the second most numerous type of cortical neuron. Another type of stellate neuron that has only sparse spines is inhibitory and uses GABA (gamma-amino-butyric-acid) as its transmitter.

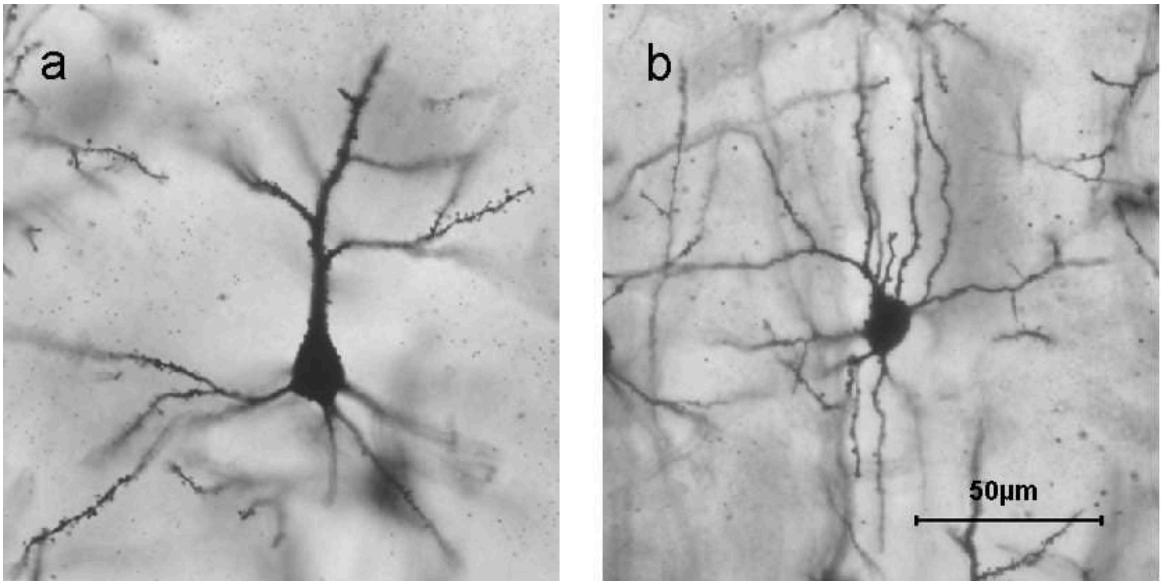

Figure 1.7.1.12: Golgi stained neurons in different layers of cerebral cortex: a) Layer II/III pyramidal cell; b) layer IV spiny stellate cell. Dendritic spines are visible on branching dendrites as clusters of tiny thorn-like bristles. (Image and one sentence caption from Wikipedia, Stellate Cell, retrieved 8/30/21; description of dendritic spines by Kenneth A. Koenigshofer, Ph.D.).

Brown et al. (2019) found different processing roles for basket neurons (see Figure 5.1.13) and stellate neurons in the cerebellum. Stellate cells and basket cells both make inhibitory synapses directly onto Purkinje neurons in the cerebellum. Stellate neurons influence pattern of firing and basket neurons affect rate of firing of the Purkinje neurons in the cerebellum. Basket cells are also found in the neocortex (cerebral cortex). Basket cells are inhibitory interneurons. They envelop pyramidal cell bodies in the neocortex in dense complexes resembling baskets (Kirkcaldie, 2012). Figure 1.7.1.13 shows a variety of interneurons classified by shape.

"Approximately 95% of the cortical neuronal activity is mediated by fast excitatory (glutamate, 80%) and fast inhibitory (GABA, 15%) neurons. The remaining 5% percent is associated with the slow modulatory action of monoaminergic (dopamine, serotonin, noradrenaline) and non-monoaminergic (acetylcholine, endorphins, etc.) neurons located in small subcortical nuclei of the mesencephalon and projecting to the cerebral cortex" (Marco Catani, in Encyclopedia of Behavioral Neuroscience, 2nd edition, 2022, Science Direct; https://www.sciencedirect.com/topics...pyramidal-cell; retrieved 4/25/22).

Though several basic types of neurons have been classified, the picture in the brain with regard to types of neurons present is quite complex, as expressed in this quote: "Whereas in the spinal cord we could easily distinguish neurons based on their function [sensory, interneuron, motor], that isn't the case in the brain. Certainly, there are brain neurons involved in sensory processing – like those in visual or auditory cortex – and others involved in motor processing – like those in the cerebellum or motor cortex. However, within any of these sensory or motor regions, there are tens or even hundreds of different types of neurons. In fact, researchers are still trying to devise a way to neatly classify the huge variety of neurons that exist in the brain . . . part of what gives the brain its complexity is the huge number of specialized neuron types. Researchers are still trying to agree on what these are" (University of Queensland, n.d.).

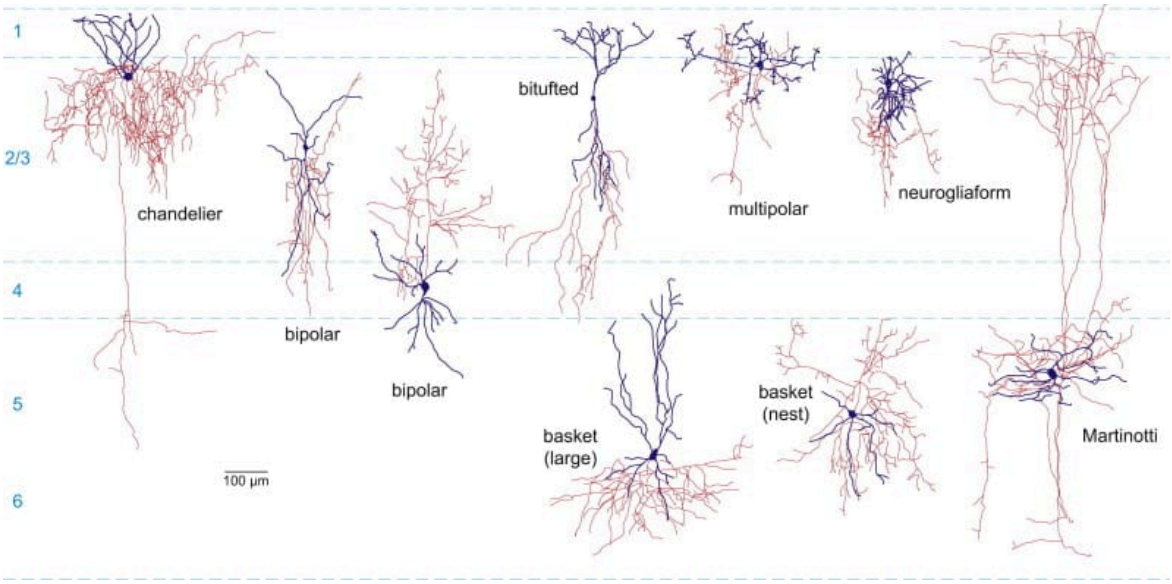

Figure 1.7.1.13: (above). Variety of types of interneurons classified by shape. Representative morphologies of mouse interneuron types. Note that the axon (red) and dendrite (blue) arbors are typically less elaborate than in primate cortex. Two variants of bipolar cells and basket cells (large and nest) are shown (Kirkcaldie, 2012).

Yet another way to classify neurons is by the neurotransmitter they use (see Synaptic Transmission below). Perhaps equally important is to attempt to trace the connections that neurons make with other neurons to try to understand their inputs and outputs and what roles they play in processing. This has been done for many stellate and basket cells, inhibitory interneurons synapsing on Purkinje cells in the cerebellum. However, because of the complexity of brain circuitry this is very difficult to accomplish, especially in the cerebral cortex, although possible in cases where neurons belong to large neural tracts or pathways with straightforward connections which are easier to trace, such as from the pyramidal neurons in motor cortex to spinal cord motor neurons or from thalamus to sensory cortex. Understanding the complex circuitry of the brain in its entirety may never be fully accomplished. With 80-100 billion neurons in the human brain and most making perhaps many thousands of connections, the number of connections in the human brain is astronomical!

1.7.2: Neurons Generate Voltage Changes to Code Information

Overview

According to materialists (those who believe that everything in the universe is physical), all of the mental activities of our minds and all of our behaviors are products of the physical activities of the brain and nervous system. These information processing operations that create our minds and control our behavior depend upon neurons and their electrical and chemical interactions. Neurons produce electrical potentials (voltages) that act as signals in the information processing activities of the brain. As previously mentioned, neurons communicate with one another across synaptic spaces using chemicals known as neurotransmitters. In this module, we examine how neurons create electrical potentials including the graded potentials (post-synaptic potentials) and the nerve impulse (the action potential), and the processes of synaptic transmission. The graded potentials can vary in voltage, while the action potential is fixed in voltage for any particular neuron and is said to be all or none--if it occurs, it occurs at its full strength or not at all. This is analagous to the firing of a gun. It has a trigger threshold equal to a particular amount of pressure applied to its trigger and then that threshold pressure is reached, the gun fires, and it fires at its full "strength." In a like manner, the action potential will only be generated if its trigger threshold, a particular voltage within the neuron, is reached. When this happens, the action potential is generated in the neuron at its full "strength," measured in voltage, and this nerve impulse is conducted along the axon to the axon endings which then release neurotransmitter onto receptor sites located on the receiving neuron. We now examine these processes in greater detail in this module and the next.

How Do Neurons Produce Electrical Potentials?

As described in Module 5.1, neurons, regardless of type, use voltage changes, known as electrical potentials, to code and process information. But how do they do it? How do neurons make voltage which they then use as electrical signals in the brain's electrochemical code? More specifically, the question is, how do neurons produce electrical potentials such as the resting potential, the action potential, and the post-synaptic potentials?

Neurons produce electrical potentials or voltages by the unequal distribution and the movement of electrically charged atoms called ions across the neuron's cell membrane. These ions come mainly from dissolved salts in the body fluids inside and outside neurons. The main ions used by neurons to produce their voltages are sodium (Na+), potassium (K+), and chloride (Cl-). Notice that the first two are positive ions and the last, chloride ions, are negatively charged. A fourth ion, organic anions (A-), which are large (on the molecular scale) negatively charged proteins, are manufactured inside the neuron. They are too large to cross the cell membrane, and therefore give the neuron's resting voltage a negative bias. The distribution or concentrations of these ions inside and outside a neuron determine its voltage (voltage is just the physical separation of charged particles, like in a car battery with its positive and negative poles around which are concentrated positively and negatively charged particles floating in battery acid).

By these means, four main types of neuron voltages or neuron potentials are produced by neurons: 1) the resting potential (often equal to about negative 70 thousandths of a volt, -70 millivolts) 2) two types of post-synaptic potentials (PSPs)--excitatory post-synaptic potentials (EPSPs) and inhibitory post-synaptic potentials (IPSPs) and 3) the action potential (AP, the nerve impulse). Let's examine these potentials in more detail and see how they are generated inside neurons. These electrical potentials in large populations of interacting neurons encode the information that guides our behavior and produces our psychological experience of the world.

The Neuron Cell Membrane

The **cell membrane**, which is composed of a lipid bilayer of fat molecules, separates the fluid inside of the cell from the surrounding extracellular fluid. There are proteins that span the membrane, forming **ion channels** that allow, when open, particular ions to pass between the intracellular and extracellular fluid (see Figure 8). These ions are in different concentrations inside the cell relative to outside the cell, and the ions have different electrical charges. Due to this difference in ion concentration and charge, in part enforced by the physical barrier of the cell membrane when ion channels to specific ions are closed, a voltage is produced, the resting potential.

The Resting Membrane Potential

The resting potential can be thought of as a baseline voltage from which the other neuron potentials are generated. It is the voltage inside a nerve cell when it is at rest, that is, it is neither receiving inputs (PSPs) at the moment nor generating any outputs (action potentials) at the moment. In this state of "rest", the voltage inside the nerve cell is approximately -70 mv. It is negative inside the neuron at "rest" because there are more negative ions inside the neuron (the intracellular fluid) and more positive ions on the outside (the extracellular fluid).

Specifically, there are large numbers of Na+ ions (sodium ions) outside the neuron and very few of these on the inside, when the neuron is "at rest" (when it is at resting potential). And there are more negatively charged ions inside the cell than on the outside during resting potential. This unequal distribution of ions across the cell membrane sets up the electrical "resting potential," making it equal to approximately -70 mv in the typical neuron. During resting potential (resting membrane potential) ion channels to Na+ are closed.

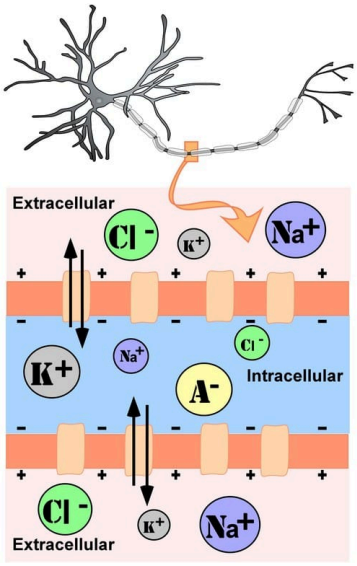

Figure 1.7.2.1: Representation of ion concentrations inside (intracellular) and outside (extracellular) a neuron in the unmyelinated segment of the axon. Size of the circles represents relative concentrations of each ion inside and outside the neuron; note that when the neuron is "at rest" it has a net negative charge inside, the resting potential, equal to about -70 millivolts in most neurons. Also note the higher concentrations of sodium (Na+) and chloride (Cl-) ions outside the cell. Sodium on the outside of the neuron "would like" to move into the cell along its charge and concentration gradients, but it can't when the cell is at rest, because the ion channels for sodium ions are closed, creating a physical barrier keeping most of the extracellular sodium ions from crossing through the cell membrane. But what happens when the sodium channels open? And, test yourself, what opens the ion channels?

The Sodium-Potassium Pump

During the resting potential, the sodium-potassium pump maintains a difference in charge across the cell membrane of the neuron. The sodium-potassium pump is a mechanism of active transport that moves sodium ions out of cells and potassium ions into cells. The sodium-potassium pump moves both ions from areas of lower to higher concentration, using energy in ATP and carrier proteins in the cell membrane (see Figure 5.2.2).

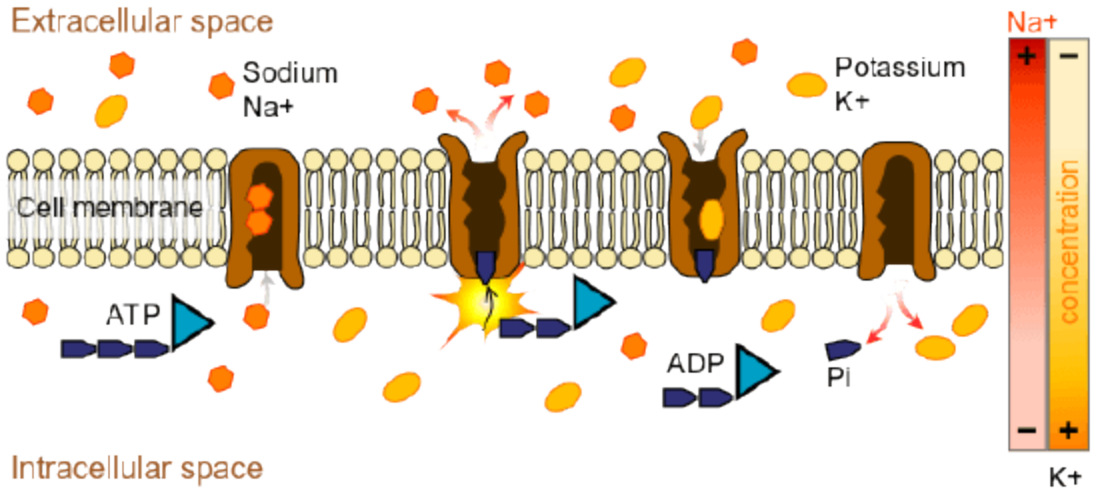

Figure 1.7.2.2: The sodium-potassium pump helps maintain the resting potential of a neuron. During resting potential, there is more negative charge inside than outside the cell creating a resting potential of -70mv. During resting potential, some Na+ leaks into the neuron and some K+ leaks out. ATP (Adenosine triphosphate) provides energy to pump sodium out and potassium into the cell. There is more concentration of sodium outside the membrane and more concentration of potassium inside the cell due in part to the unequal movement of these ions by the pump. The presence of negatively charged organic anions (A-) contributes to the net negative charge (-70mv) inside the neuron at rest. (Image from Wikimedia Commons; File:Scheme sodium-potassium pump-en.svg; https://commons.wikimedia.org/wiki/F...um_pump-en.svg; by LadyofHats Mariana Ruiz Villarreal; released into the **public domain** by its author, **LadyofHats**. This applies worldwide).

Producing Other Membrane Potentials: Post-synaptic potentials and the Action potential

How are the other neuron potentials produced? To generate the other neuron potentials, which are just voltage shifts away from resting potential, there must occur a redistribution of ions (and their electrical charges) across the cell membrane. In short, ions must move.

There are two main forces (called gradients) that can cause these ions to move.

First, opposite charges attract one another ("opposites attract"), and like charges repel one another. When ions of opposite charge are unequally distributed across the cell membrane (as is the case during the resting potential), this sets up what is called a **charge gradient** (an unequal distribution of charged particles) that creates an **electrostatic force.** If these ions are allowed to move freely, they will move along the charge gradient. Positive charges will move toward negative ones and vice versa.

Secondly, when ions of any particular type (for example, sodium ions) are unequally distributed across the cell membrane (like more Na+ outside the neuron than inside during resting potential), this sets up what is called a **concentration gradient** which can cause **diffusion,** the net movement of ions from a region of higher concentration to a region of lower concentration. Diffusion is driven by a gradient in concentration. Such concentration gradients for several ions (sodium, potassium, and chloride ions) exist when the neuron is at resting potential (see Figure 10). Ions, if allowed to move freely, will move along their concentration gradients, such that ions of a particular type (like Na+ ions) will move from a region of high concentration (of Na+) to a region of lower concentration (of Na+).

In short, ions, if allowed to move freely, will move along the charge gradient and along their concentration gradients. Ions "want" to move to equalize their concentrations across the cell membrane and also "want" to move to equalize the charges across the cell membrane (by moving toward opposite charges and away from like charges).

However, it is important to note that **these two forces created by the charge gradient and concentration gradient for each ion can oppose one another** in the case of some ions, **or can act in concert** (as is the case with Na+ ions during the resting potential).

Let us see how these two forces, diffusion (due to concentration gradients) and electrostatic pressure (due to a charge gradient), act on the four groups of ions mentioned above.

1. ***Anions (A-)****:* Anions are highly concentrated inside the cell and contribute to the negative charge of the resting membrane potential. Diffusion and electrostatic pressure are not forces that determine A- concentration because A- is impermeable to the cell membrane. There are no ion channels that allow for A- to move between the intracellular and extracellular fluid.
2. ***Potassium (K+)****:* The cell membrane is very permeable to potassium at rest, but potassium remains in high concentrations inside the cell. Diffusion created by the concentration gradient pushes K+ to the outside of the cell because it is in high concentration inside the cell. However, electrostatic pressure created by the charge gradient pushes K+ into the cell because the positive charge of K+ is attracted to the negative charge inside the cell. In combination, these forces oppose one another with respect to K+ *with the charge gradient (opposite charges attract) overpowering the concentration gradient so that the net effect is to push and keep K+ inside the neuron in higher concentrations*.
3. ***Chloride (Cl-)****:* The cell membrane is also very permeable to chloride at rest, but chloride remains in high concentration outside the cell. Diffusion created by a concentration gradient for Cl- pushes Cl- toward the inside of the cell because it is in high concentration outside the cell. However, electrostatic pressure created by the charge gradient for Cl- pushes Cl- toward the outside of the cell because the negative charge of Cl- is attracted to the positive charge outside the cell created primarily by the high concentration of Na+ there. Similar to K+, these forces oppose one another with respect to Cl- *and again, in this case, like Na+, the more powerful charge gradient (like charges repel) overcomes the weaker concentration gradient for Cl-*.
4. ***Sodium (Na+)****:* The cell membrane is not very permeable to sodium when the neuron is at rest. Diffusion created by a concentration gradient pushes Na+ toward the inside of the cell because it is in high concentration outside the cell. Electrostatic pressure created by the charge gradient for Na+ also pushes Na+ toward the inside of the cell because the positive charge of Na+ is attracted to the negative charge inside the cell. Both of these forces push Na+ inside the cell; however, as discussed above, Na+ cannot permeate the cell membrane because the channels for Na+ are closed and so Na+ remains in high concentration outside the cell. The small amounts of Na+ inside the cell are removed by the **sodium-potassium pump** (Figure 5.2.2), which uses the neuron's energy (adenosine triphosphate, ATP) to pump three Na+ ions out of the cell in exchange for bringing two K+ ions inside the cell.

Though ions "want" to move in these ways dictated by their charge gradients and concentration gradients, Na+ can't move freely when the neuron is at resting membrane potential because Na+ ion channels are closed and the cell membrane acts as a physical barrier to Na+ ions, preserving the unequal distributions of Na+ ions inside and outside the neuron. To get ion movement, pores or ion channels in the cell membrane of the neuron "at rest" must be opened, overcoming the physical barrier created by the cell membrane when the neuron is "at rest" (not receiving any inputs via its dendrites and not generating any outputs, action potentials, via its axon) and its sodium channels are closed.

What is it that causes the ion channels to open, allowing the ions to move along their gradients? You can test yourself here to see how much you have retained from your reading thus far. What is it that opens the ion channels?

The arrival of transmitter molecules from the axon ending of a pre-synaptic neuron, and their attachment to post-synaptic receptor sites, is the key event. This "lock and key" interaction between molecules of transmitter and the post-synaptic receptor sites causes "doors", specific ion channels, to open.

When specific ion channels get opened in this way (Na+ channels, for example), those specific ions (Na+, in this case) move through the cell membrane along their specific concentration and charge gradients. This will cause a voltage shift away from resting potential. This voltage shift is the post-synaptic potential (PSP), in this case it is an excitatory post-synaptic potential (EPSP), a positive shift in voltage away from resting potential because when Na+ channels in the cell membrane are opened by neurotransmitter, then Na+ ions will move along their charge gradient and concentration gradient into the cell, making the inside of the neuron more positively charged.

Excitatory and Inhibitory Post-Synaptic Potentials

1. **Excitatory postsynaptic potentials** (EPSPs): a *depolarizing* current that causes the membrane potential to become more positive and closer to the threshold of excitation (the "trigger threshold" of minus 55 millivolts) which lead to generation of an action potential (see Figure 5.2.4); caused by excitatory transmitter.
2. **Inhibitory postsynaptic potentials** (IPSPs): a *hyperpolarizing* current that causes the membrane potential to become more negative (see Figure 5.2.4) and further away from the threshold of excitation (the "trigger threshold" of minus 55 millivolts), caused by inhibitory transmitter.

The post-synaptic potentials occur in a post-synaptic neuron (thus the name), a receiver neuron. When such a neuron receives an input from a pre-synaptic neuron, in the form of transmitter molecules which attach to the **post-synaptic receptor sites (which are proteins that are embedded in the membrane of the post-synaptic cell)**, ion channels then open, ions move across the cell membrane, carrying with them their electrical charges. These events change the voltage inside the post-synaptic neuron. It

is this voltage shift away from resting potential that constitutes the post-synaptic potential (PSP).

An **EPSP (Excitatory Post-synaptic Potential)** is a positive shift in voltage (depolarization) from the resting potential, say from -70 mv to -60 mv; as described above, an EPSP occurs when Na+ channels open and Na+ ions flow into the neuron along their concentration and charge gradients, carrying with them their positive charges, making the interior of the post-synaptic neuron more positively charged. This positive shift in voltage is also known as *depolarization* of the neuron and is caused by excitatory transmitter molecules binding to post-synaptic receptor sites of the receiving neuron.

An **IPSP (Inhibitory Post-synaptic Potential)** is a negative shift in voltage (hyperpolarization) from the resting potential, say from -70 mv to -80 mv; an IPSP occurs when Cl- and K+ channels open. These ions then flow along charge and concentration gradients, which cause negatively charged Cl- ions to move in and positively charged K+ ions to move out of the post-synaptic neuron, making it more negatively charged. This increase in net negative charge inside the cell is the IPSP (inhibitory post-synaptic potential). Cl- ions move in against their charge gradient (the negative voltage of the resting potential repels Cl- ions) because the concentration gradient pushing them inward into the neuron is stronger than the opposing charge gradient that tries to push them out of the neuron (like charges repel). Similarly, K+ ions move out in opposition to the charge gradient pulling them in, again, because the concentration gradient pulling them outward is stronger than the charge gradient which tries to pull them inward. These movements are prevented during the resting potential by the added physical barrier, the cell membrane, but when these ion channels are opened more than they are during the resting potential, the gradients move the ions causing the IPSP. As noted above, in the case of Na+ both charge and concentration gradients pull Na+ inward when Na+ ion channels in the neuron's cell membrane open.

Note, again, that in both the EPSP and the IPSP, it is the attachment of molecules of transmitter to post-synaptic receptor sites (like keys going into locks of a specific shape) that opens the "doors", the ion channels, allowing ions to move through the cell membrane.

But there is one more key issue here. What is it that determines *which* ion channels open, and therefore, whether an EPSP or an IPSP occurs? The answer was implied above. The answer is: it is the type of neurotransmitter and type of receptor site receiving the transmitter molecules. There are **two basic types of neurotransmitter, excitatory and inhibitory.**

Excitatory transmitters (such as glutamate, acetylcholine--ACh, norepinephrine--NE, dopamine--DA) are those which **open sodium (Na+) channels** in the post-synaptic membrane, allowing sodium ions, carrying their positive charge, into the cell, making an EPSP.

Inhibitory transmitters (such as gamma-amino-butyric acid--GABA, serotonin--5-HT, or dopamine--DA) are those which affect **chloride and potassium channels i**n the post-synaptic membrane, allowing chloride to follow its concentration gradient (overcoming the opposing charge gradient) into the post-synaptic neuron and allowing potassium to follow its concentration gradient (overcoming its opposing charge gradient) and moving out. These ion movements make the inside of the neuron more negative, making an IPSP.

Notice that DA is listed as both excitatory and inhibitory. That's because some post-synaptic DA receptors are inhibitory, leading to IPSPs when activated by DA, and other DA receptors are excitatory, producing EPSPs when they bind with DA.

Spatial and Temporal Summation

There is one additional factor in this process. Each neuron connects with numerous other neurons, often receiving multiple impulses from them. Sometimes, a single excitatory postsynaptic potential (EPSP) is strong enough to induce an action potential in the postsynaptic neuron, but often multiple presynaptic inputs must create EPSPs around the same time for the postsynaptic neuron to be sufficiently depolarized to fire an action potential. Summation, either spatial or temporal, is the addition of these impulses at the axon hillock. Together, synaptic summation and the threshold for excitation act as a filter so that random “noise” in the system is not transmitted as important information.

At any moment in time, each neuron can be receiving mixed messages, both EPSPs and IPSPs. Thus, receiver neurons (post-synaptic neurons) can receive multiple inputs--simultaneously or over time or space. The multiple inputs can add up--this is called summation and there are two types. **Spatial summation** refers to two or more PSPs arriving at different locations (i.e. different spaces on the receiving neuron, thus spatial summation) on the post-synaptic (receiver) neuron simultaneously or close enough in time so that their voltages add together. For example, an IPSP of negative 25 millivolts (thousandths of a volt) might add to an EPSP of 50 millivolts occurring at the same time = 50 millivolts positive - 25 millivolts = net positive 25 millivolts. That would be spatial summation. The other kind of summation is **temporal summation** when the PSPs from a single pre-synaptic

source, arriving to the post-synaptic neuron in "rapid fire," add together. For example, three EPSPs of 10 millivolts each occurring in rapid sequence would add together. Spatial and temporal summation are important in determining whether "trigger threshold" will be reached in the receiving neuron, triggering an action potential in that neuron. Summation permits activity from many input neurons to be integrated in the neuron receiving the inputs. If membrane depolarization does not reach the threshold level, an action potential will not happen.

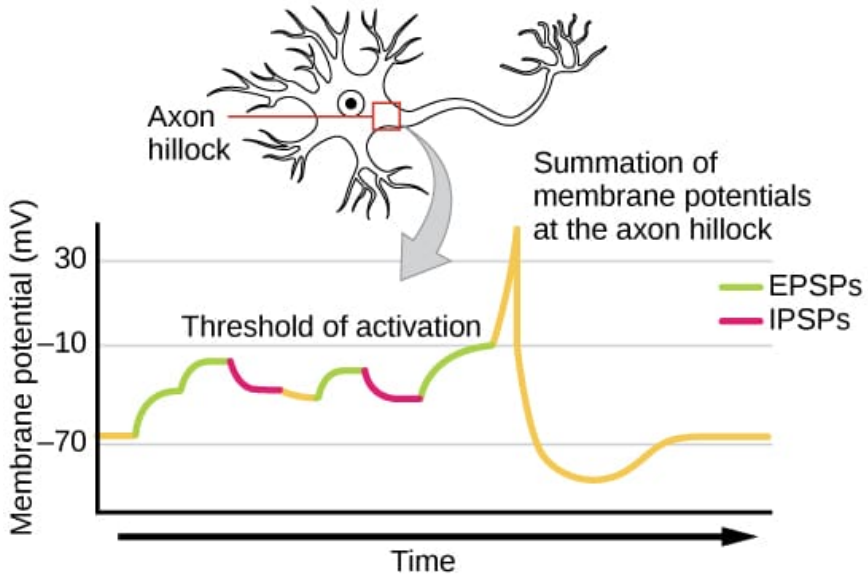

Figure 1.7.2.3: **Signal summation at the axon hillock**: A single neuron can receive both excitatory and inhibitory inputs from multiple neurons. All these inputs are added together at the axon hillock. If the EPSPs are strong enough to overcome the IPSPs and reach the threshold of excitation, the neuron will fire an action potential. (Image from Biology, Signal Summation; Libretexts; https://bio.libretexts.org/Bookshelv...%20will%20fire. Unless otherwise noted, LibreTexts content is licensed by CC BY-NC-SA 3.0).

One neuron often has input from many presynaptic neurons, whether excitatory or inhibitory; therefore, inhibitory postsynaptic potentials (IPSPs) can cancel out EPSPs and vice versa. The net change in postsynaptic membrane voltage determines whether the postsynaptic cell has reached its threshold of excitation ("trigger threshold") needed to fire an action potential. If the neuron only receives excitatory impulses, it will also generate an action potential. However, if the neuron receives both inhibitory and excitatory inputs, the inhibition may cancel out the excitation and the nerve impulse will stop there. To review, spatial summation means that the effects of impulses received at different places on the neuron add up so that the neuron may fire when such impulses are received simultaneously, even if each input on its own would not be sufficient to cause firing. Temporal summation means that the effects of impulses received at the same place can add up if the impulses are received in close temporal succession. Thus, the neuron may fire when multiple inputs are received, even if each input on its own would not be sufficient to cause firing.

Key Points

- Simultaneous impulses may add together from different places on the neuron to reach the threshold of excitation during spatial summation.
- When individual impulses cannot reach the threshold of excitation on their own, they can can add up at the same location on the neuron over a short time; this is known as temporal summation.
- The action potential of a neuron is fired only when the net change of excitatory and inhibitory impulses is non-zero.

Key Terms

- **temporal summation**: the additive effect when successive impulses (and the resulting PSPs) received at the same place on the neuron add up
- **spatial summation**: the additive effect when simultaneous impulses (and the resulting PSPs) received at different places on the neuron add up
- **axon hillock**: the specialized part of the soma of a neuron at the root of the axon where impulses are added together

The Action Potential (the "nerve impulse")

The nerve impulse, or action potential, is generated in the post-synaptic neuron only if a **"trigger threshold" ("threshold of excitation") of -55 millivolts** (minus 55 mv) is reached (the trigger threshold varies from neuron to neuron and may be anywhere from minus 65 to minus 55, but will always be the same for any particular neuron. For purposes of our discussion, we will continue to refer to the trigger threshold of neurons as minus 55 millivolts, not minus 65 as is sometimes indicated in some textbooks). When that trigger voltage is attained (for example, as a result of an EPSP of at least 15 millivolts), then **all the voltage-gated sodium ion channels suddenly open**, allowing a massive inflow of sodium ions, Na+, into the cell along both concentration and electrical gradients for sodium. This produces a rapid, **large positive shift or "spike"** in the voltage of the post-synaptic neuron. This is the **nerve impulse or action potential**. In most neurons, it is a positive shift of about 100 to 130 millivolts, if we measure from the -70 millivolts of the resting potential, up to about a positive 30 to 60 millivolts, depending on the neuron. This value for any particular neuron is always the same for that neuron. Typically neurons with larger diameters (such as A fibers which are typically myelinated as well as large diameter) produce the largest action potentials (up to about positive 60mv, i.e. 130 mv above resting potential), while the neurons with smaller diameter axons (classified as C fibers, typically unmyelinated) produce action potentials in the lower range.

As fast as the voltage of the action potential rises, it starts to fall after reaching its peak (corresponding to peak Na+ concentration inside the neuron). It quickly falls back to the resting potential and even a bit below resting potential (the so-called refractory period), as Na+ and K+ ions move out, before the return of the neuron's potential back to -70 mv, the resting potential. This rapid rise to the action potential's peak and then its rapid fall gives the action potential, when graphed, a spike appearance. For this reason, action potentials are often called "spikes" by neuroscientists. See the diagram of the action potential (Figures 11, 12) to get a clearer picture of these events. Note that an **EPSP**, an excitatory post-synaptic potential, **moves the neuron's voltage closer to "trigger threshold"**, increasing the chances that the neuron will be sufficiently "excited" to generate an action potential. By contrast, the **IPSP**, the inhibitory post-synaptic potential, **moves the neuron's voltage further away from "trigger threshold"** inhibiting the neuron from firing an action potential.

Once **trigger threshold ("threshold of excitation")** is reached (dotted line in Figure 9) and an action potential is generated, it is then conducted down the length of this neuron's axon (saltatory conduction in a myelinated axon; see above). **Once the AP reaches this neuron's axon ending** or terminal button, its arrival causes the **release of neurotransmitter** molecules from the synaptic vesicles located there. Now this neuron is no longer called a post-synaptic neuron, but becomes a pre-synaptic neuron (a sender neuron) with respect to the next cell in line. It's the release of transmitter (step 3 in the list of 8 steps in synaptic transmission shown in Synaptic Transmission below) leads to steps (4 and 5 in the list of 8 steps) and an EPSP or IPSP is generated in the next cell in line. Remember that whether an EPSP or an IPSP is caused in the next cell in line is determined by whether an excitatory or an inhibitory transmitter has been released from the pre-synaptic neuron (see the 8 steps below).

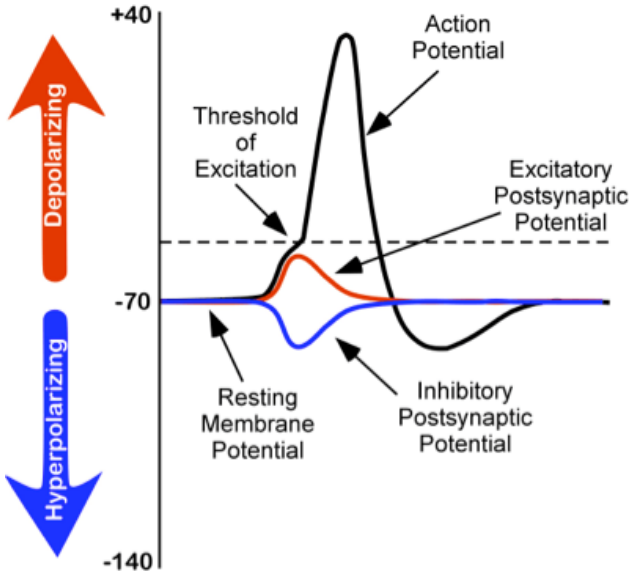

Figure 1.7.2.4: Changes in membrane potentials of neurons. (left) Dotted line represents trigger threshold ("threshold of excitation"), about -55 millivolts, an action potential is generated once trigger threshold voltage is reached.

Note that an EPSP (depolarization) moves the neuron's voltage more positive and thus closer to trigger threshold, making it more likely that the voltage reaches trigger threshold, "firing" an action potential down the axon of the neuron; thus it is excitatory. An IPSP does the opposite. It moves the voltage in the negative direction, further from trigger threshold, and thus inhibiting the neuron from producing an output (an action potential) in its axon. Also note that the peak of the action potential (top of the black line shaped like a spike) is the peak of its positive voltage and corresponds to the maximum concentration of Na+ ions inside the cell as a result of Na+ ion channels opening after trigger threshold has been reached. After this peak concentration of Na+ making the peak of the voltage of the action potential, positively charged ions (including K+ ions) begin to leave the interior of the cell and as they do so, the positive voltage inside the neuron progressively drops, corresponding to the downward slope of the spike. Note in addition that the spike goes further negative than the resting potential. In this state the neuron is inhibited by this **refractory period** and cannot fire another action potential for a brief time. This keeps the action potential as a discrete digital event. This is important for source coding, an important feature of neural coding, discussed in the chapter on learning and memory in this text. The entire process from the triggering of the action potential (which starts in the root of the axon, called the **axon hillock**, nearest the cell body) to the end of the refractory period takes about 1 millisecond, making the maximum rate at which a neuron can generate and "fire" action potentials (nerve "impulses") about 1,000 per second, although most neurons when active fire at a much lower frequency. Frequency of action potentials is one code that the nervous system uses to represent information. For example, the brighter a light source is, the higher the frequency of action potentials in the optic nerve in response to it.

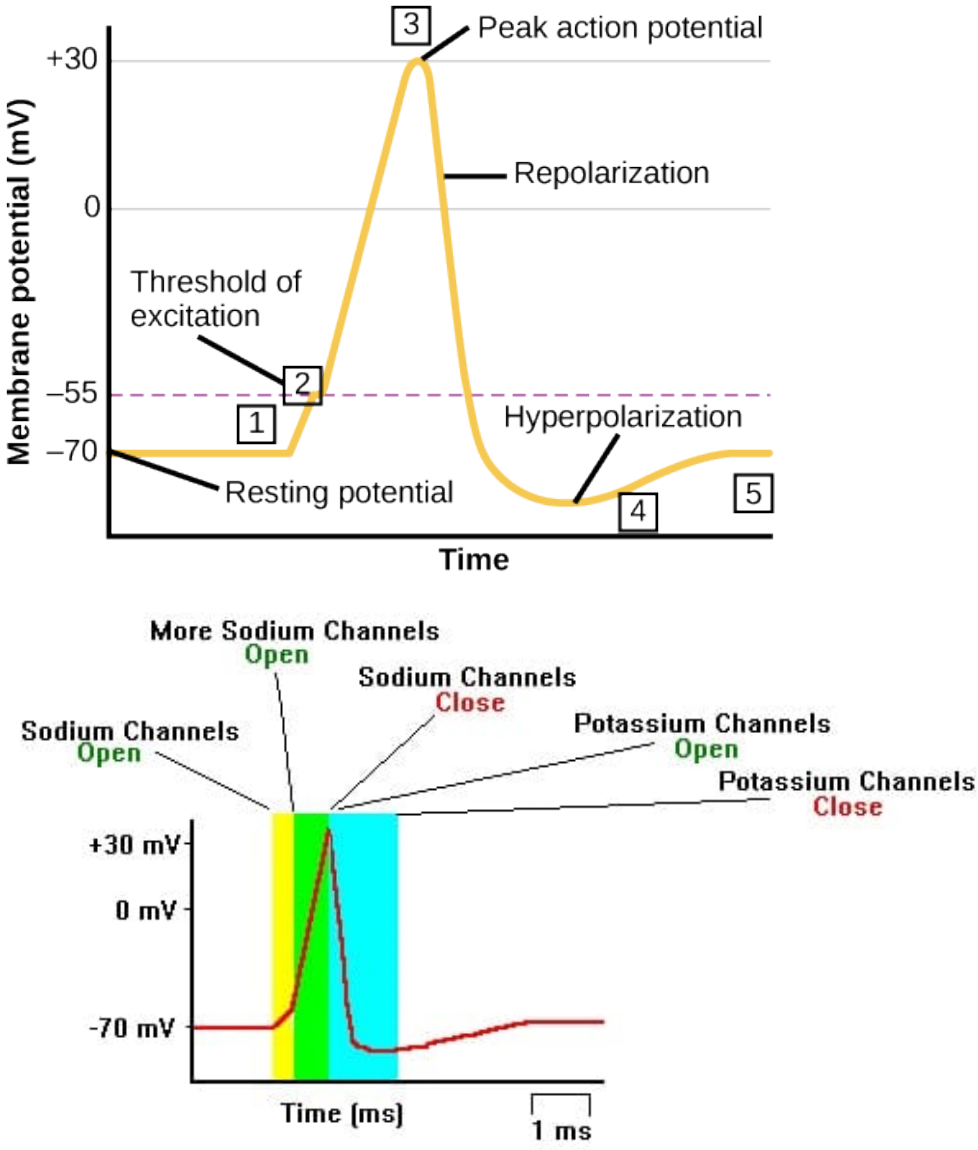

Figure 1.7.2.5: Formation of an action potential. (left) The formation of an action potential can be divided into five steps. (1) A

stimulus from a sensory cell or another neuron causes the target cell to depolarize toward the threshold potential. (2) If the threshold of excitation is reached, all Na+ channels open and the membrane depolarizes. (3) At the peak action potential, K+ channels open and K+ begins to leave the cell. At the same time, Na+ channels close. (4) The membrane becomes hyperpolarized as K+ ions continue to leave the cell. The hyperpolarized membrane is in a refractory period and cannot fire. (5) The K+ channels close and the Na+/K+ transporter (requiring energy expenditure) restores the resting potential. (right) Sequence of opening and closing of Sodium (Na+) and Potassium (K+) ion channels producing the rising and falling phases of the action potential. A single neuron by itself can't generate psychological states like feelings, perceptions, or thoughts. Neurons must interact with other neurons. The generation of a thought, or other complex psychological/mental experience, requires that enormous numbers of neurons interact with one another. To interact, they must communicate with other neurons.

As described in module 5.1, neurons communicate with one another, across spaces between them known as "synaptic gaps" by the release of chemicals (called neurotransmitters or simply transmitters) from one neuron's axon ending onto receptor sites on the dendrites or soma of the target neuron (a post-synaptic neuron). The neurotransmitters involved in this communication between neurons are manufactured in the soma of the neuron and are then transported down a long axon where they are stored in the synaptic vesicles until released from the axon ending into the synaptic space; the release is triggered by the arrival of an action potential (the nerve impulse) at the axon ending.

As discussed in module 5.1, the synapse includes the pre-synaptic neuron (the sender cell) and its axon ending with its synaptic vesicles, along with the synaptic gap, and the post-synaptic neuron (the receiving cell) with its receptor sites. There are an enormous number of neurons in the human brain, but the number of *possible* different combinations of synaptic connections among those 80-100 billion neurons is unimaginable--one neuroscientist estimated that the number of possible patterns of interconnect between neurons in a human brain exceeds the number of atoms in the entire universe! This neural complexity appears to be sufficient to code all the information contained in a human brain including all the thoughts, feelings, perceptions and memories of a human lifetime.

Key Points

- The resting potential, typically equal to -70 millivolts, is the voltage inside a neuron when it is receiving no inputs from other neurons and producing no outputs (no action potentials)
- Post-synaptic potentials (PSPs), EPSPs (excitatory; depolarizations) and IPSPs (inhibitory; hyperpolarizations) are positive and negative voltage shifts, respectively, away from the neuron's resting potential. These voltage shifts, PSPs, in the post-synaptic neuron result from release of transmitter from one or more pre-synaptic neurons.
- Action potentials are formed when inputs (summed EPSPs and IPSPs) cause the cell membrane to depolarize past the threshold of excitation ("trigger threshold"), causing all sodium ion channels to open, leading to a large positive shift in the neuron's voltage (Figures 5.2.4 and 5.2.5).
- When the potassium ion channels are opened and sodium ion channels are closed, the cell membrane becomes hyperpolarized as potassium ions leave the cell; the cell cannot fire during this refractory period (Figures 5.2.4 and 5.2.5).
- The action potential travels down the axon as the membrane of the axon depolarizes and repolarizes (see 5.1, Figures 5.1.4 and 5.1.5) .
- Myelin insulates many axons to prevent leakage of the current as it "leaps" from node to node down the axon.
- Nodes of Ranvier are gaps in the myelin along the axons; they contain sodium and potassium ion channels, allowing the action potential to travel quickly down the axon by jumping from one node to the next (saltatory conduction; see module 5.1).

Key Terms

- **action potential**: a short term change in the electrical potential that travels along a cell
- **depolarization**: a decrease in the difference in voltage between the inside and outside of the neuron
- **hyperpolarize**: to increase the polarity of something, especially the polarity across a biological membrane
- **node of Ranvier**: a small constriction in the myelin sheath of axons
- **saltatory conduction**: the process of regenerating the action potential at each node of Ranvier

1.7.3: Synaptic Transmission

Learning Objectives

1. Describe ion channels, and what changes they undergo when neuron potentials are produced; what causes ion channels to change during synaptic transmission?
2. Define ionotropic and metabotropic receptors and discuss in what ways they differ from one another in their effects during synaptic transmission
3. Explain the steps in synaptic transmission from pre-synaptic neuron to post-synaptic neuron
4. Describe how excitatory and inhibitory transmitters differ in their effects on post-synaptic neurons during synaptic transmission
5. Discuss how layers of neurons, simulated by processing units in artificial neural networks, might produce psychological processes such as learning

Overview

After an action potential is generated in the presynaptic neuron, this all or none impulse is conducted along the axon to the axon ending (the terminal button). In the presynaptic terminal button, the arrival of the action potential triggers the release of neurotransmitters (see Figure 5.3.2). Neurotransmitters cross the synaptic gap and open subtypes of receptors in a lock-and-key fashion (see Figure 5.3.2). Depending on the type of neurotransmitter, an EPSP or IPSP occurs in the dendrite of the post-synaptic cell. Neurotransmitters that open Na+ or calcium (Ca+) channels cause an EPSP; an example is the NMDA receptors, which are activated by glutamate (the main excitatory neurotransmitter in the brain). In contrast, neurotransmitters that open Cl- or K+ channels cause an IPSP; an example is gamma-aminobutryric acid (GABA) receptors, which are activated by GABA, the main inhibitory neurotransmitter in the brain. Once the EPSPs and IPSPs occur in the postsynaptic site, the process of communication within and between neurons cycles on (see Figure 5.3.3). A neurotransmitter that does not bind to receptors is broken down and inactivated by enzymes or glial cells, or it is taken back into the presynaptic terminal button in a process called *reuptake* (Figure 5.3.2, Step 6).

SYNAPTIC TRANSMISSION

The transmission of neural messages across the synaptic gap, via the release of transmitter from a pre-synaptic neuron onto **post-synaptic receptor sites** on a post-synaptic neuron, is called **synaptic transmission or neurotransmission**. Synaptic transmission is central to the brain's capacity to process information, to generate mental states, and to generate adaptive behavior. Some synapses are purely electrical and make direct electrical connections between neurons (for example, between basket cells in the cerebellum). However, most synapses are chemical synapses, involving neurotransmitters. The transmission of neural signals across **chemical synapses** is more complex than at **electrical synapses** and involves many steps.

Electrical Synapses

Electrical synapses are much less common than chemical synapses, but they are nevertheless distributed throughout the brain. In chemical synapses neurotransmitter is needed for communication between neurons, but for electrical synapses this is not the case. In electrical synapses current, ions, and molecules can flow between two neurons through direct physical connections that allow cytoplasm to flow between them. The physical connection between neurons with electrical synapses is in the form of large pore structures, called connexons, at **gap junctions** between such neurons. Communication between neurons with electrical synapses is faster than at chemical synapses which must go through more steps to transmit signals to another neuron. Therefore, electrical synapses are often found in neural systems that require rapid response such as defensive reflexes. Electrical synapses can communicate signals in both directions between neurons in contrast to chemical synapses which transmit messages in one direction, from pre-synaptic by transmitter release to post-synaptic neuron.

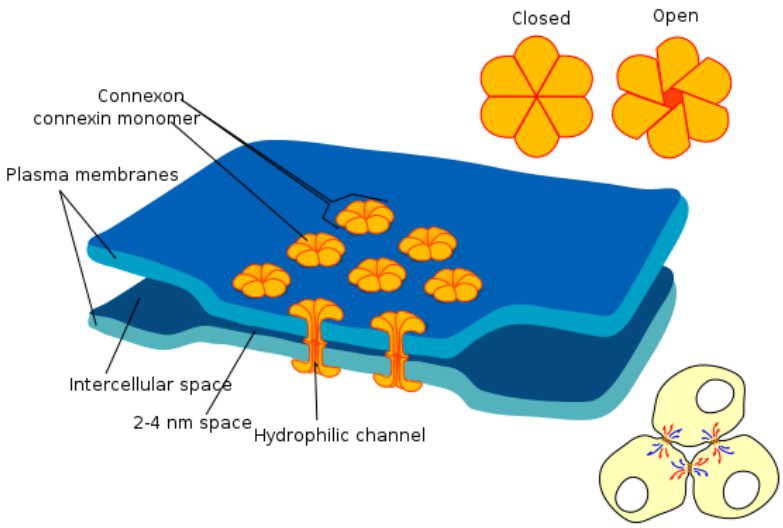

Figure 1.7.3.1: Gap junction at an electrical synapse. Two adjacent neurons with electrical synapse between them can communicate through hydrophilic channels Note that the gap between cell membranes of pre and post-synaptic neurons at electrical synapses is much smaller than the synaptic gap at chemical synapses which is about 10 times larger. (Image from Wikimedia Commons; File:Gap cell junction-en.svg; by Mariana Ruiz LadyofHats.https://commons.wikimedia.org/wiki/F...unction-en.svg; by Mariana Ruiz LadyofHats; **public domain** by its author, **LadyofHats**).

Chemical Synapses

We discussed previously which ions are involved in maintaining the resting membrane potential. Not surprisingly, some of these same ions are involved in the action potential. When the cell becomes depolarized (more positively charged) and reaches the threshold of excitation, this causes a voltage-dependent Na+ channel to open. A voltage-dependent ion channel is a channel that opens, allowing some ions to enter or exit the cell, depending upon when the cell reaches a particular membrane potential (i.e. a particular voltage).

When the cell is at resting membrane potential, these voltage-dependent Na+ channels are closed. As we learned earlier, both diffusion from concentration gradients and electrostatic pressure from charge gradients are pushing Na+ ions toward the inside of the cell. However, Na+ cannot permeate the membrane when the cell is at rest.

Once these channels are opened when trigger threshold has been reached, Na+ rushes inside the cell, causing the cell to become very positively charged relative to the outside of the cell. This is responsible for the rising or depolarizing phase of the action potential (see Module 5.2). The inside of the cell becomes very positively charged, from about +30mV to about +60mv, depending upon the particular neuron. At this point, the Na+ channels close and become *refractory*. This means the Na+ channels cannot reopen again until after the cell returns to the resting membrane potential. Thus, a new action potential cannot occur during the refractory period. The refractory period also ensures the action potential can only move in one direction down the axon, away from the soma.

As the cell becomes more depolarized, a second type of voltage-dependent channel opens; this channel is permeable to K+. With the inside of the cell very positive relative to the outside of the cell (depolarized) and the high concentration of K+ within the cell, both the force of diffusion, along concentration gradients, and the force of electrostatic pressure, along charge gradients, drive K+ outside of the cell. The movement of K+ out of the cell causes the cell potential to return back to the resting membrane potential; this is the falling or hyperpolarizing phase of the action potential (see Module 5.2).

A short hyperpolarization occurs partially due to the gradual closing of the K+ channels. With the Na+ channels closed, electrostatic pressure from a K+ charge gradient continues to push K+ out of the cell. In addition, the sodium-potassium pump is pushing Na+ out of the cell. The cell returns to the resting membrane potential, and the excess extracellular K+ diffuses away. This exchange of Na+ and K+ ions happens very rapidly, in less than one millisecond. The action potential occurs in a wave-like motion down the axon until it reaches the terminal button. Only the ion channels in very close proximity to the action potential are affected, causing the action potential to be regenerated along the axon--this creates the movement of the action potential

down the axon.

The binding of a neurotransmitter to its receptor is reversible, and for good reason. As long as it is bound to a post synaptic receptor, a neurotransmitter continues to affect membrane potential, so must be removed from the synapse. The effects of the neurotransmitter generally lasts a few milliseconds before being terminated. If the used transmitter is not removed or inactivated it can cause over-activation of neurons, potentially leading to pathological mental states and behavior if enough synapses are affected. Neurotransmitter termination can occur in three ways: First, reuptake by astrocytes or by the presynaptic terminal where the used transmitter can be destroyed by enzymes (Figure 5.3.2, step 6). Second, degradation by enzymes in the synaptic cleft such as the enzyme, acetylcholinesterase, which destroys used acetylcholine transmitter. Third, diffusion of the neurotransmitter as it moves away from the synapse. Again, destruction or removal of used transmitter from the synapse after it has done its work is essential to normal functioning of the nervous system.

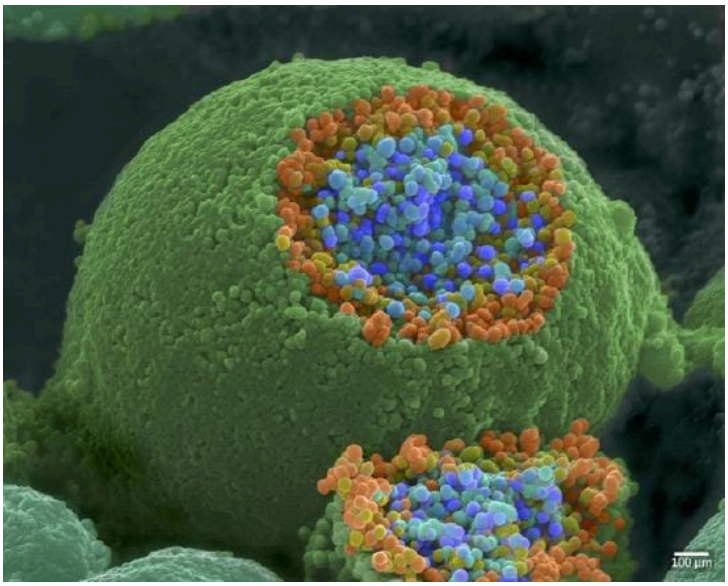

Figure 1.7.3.2: **Synaptic vesicles inside a neuron**: This pseudocolored image taken with a scanning electron microscope shows an axon terminal that was broken open to reveal synaptic vesicles (blue and orange) inside the neuron. (Image and caption adapted from: General Biology (Boundless), Chapter 35, The Nervous System; https://bio.libretexts.org/Bookshelv...gy_(Boundless); LibreTexts content is licensed by CC BY-NC-SA 3.0. Legal).

Ionotropic and Metabotropic Synapses

There are two major categories of post-synaptic receptors: ionotropic receptors and metabotropic receptors.

Ionotropic receptors, when activated by transmitter from a pre-synaptic neuron, cause ion channels to open, allowing ions, with their electrical charges, to move across the cell membrane of the receiving (post-synaptic) neuron, causing an EPSP or an IPSP (see above). These are fast acting receptors and are involved in the kind of neural transmission we have been describing above. Ionotropic receptors are receptors on ion channels that open, allowing some ions to enter or exit the cell, depending upon the presence of a particular neurotransmitter. The type of neurotransmitter and the permeability of the ion channel it activates will determine if an EPSP or IPSP occurs in the dendrite of the post-synaptic cell. These EPSPs and IPSPs summate and determine whether an action potential will be generated. For a video summary, copy and paste this web address into your browser: https://nobaproject.com/modules/neurons.

By contrast, **metabotropic receptors** (usually coupled with G-proteins; i.e. guanine nucleotide-binding proteins), when activated by transmitter from a pre-synaptic neuron, act indirectly and more slowly, using second messengers to produce a variety of metabolic effects to modulate cell activity. These effects include changes in gene transcription, regulation of proteins in the cell, release of Ca+ (calcium ions) within the cell, and effects on ion channels on the neuron's cell membrane (Sterling & Laughlin, 2015). Such modulation of neurons and synapses can be more long-lasting than effects of the activation of ionotropic receptors and may play an important role in cellular level mechanisms of learning and memory (Nadim and Bucher, 2014).

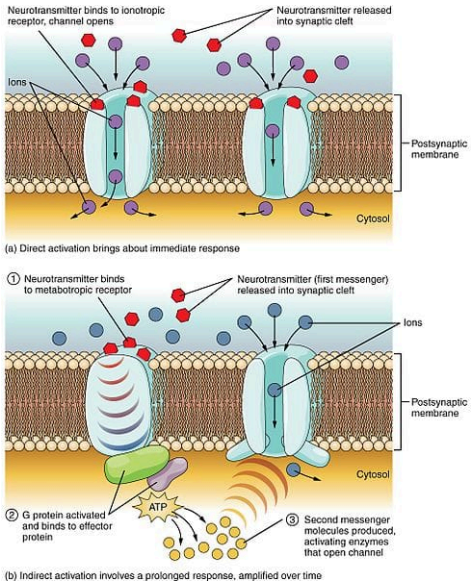

Figure 1.7.3.3: Comparison of Ionotropic and Metabotropic Post-Synaptic Receptors. The image at the top (a) shows ionotropic receptors which when activated by transmitter open ion channels immediately resulting in ion movement and an immediate response, a post-synaptic potential. The image at the bottom (b) shows metabotropic receptors which when activated by transmitter initiate a second messenger system. Second messengers can have a variety of effects including indirectly opening ion channels (Image from Wikimedia Commons; File:1226 Receptor Types.jpg; https://commons.wikimedia.org/wiki/F...ptor_Types.jpg; by OpenStax; licensed under the Creative Commons Attribution 4.0 International license).

8-Step Summary of Synaptic Transmission

Here's a somewhat simplified but useful 8-step summary of the **steps in synaptic transmission** at synapses with **ionotropic receptors**:

2) increased intracellular Ca+2 at the axon ending **binds synaptic vesicles to pre-synaptic membrane triggering release of transmitter** from synaptic vesicles in the axon ending of this pre-synaptic neuron

3) **molecules of neurotransmitter cross the fluid-filled synaptic space** between pre- and post-synaptic neurons

4) **molecules of transmitter attach to post-synaptic** ionotropic **receptor sites on** the dendrite or soma of the **post-synaptic neuron** on the other side of the synaptic space

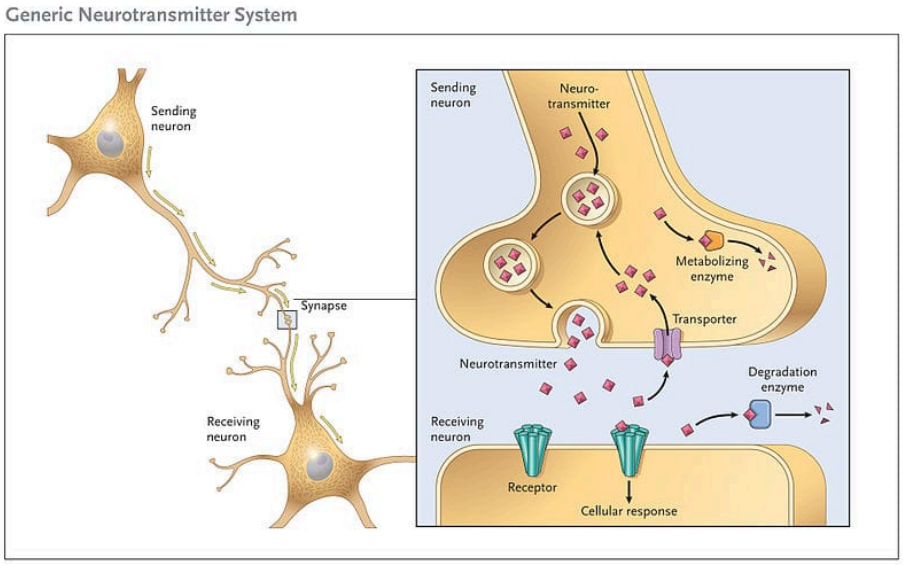

Figure 1.7.3.4: Image on left shows two neurons communicating with one another (synaptic transmission). The neuron at the top is the sender or pre-synaptic neuron. The neuron on the bottom is the receiver or post-synaptic neuron. In the image on the left of the figure, notice the small box at the synapse. This box is enlarged in the image on the right side of the figure to reveal details of the synapse and events there during synaptic transmission. The axon ending or bouton/button of the pre-synaptic neuron is at the top. We see transmitter molecules (small red squares) transported down the axon (arrow) from the cell body to the axon ending where they are stored in synaptic vesicles (yellow circles containing small red squares, i.e. transmitter molecules). When a nerve impulse (action potential) reaches the axon ending, calcium ions enter the axon ending/bouton/button causing synaptic vesicles to move to the axon ending's cell membrane (steps 1 and 2 referred to above) causing release of transmitter molecules into and across the synaptic gap (steps 2 and 3). Transmitter molecules bind to post-synaptic receptors (green) causing specific ion channels ("doors") to open to specific ions (steps 4 and 5). Ions (not shown in this figure) move through the ion channels in the post-synaptic neuron's cell membrane (step 6) with their electrical charges changing the voltage inside the post-synaptic neuron (either an EPSP or an IPSP). If trigger threshold (about negative 55 millivolts) is reached, an action potential is generated in the receiver neuron, which now becomes a sender neuron for the next cell in line (not shown in this figure). Inactivation of the used transmitter is the final step, step 8, and is depicted in this figure by "enzyme degradation" (enzymatic destruction). (Image from Wikimedia Commons; File:Generic Neurotransmitter System.jpg; https://commons.wikimedia.org/wiki/F...ter_System.jpg; by NIDA(NIH); this work is in the **public domain** in the United States. Caption by Kenneth A. Koenigshofer, Ph.D.).

5) **this "lock and key" interaction, between transmitter molecules and** the **receptor sites** that they attach to, "opens doors," that is, causes holes or pores (**ion channels) in the post-synaptic neuron's cell membrane to open to specific ions** (electrically charged atoms; sodium, chloride, potassium)

6) **ions move (along charge and concentration gradients)** through specific ion channels across the cell membrane into or out of the post-synaptic neuron, carrying with them their electrical charges, **altering the electrical potential inside the post-synaptic neuron** (as noted above, this voltage shift is called a post-synaptic potential or **PSP**). **If the transmitter is excitatory**, then **sodium channels open** and **sodium ions (Na+) follow the electric and charge gradients into the post-synaptic neuron** making the **voltage inside the neuron more positive (an EPSP)**. **If the transmitter is inhibitory**, think of chloride ions (Cl -) moving in and potassium ions (K+) moving out, making the **inside of the post-synaptic neuron more negatively charged**, moving the neuron's voltage further away from trigger threshold, thus inhibiting the neuron from firing (this is **an IPSP**). EPSPs and IPSPs can summate.

7) **if the voltage shift** in the post-synaptic neuron is positive (an EPSP) and if it is large enough, or if summated inputs (summation) are **positive enough to reach "trigger threshold"** of the post-synaptic neuron (-55 millivolts), then **Na+ channels suddenly open (voltage gated channels), Na+ rushes inside the cell, and an action potential is generated** in the post-synaptic (receiver) neuron, which now becomes a pre-synaptic (sender) neuron for the next cell in line. The action potential is generated at the axon hillock and then is **conducted down the length of the axon**, jumping from node to node if the axon is myelinated. As the Na+ rushes inside the cell, this is responsible for the rising or depolarizing phase of the action potential (see Figure 5.3.2).

8) **Inactivation of used transmitter** (by its reuptake into the pre-synaptic neuron or by its enzymatic destruction by specific

enzymes)

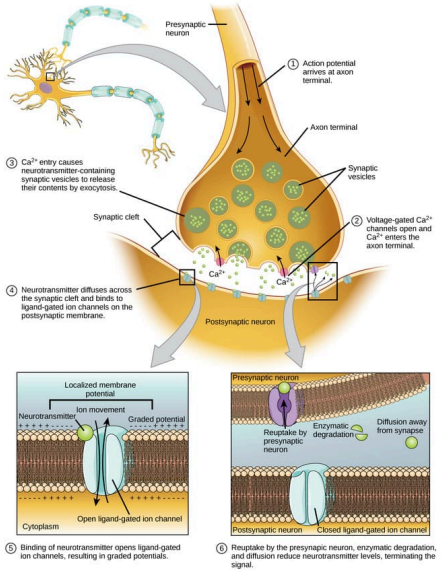

Figure 1.7.3.5: **Communication at a chemical synapse**: Communication at chemical synapses requires release of neurotransmitters (refer to 8-step summary above). When the pre-synaptic membrane is depolarized, voltage-gated Ca2+ channels open and allow Ca2+ to enter the cell. The calcium entry causes synaptic vesicles to fuse with the membrane and release neurotransmitter molecules into the synaptic cleft. The neurotransmitter diffuses across the synaptic cleft and binds to ligand-gated ion channels (channels opened by chemical transmitter) in the post-synaptic membrane, resulting in a localized depolarization (EPSP) or hyperpolarization (IPSP) of the post-synaptic neuron depending upon the type of transmitter, excitatory or inhibitory. (Image and caption adapted from: General Biology (Boundless), Chapter 35, The Nervous System; https://bio.libretexts.org/Bookshelv...gy_(Boundless); LibreTexts content is licensed by CC BY-NC-SA 3.0. Legal).

Types of Neurotransmitter

There are at least 60-100 neurotransmitters and probably many others yet to be discovered. The best known can be grouped into types based on their chemical structure.

Today, the majority of neuroscientists will tell you that most neurons release the same neurotransmitter from their axons—which is why you may see some neurons referred to as “dopaminergic” or “serotonergic,” releasing dopamine or serotonin, respectively. But new work in the field has uncovered that neurons are not fixed when it comes to the chemicals they release.

Some cells change the type of neurotransmitters they release depending on the circumstances, sometimes releasing up to five different kinds. Scientists call this phenomenon “neurotransmitter switching.”

Neurotransmitters, at the highest level, can be sorted into two types: small-molecule transmitters and neuropeptides. Small-molecule transmitters, like dopamine and glutamate, typically act directly on neighboring cells. The neuropeptides, small molecules like insulin and oxytocin, work more subtly, modulating, or adjusting, how cells communicate at the synapse. These powerful neurochemicals are at the center of neurotransmission, and, as such, are critical to human cognition and behavior.

Often, neurotransmitters are talked about as if they have a single role or function. Dopamine is a “pleasure chemical” and GABA is a “learning” neurotransmitter. But neuroscientists are discovering they are multi-faceted and complex, working with and against each other to facilitate neural signaling across the cortex. Here is a list of some of the most common neurotransmitters discussed in neuroscience.

Amino acids neurotransmitters

- **Glutamate (GLU).** This is the most common and most abundant excitatory neurotransmitter. Glutamate has an important role in cognitive functions like thinking, learning and memory. Too much glutamate results in excitotoxicity, or the death

of neurons due to stroke, traumatic brain injury, or amyotrophic lateral sclerosis (ALS), the debilitating neurodegenerative disorder better known Lou Gehrig's disease. GLU is also important to learning and memory: long term potentiation (LTP), occurs in glutamatergic neurons in the hippocampus and cortex.

- **Gamma-aminobutryic acid (GABA).** GABA works to inhibit neural signaling. GABA is the most common inhibitory neurotransmitter in the nervous system, particularly in the brain. New research suggests that GABA helps lay down important brain circuits in early development. GABA also has a nickname: the "learning chemical." Studies have found a link between the levels of GABA in the brain and whether or not learning is successful.
- **Glycine.** Glycine is the most common inhibitory neurotransmitter in the spinal cord and is involved in auditory processing, pain and metabolism.

Monoamines neurotransmitters

Monoamines neurotransmitters are involved in consciousness, cognition, attention and emotion.

- **Serotonin (5HT).** Serotonin is an inhibitory neurotransmitter. Serotonin helps regulate mood, sleep patterns, sexuality, anxiety, appetite and pain. Diseases associated with serotonin imbalance include seasonal affective disorder, anxiety, depression, fibromyalgia and chronic pain. Medications that regulate serotonin and treat these disorders include selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs), which increase the levels of transmitter by inhibiting their reuptake after they have done their work at the postsynaptic receptor sites. Serotonin (5HT), sometimes called the "calming chemical," is best known for its mood modulating effects. A lack of 5HT has been linked to depression and related neuropsychiatric disorders. 5HT has also been implicated in facilitating memory, and, most recently, in decision-making behavior
- **Histamine.** Histamine regulates body functions including wakefulness, feeding behavior and motivation.
- **Dopamine (DA).** Dopamine is involved in the brain's reward system, feelings of pleasure, cognitive arousal, learning, focus of attention, concentration, memory, sleep, mood and motivation. Dopamine is often referred to as the "pleasure chemical" because it is released when mammals receive a reward in response to their behavior; that reward could be food, drugs, or sex. Diseases associated with dysfunctions of the dopamine system include Parkinson's disease, schizophrenia, bipolar disease, restless legs syndrome and attention deficit hyperactivity disorder (ADHD). Many highly addictive drugs (cocaine, methamphetamines, amphetamines) act directly on the brain's dopamine circuits.
- **Epinephrine.** Epinephrine (also called adrenaline) and norepinephrine (see below) are responsible for the "fight-or-flight response" to fear and stress, activating the sympathetic nervous system (see Chapter 4).
- **Norepinephrine (NE).** Norepinephrine is both a hormone and a neurotransmitter. Some refer to it as noradrenalin. It has been linked to mood, arousal, vigilance, memory, and stress. Newer research has focused on its role in both post-traumatic stress disorder (PTSD) and Parkinson's disease. Norepinephrine (noradrenaline) increases blood pressure, heart rate, alertness, arousal, attention and focus. Many medications (stimulants and depression medications) increase norepinephrine to improve focus or concentration to treat ADHD or to reduce symptoms of depression.

Peptide neurotransmitters

Peptides are short chains of amino acids.

- **Endorphins.** Endorphins are natural pain killers. They are natural opiate-like substances, similar in molecular properties to morphine. Release of endorphins reduces pain, and elevates mood. They are endogenous opiates released by the hypothalamus and pituitary gland during stress or pain.

Acetylcholine (ACh)

This excitatory neurotransmitter is found in both the central and peripheral nervous systems, specifically in the autonomic nervous system and in spinal motor neurons releasing acetylcholine onto skeletal muscles producing movements. It is also involved in memory, motivation, sexual desire, sleep and learning. Abnormalities in acetylcholine levels are associated with Alzheimer's disease. But it also has other roles in the brain, including helping direct attention and playing a key role in facilitating neuroplasticity across the cortex.

Other Neurotransmitters

Neurochemicals like oxytocin and vasopressin are also classified as neurotransmitters. Made and released from the

hypothalamus, they act directly on neurons and have been linked to pair-bond formation, monogamous behaviors, and drug addiction. Hormones like estrogen and testosterone can also work as neurotransmitters and influence synaptic activity.

Other neurotransmitter types include corticotropin-releasing factor (CRF), galanin, enkephalin, dynorphin, and neuropeptide Y. CRH, dynorphin, and neuropeptide Y have been implicated in the brain's response to stress. Galanin, encephalin, and neuropeptide Y are often referred to as "co-transmitters," because they are released and then work in partnership with other neurotransmitters. Enkephalin, for example, is released with glutamate to signal the desire to eat and process rewards.

As neuroscientists are learning more about the complexity of neurotransmission, it's clear that the brain needs these different molecules so it can have a greater range of flexibility and function.

Glia Release Neurotransmitters, Too

It was once believed that only neurons released neurotransmitters. New research, however, has demonstrated glia, the cells that make up the "glue" that fills the space between neurons to help support and maintain those cells, also have the power to release neurotransmitters into synapses. In 2004, researchers found that glial cells release glutamate into synapses in the hippocampus, helping synchronize signaling activity.

Astrocytes, a star-shaped glial cell, are known to release a variety of different neurotransmitters into the synapse to help foster synaptic plasticity, when required. Researchers are working diligently to understand the contributions of these different cell types–and the neurotransmitter molecules they release—on how humans think, feel, and behave.

Different Types of Receptors Activated by the Same Transmitter

There are different types of receptor for transmitters of a specific type. For example, for dopamine there are at least 5 types, D1 through D5 receptors, all for dopamine transmitter. Different receptor types for a specific transmitter may be localized in different parts of the brain and therefore may produce different effects and have different functions.

The function of each dopamine receptor type (Mishra, et al., 2018):

- D1: memory, attention, impulse control, regulation of renal (kidney) function, locomotion (movement)
- D2: locomotion, attention, sleep, memory, learning
- D3: cognition, impulse control, attention, sleep
- D4: cognition, impulse control, attention, sleep
- D5: decision making, cognition, attention, renin secretion (by the kidney)

Of particular interest, the mental disorder schizophrenia, characterized by disordered thought, hallucinations, and delusions, is associated with excess dopamine neuron activity in the brain. Some drug treatments for schizophrenia decrease activity primarily at D2 receptors.

Another example is acetylcholine transmitter. There are two distinct types of acetylcholine receptors affected by two different substances, either muscarine or nicotine. Those postsynaptic acetylcholine receptors that respond to muscarine are called muscarinic receptors. Those that respond to nicotine (in tobacco products, for example) are called nicotinic. Nicotinic receptors cause sympathetic postganglionic neurons and parasympathetic postganglionic neurons to fire and release their chemicals and cause skeletal muscle to contract. Muscarinic receptors are associated mainly with parasympathetic functions and stimulate receptors located in peripheral tissues (e.g., glands, smooth muscle). Acetylcholine transmitter activates all of these sites.

Synaptic Transmission in Review

Let's summarize the sequence of events in synaptic transmission in synapses with ionotropic receptors:

Action potential in pre-synaptic neuron --- transmitter release --- transmitter crosses synaptic gap --- transmitter attaches to post-synaptic receptor sites --- ion channels open --- ions move --- PSP results --- if the PSP is an EPSP and if the EPSP is big enough (or if summation results in voltage change big enough), then trigger threshold of -55mv is reached in post-synaptic neuron ---post-synaptic neuron produces its own action potential. These same steps are summarized in the first 7 of the 8 steps in synaptic transmission listed above. The last step is transmitter inactivation.

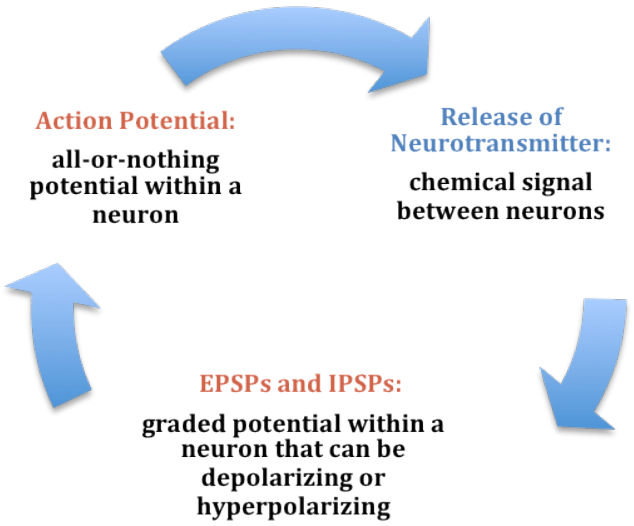

Figure 1.7.3.6: Summary of the electrochemical communication within and between neurons. (Image from Furtak, S. (2021). Neurons. In R. Biswas-Diener & E. Diener (Eds), *Noba textbook series: Psychology.* Champaign, IL: DEF publishers. Retrieved from http://noba.to/s678why4).

Step 8 in the list of 8 steps above simply refers to the fact that after the released transmitter molecules have done their job, the used transmitter molecules must be cleaned out of the synapse. If not, the receiving neuron will be affected for too long and this may result in dysfunction at the synapse, resulting in pathological effects, and if occurring at a large number of synapses can lead to abnormalities such as seizures or hallucinations or other maladaptive effects.

As noted above, removal of used transmitter is accomplished by two mechanisms, reuptake and enzymatic destruction. Reuptake means that the used transmitter is reabsorbed back into the pre-synaptic ending from which it was released. Enzymatic destruction means that the used transmitter is chemically destroyed by an enzyme, and thereby inactivated.

If step 8, transmitter inactivation, didn't occur, in the case of excitatory transmitters, then the post-synaptic neuron would be over activated. If this occurs on a large scale, at many synapses, as noted above, behavioral and mental abnormalities will result. For example, there are some drugs (Soman, Sarin, Malathion) that block enzymatic destruction of the neurotransmitter Acetylcholine, ACh. As noted above, ACh is a transmitter involved in various functions in the brain and peripheral nervous system, including stimulation of skeletal muscles, which are responsible for movement. Soman and Sarin are nerve agents. They block the enzyme acetylcholinesterase, AChE, and thereby prevent the enzymatic destruction of ACh at motor synapses which stimulate the muscles. As a result, the excess ACh at the muscles causes their over activation. The result? Epileptic seizures so intense that death may occur. The treatment for poisoning by these agents is a drug that blocks acetylcholine neurotransmitter at the acetylcholine receptor sites, counteracting effects of the excess acetylcholine neurotransmitter, thereby preventing or reversing the seizures otherwise caused by these nerve agents.

Neurons, The Mind, and Artifical Neural Networks

How do these neural processes relate to the real world of our everyday conscious experience and behavior? As mentioned in module 5.2, in complex vertebrate species, single nerve cells and their activity do not control a behavior or create a thought or a feeling. Instead, information is processed, mental states are created, and behaviors are organized by neural events in complex circuits involving very large numbers of neurons. It is the interaction among huge numbers of neurons, interconnected by enormous numbers of synapses, that create our perceptions, thoughts, emotions, or a complex behavior such as human speech or the creation of a work of art.

How groups of neurons in complex circuits might produce complex things like a perception or a memory has been studied using computer modeling (see Module 10.9). Artificial neural networks are computer-based models of neural circuits and their functioning. In a computer program, artificial information processing units, sometimes called "neurodes", are programmed to code and process information similar to how neurons process information. These neuron-like processing units are interconnected with one another and organized into layers, and then these layers of processing units are connected.

A three-layered artificial neural network (see Module 10.9) is capable of performing some very complex information processing tasks, producing responses similar to those that a real brain might produce. Furthermore, because the artificial neurodes or processing units are given (by programmers) the capability of altering the strengths or "weights" of their "synaptic connections", artificial neural networks are capable of learning when given feedback about their performance. Given these properties, it has been shown by researchers (many of whom are at UC San Diego) that artificial neural networks can learn patterns and regularities in inputs to make generalizations, to form categories, and to solve complex problems (Churchland, 2013).

For example, one neural network, trained (electronically) in the mathematical principles used to find mathematical proofs, discovered a proof that had eluded human mathematicians for many decades. Another, known as NETtalk, equipped with a voice synthesizer and photocell "eyes" learned from scratch to read and correctly pronounce written English text. It accomplished this astounding feat after only 10 hours of trial and error learning, during which it was given feedback about its attempts at pronunciation. It went through a babbling stage initially, like a child would, but soon was articulating comprehensible speech. When tested on new material, it generalized what it had learned to the new text including many new words that it had not "seen" before. An analysis by researchers of how it did this showed that it had formed categories of letters, learning to divide them into vowels and consonants, with rules of pronunciation for each category. It accomplished this without direct programming by humans. It extracted regularities from the words presented to it, and made generalizations, rules which it applied to new cases (Churchland, 2013).

Artificial neural networks use a form of information processing called parallel distributed processing (PDP). Though these networks are not brains, they have come closer than any other computer models to simulating brain function and psychological capabilities of real brains. This suggests that biological brains may use PDP, carried out by PDP networks made of real neurons, to produce the kinds of psychological and behavioral capacities which real brains like ours demonstrate. This is a very promising area of research being carried out in the psychology, computer science, and neuroscience departments at many universities worldwide.

Keep in mind that the circuitry in biological brains, such as the human brain, though modifiable by experience, is also hard-wired to a significant extent by natural selection and other forces of evolution (see Chapter 3). This accounts for the fact that human beings have an innate or inborn human nature just like other animals have their own innate natures. Humans relate to the world in a distinctively human way whereas wolves, tigers, birds, wildebeests, and other animal species understand and relate to the world in their own particular species-typical ways. Each species' distinctive psychological nature is a result of the brain circuitry inherited from its predecessors--circuitry molded by eons of evolution (Koenigshofer, 2011).

Chapter 5 Review

1. Define nerve impulse.
2. What is the resting potential of a neuron, and how is it maintained?
3. Explain how and why an action potential occurs.
4. Outline how a signal is transmitted from a presynaptic cell to a postsynaptic cell at a chemical synapse.
5. What generally determines the effects of a neurotransmitter on a postsynaptic cell?
6. Identify three general types of effects neurotransmitters may have on postsynaptic cells.
7. Explain how an electrical signal in a presynaptic neuron causes the transmission of a chemical signal at the synapse.
8. The flow of which type of ion into the neuron results in an action potential?
    1. How do these ions get into the cell?
    2. What does this flow of ions do to the relative charge inside the neuron compared to the outside?
9. The sodium-potassium pump:
    1. is activated by an action potential
    2. requires energy
    3. does not require energy
    4. pumps potassium ions out of cells
10. *True or False*. Some action potentials are larger than others, depending on the amount of stimulation.
11. *True or False*. Synaptic vesicles from the presynaptic cell enter the postsynaptic cell.
12. *True or False*. An action potential in a presynaptic cell can ultimately cause the postsynaptic cell to become inhibited.
13. Name three neurotransmitters.

Chapter 5 Discussion Questions

1. What structures of a neuron are the main input and output channels of that neuron?
2. What does the statement mean that communication within and between cells is an electrochemical process?
3. How does myelin increase speed and efficiency of the action potential?
4. How does diffusion (concentration gradients) and electrostatic pressure (electrical gradients) contribute to the resting membrane potential and the action potential?
5. Describe the cycle of communication within and between neurons.

Chapter 5 Vocabulary

Action potential (nerve impulse)

A transient all-or-nothing positive electrical current (depolarization) that is conducted down the axon when the membrane potential reaches the threshold of excitation (trigger threshold equal to about negative 55 millivolts).

Axon

Part of the neuron that extends off the soma, splitting several times to connect with other neurons; main output of the neuron.

Cell membrane

A bi-lipid layer of molecules that separates the cell from the surrounding extracellular fluid.

Dendrite

Part of a neuron that extends away from the cell body and is the main input to the neuron.

Diffusion (along a concentration gradient or inequality)

The force on molecules to move from areas of high concentration to areas of low concentration.

Electrostatic pressure (charge gradient)

The force on two ions with similar charge to repel each other; the force of two ions with opposite charge to attract to one another.

Excitatory postsynaptic potentials (EPSPs)

A graded depolarizing postsynaptic current that causes the membrane potential to become more positive and move towards the threshold of excitation (trigger threshold). EPSPs and IPSPs can summate with one another.

Inhibitory postsynaptic potentials (IPSPs)

A graded hyperpolarizing postsynaptic current that causes the membrane potential to become more negative and move away from the threshold of excitation (trigger threshold). EPSPs and IPSPs can summate with one another.

Ion channels

Proteins that span the cell membrane, forming channels that specific ions can flow through between the intracellular and extracellular space (the "doors" in step 5 in the list of 8 steps of synaptic transmission above; see Figure 5.3.2).

Ionotropic receptor

Receptor (receives transmitter molecules and binds to them) and its associated ion channel that opens to allow ions to permeate the cell membrane under specific conditions, such as the presence of a neurotransmitter (chemically-gated channel) or a specific membrane potential (voltage-gated channel).

Myelin sheath

Substance around the axon of a neuron that serves as insulation to allow the action potential to conduct rapidly toward the terminal buttons.

Neurotransmitters or transmitters

Chemical substance released by the presynaptic terminal button that acts on the postsynaptic cell.

Nucleus

Collection of nerve cells found in the brain which typically serve a specific function.

Resting membrane potential

The voltage inside the cell relative to the voltage outside the cell while the cell is a rest (approximately -70 mV).

Sodium-potassium pump

An ion channel that uses the neuron's energy (adenosine triphosphate, ATP) to pump three Na+ ions outside the cell in exchange for bringing two K+ ions inside the cell.

Soma

Cell body of a neuron that contains the nucleus and genetic information, and directs protein synthesis.

Spines

Protrusions on the dendrite of a neuron that form synapses with terminal buttons of the presynaptic axon.

Synapse

Junction between the presynaptic terminal button of one neuron and the dendrite, axon, or soma of another postsynaptic neuron.

Synaptic gap or synaptic space

Also known as the synaptic cleft; the small space between the presynaptic terminal button (axon ending) and the postsynaptic dendritic spine, axon, or soma.

Synaptic vesicles

Groups of neurotransmitters packaged together and located within the terminal button.

Terminal button or axon ending

The part of the end of the axon that form synapses with postsynaptic dendrite, axon, or soma.

Trigger threshold (Threshold of excitation)

Specific membrane potential that the neuron must reach to initiate an action potential.

Neurochemistry is the study of all the chemical processes that occur within the brain. This chapter will focus on the production, storage, release, receptor actions and inactivation of a selection of chemicals that are most relevant to the study of behavioral neuroscience. The basis of consciousness, as far as is known today, depends primarily upon the communications between neurons. Neurons communicate with each other by releasing chemicals called neurotransmitters that allow one neuron to influence the behavior of other neurons. The human brain uses over 100 different neurotransmitters. Some neurotransmitters are released by many millions of neurons that impact function throughout the brain; in contrast, some neurotransmitters are released by only a few thousand neurons that have a very limited impact on only a few brain regions. Figure 3.2 shows the distribution of some neurotransmitter systems that will be discussed below. Understanding the anatomy of these neurotransmitter systems is important because their anatomy defines their function.

1.8.2: General Neurochemistry Principles

Learning Objectives

By the end of this section, you should be able to

- 3.1.1 Explain the basic mechanisms that neurons use to produce and release neurotransmitters
- 3.1.2 Describe the ways that neurotransmitters interact with receptors

In the following sections, you will learn general principles about brain chemistry. Neurons access nutrients from the diet, or from their own neuronal membranes, to produce the neurotransmitters that underlie behavior. These nutrients, including amino acids, fatty acids or sugar molecules, are taken inside a neuron or glial cell where they are acted upon by enzymes to produce a neurotransmitter that is stored in a vesicle and later released in response to specific intracellular signals. Neurons release the most recently produced neurotransmitter molecules first, thus guaranteeing that the communication between neurons is successful.

How do neurons produce neurotransmitters?

Neurotransmitters are produced inside neurons. Their production depends upon the neuron obtaining an adequate supply of precursors from the blood. This is not as easy as it sounds. The production of neurotransmitters requires a variety of amino acids, sugar, fats, vitamins, and minerals. These nutrients float around in the blood after each meal. Every cell in the body competes with the brain for access to these nutrients. The brain is at a distinct disadvantage because it sits behind a firewall called the blood-brain barrier (see Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy). However, fortunately, the blood-brain barrier possesses a variety of specialized transporting mechanisms that can actively transfer nutrients into the brain (Step 1 in Figure 3.3). Once a nutrient crosses the blood-brain barrier it is usually transported to neurons with the assistance of astrocytes.

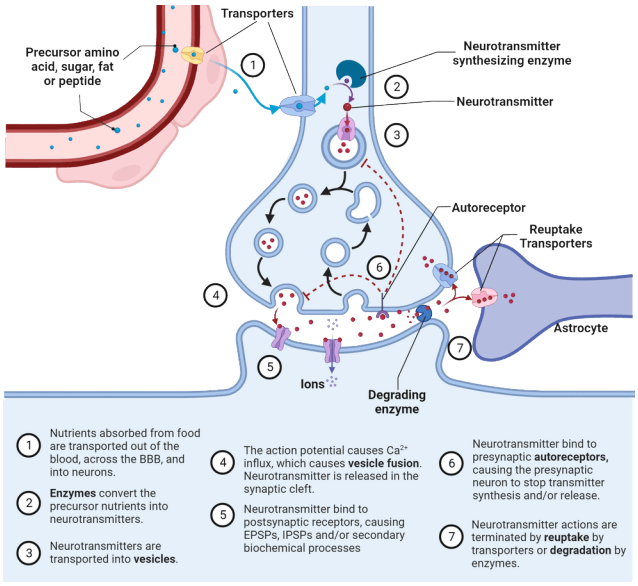

Figure 3.3 Neurotransmitter lifecycle

After an amino acid, fatty acid or sugar molecule is inside a neuron, it is generally acted upon by synthesizing enzymes (Step 2 in Figure 3.3). Enzymes are proteins that help build, breakdown or otherwise modify substances in our cells. The action of many of these enzymes uses metal ions as co-factors to assist with the conversion process. For example, neurons in the substantia nigra contain iron, neurons in the hippocampus contain zinc, neurons in the locus coeruleus contain copper, and neurons in the red nucleus contain cobalt. The presence of these metals is critical for normal neurotransmitter metabolism.

Brains demonstrate a degree of energy efficiency in terms of which of these transmitters it utilizes most extensively. For example, GABA and glutamate are simple amino acids and are the most abundant neurotransmitters in the human brain. They require only single-step enzymatic modification. Four amine neurotransmitters (dopamine, norepinephrine, epinephrine, and serotonin) require enzymatic modification of dietary amino acids to produce and inactivate. The brain contains 1000-fold fewer of these amine-releasing neurons, as compared to glutamate and GABA, probably because they require more energy to function. Finally, the other, far less abundant neurotransmitters, such as the neuropeptides (which are a string of amino acids) require a considerable amount of energy by the neuron to produce and inactivate. Neuropeptides occur roughly one-million-fold lower concentration in the brain than glutamate and GABA. These neurotransmitters, as well as the fat-derived neurotransmitters endocannabinoids and prostaglandins, all utilize the DNA in the nucleus to produce the necessary enzymes and precursors. The endogenous levels of these two fat-derived are kept quite low and are produced only when needed.

How are neurotransmitters stored and released?

Once synthesized, most neurotransmitter molecules are then actively transported into synaptic vesicles (step 3 Figure 3.3); these are very tiny spheres clustered at the presynaptic terminal with hollow centers into which approximately 10,000 molecules of a typical neurotransmitter can be stored for later release from a neuron. Neurons pay attention to the shelf life of their neurotransmitters; they prefer to release the most recently produced neurotransmitter molecules first. This means that the freshest products are released first, thus guaranteeing that the communication between neurons is successful. Many neurons produce two (and rarely three) different neurotransmitters; each is stored inside different vesicles and are released independently of each other.

The arrival of the action potential at the end of the axon opens a group of voltage-dependent calcium channels that allows the entry of calcium ions (see Chapter 2 Neurophysiology). The elevated intracellular concentration of calcium ions initiates the next step in the communication of one neuron with the next: A synaptic vesicle either merges into its cell wall (both are made of lipids so imagine two soap bubbles coming together), or opens a small pore into the neuronal membrane, and releases the neurotransmitter into the small space between neurons, called a synaptic cleft (step 4 Figure 3.3). Figure 3.4 shows the process of vesicle fusion in more detail. The junction at which two neurons communicate via the release of a neurotransmitter molecule is called a synapse. Because the synapse is such a small space, the concentration of neurotransmitter molecules in the synapse following release becomes very high for a brief period.

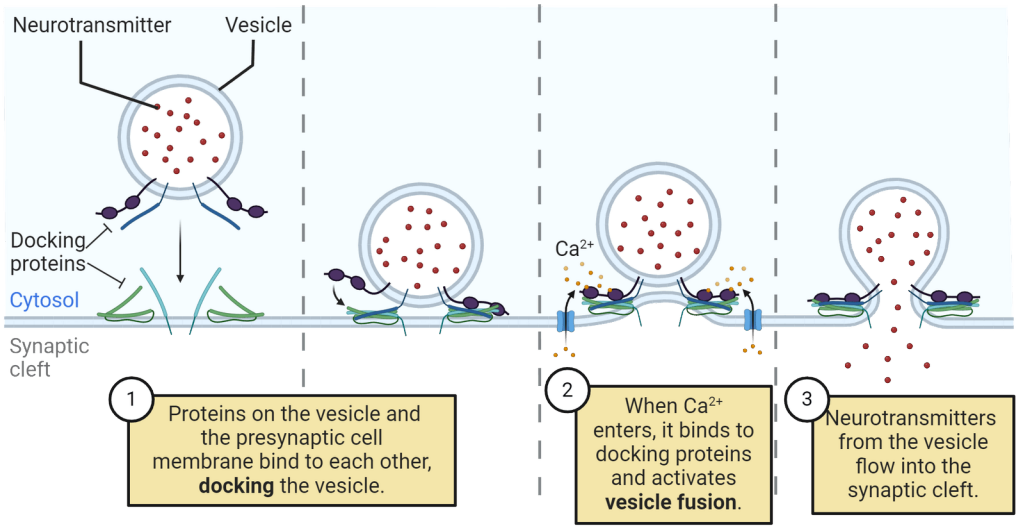

Figure 3.4 Vesicle fusion

Post-synaptic actions of neurotransmitters

Once released into the synapse, neurotransmitter molecules briefly interact or bind with a protein, called a receptor, that is (usually) located on the surface of the neuron on the other side of the synapse (step 5 in Figure 3.3). These receptors are divided into two general types: either ionotropic or metabotropic receptors (Figure 3.5). Ionotropic receptors are transmembrane molecules that can “open” or “close” a channel that would allow smaller particles to travel in and out of the cell. Ionotropic

receptors allow different kinds of ions to travel in and out of the cell. Ionotropic receptors are not opened (or closed) all the time. They are generally closed until another small molecule (called a ligand — in our case, a neurotransmitter) binds to the receptor. As soon as the ligand binds to the receptor (step 1 in the left side of Figure 3.5), the receptor changes conformation (the protein that makes up the channel changes shape), and, as they do so, they create a small opening that is big enough for ions to travel through (step 2 in the left side of Figure 3.5). Therefore, ionotropic receptors are called "ligand-gated transmembrane ion channels". The abrupt change in concentration of these ions induces secondary biochemical processes which may have either short-term or long-term consequences on the post-synaptic neuron's behavior.

Metabotropic receptors do not have a "channel" that opens or closes. Instead, they are linked to another small chemical called a "G-protein." As soon as a ligand binds the metabotropic receptor (step 1 in the right side of Figure 3.5), the receptor "activates" the G-protein (it basically changes the G-protein shape). Once activated, the G-protein itself goes on and activates another molecule (step 2 in the right side of Figure 3.5). This new molecule is called a "secondary messenger." A secondary messenger is a chemical whose function is to go and activate other particles. So far, this process is common to all metabotropic receptors. What happens from there on is different for every metabotropic receptor. In some cases, the secondary messenger travel until it binds to and opens ion channels located somewhere else on the membrane (step 3 in the right side of Figure 3.5). In some cases, the secondary messenger will go and activate other intermediate molecules inside the cell. The important thing to remember is that metabotropic receptors do not have ion channels, and binding of a ligand may or may not result in the opening of ion channels at different sites on the membrane. But they will always activate a G-protein that will in turn activate secondary messengers. G-protein coupled receptors are a large group of evolutionarily related proteins that are very common in the brain and body; over eight hundred human genes are devoted to producing these proteins.

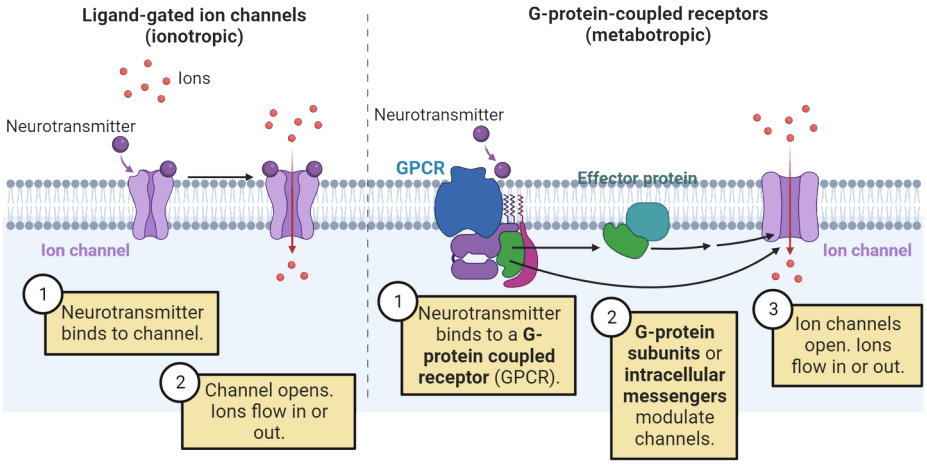

Figure 3.5 Metabotropic vs ionotropic receptors

Despite many safeguards, the synaptic communication processes described above often fail because the vesicles are empty or do not fuse properly, or the neurotransmitters are oxidized and therefore inactive (Linden, 2007). Neural systems have a built-in redundancy that allows them to compensate for failures in single neurons. Brains try to be energy efficient and not waste neurotransmitters. Many, but not all, neurotransmitters, or components of them after enzymatic inactivation, are re-absorbed by the axon terminal and re-used. Finally, although neurons utilize components of the diet to produce neurotransmitters, the production of neurotransmitters is rarely significantly enhanced by dietary supplements.

Ending neurotransmitter action

After most neurotransmitters are released into the synaptic cleft they need to be inactivated. The primary mechanism for inactivation is reuptake (step 7 in Figure 3.3). Reuptake is the reabsorption of a neurotransmitter via a protein transporter located on the (pre-synaptic) membrane of the axon terminal. Reuptake allows for the recycling of neurotransmitters. Because neurotransmitter molecules are large and hydrophilic, they cannot simply diffuse through the membrane; this is why specific transporter proteins are necessary.

Neurons benefit from feedback on how much neurotransmitter they are releasing at their axonal terminals. This feedback is

provided by a special type of protein receptor called an autoreceptor (step 6 in Figure 3.3). Autoreceptors are located on the membranes of nerve cells. They may be located on the cell body or the axonal terminal. These receptors are only sensitive to the neurotransmitters released by the neuron on which the autoreceptor sits. Activation of an autoreceptor usually leads to a reduction in the rate of release of the cell's neurotransmitter.

1.8.3: Neurotransmitters Made from Amino Acids

Learning Objectives

By the end of this section, you should be able to

- 3.2.1 Identify the neurotransmitters produced from amino acids in the diet
- 3.2.2 Describe the similarities and differences in the ways these neurotransmitters are produced, inactivated, and utilized to control behavior

Dopamine, norepinephrine, and epinephrine.

Dopamine (often abbreviated DA), norepinephrine (often abbreviated NE), and epinephrine are sequentially synthesized from the same dietary amino acid precursor, tyrosine. Norepinephrine and epinephrine are also sometimes called noradrenaline and adrenaline, and the neurons that produce them are sometimes called noradrenergic and adrenergic. Understanding the sequence of biochemical steps that lead to the production, storage, release, and receptor interactions of these three neurotransmitters has allowed neuropharmacologists to design drugs that can either enhance or inhibit specific processes to treat neurological and psychiatric diseases.

Synthesis

Tyrosine is actively transported from the blood across the blood-brain barrier (Step 1 of Figure 3.6). Tyrosine is utilized by all the cells in the brain for a variety of purposes, not just for making these neurotransmitters. Dopamine, norepinephrine, and epinephrine neurons produce a series of enzymes that convert tyrosine into each of these neurotransmitters. The process begins inside the cytoplasm of the neuron with the conversion of tyrosine into L-DOPA by the addition of a hydroxy molecule to the benzene ring via the enzyme tyrosine hydroxylase (Step 2 of Figure 3.6). This enzyme requires the presence of iron ions to function properly. This enzyme does not work well in humans with severe anemia who have difficulty absorbing enough iron from their diet. Severe anemia is typically associated with feelings of depression and mental fatigue. These symptoms offer insight into the role of these neurotransmitters in normal brain function.

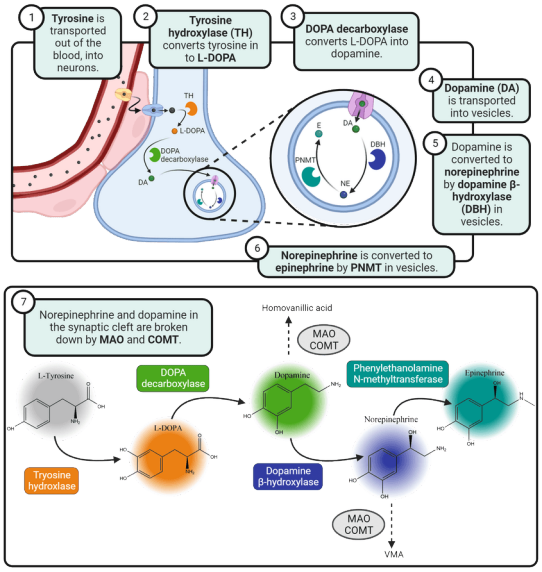

Figure 3.6

L-DOPA is converted into dopamine by the removal of a molecule of carbon dioxide via the enzyme aromatic amino acid decarboxylase, also called DOPA decarboxylase (Step 3 of Figure 3.6). This enzyme is extremely efficient, which may explain why

brain levels of L-DOPA tend to be very low and why providing exogenous L-DOPA to patients who lack sufficient dopamine—such as in patients with Parkinson's disease—leads to a dramatic increase in the production of dopamine. After synthesis, the dopamine is transported into a synaptic vesicle and stored until it is released from the axonal terminal (Step 4 of Figure 3.6).

In norepinephrine and epinephrine neurons, once dopamine is transported into the vesicle, it can be converted to norepinephrine by the vesicular enzyme, dopamine-beta-hydroxylase (Step 5 of Figure 3.6). In addition to dopamine-beta-hydroxylase, the vesicles contain copper. Copper is required for dopamine-beta-hydroxylase to function appropriately.

A very small group of neurons in the brainstem also express an enzyme, called phenolethanolamine-N-methyltransferase, that converts norepinephrine into the neurotransmitter epinephrine by adding a methyl group to the nitrogen atom (Step 6 of Figure 3.6). Epinephrine should be seen more as a hormone than intraneuronal signal. In addition to being released by neurons, it is also secreted by the medulla of the adrenal glands and does not enter the brain. It produces the peripheral manifestations of strong emotions such as fear or anger when it is released into the bloodstream.

Vesicles used for storage of dopamine, norepinephrine, and epinephrine.

Vesicles are very tiny lipid spheres with hollow centers. Neurotransmitters are actively transported into these vesicles. In Chapter 14 Psychopharmacology, you will learn about drugs that can selectively inhibit this transfer process. Many vesicles also contain the antioxidant ascorbic acid, also known as Vitamin C. The Vitamin C maintains the integrity of these neurotransmitters within the vesicle in the same way that ascorbic acid added to processed meats, such as hotdogs, lengthens the shelf life of these products. Neurons require anti-oxidants such as Vitamin C because they are continually exposed to oxygen from the blood. Without Vitamin C, most neurotransmitters oxidize easily and become inactive while in storage inside the vesicles.

Receptors

Neurotransmitters relay their messages by traveling between cells and attaching to specific receptors on target cells. When a neurotransmitter attaches to a receptor, it triggers an action in the target cells. Receptors, even for a single neurotransmitter, exist as many different types that are differentially distributed and produce unique post-synaptic effects. Norepinephrine binds to three main G-protein-linked receptors: alpha1, alpha-2, and beta receptors that are located throughout the brain. Epinephrine can also stimulate all the adrenergic receptors including alpha and beta subtypes.

Dopamine binds to five different types of receptors, labelled D1-D5. Receptors have different, but often overlapping, functions. Figure 3.7 shows two different dopamine receptors that act via G-protein-linked receptors: one activates the enzyme adenylyl cyclase while the other inactivates this enzyme.

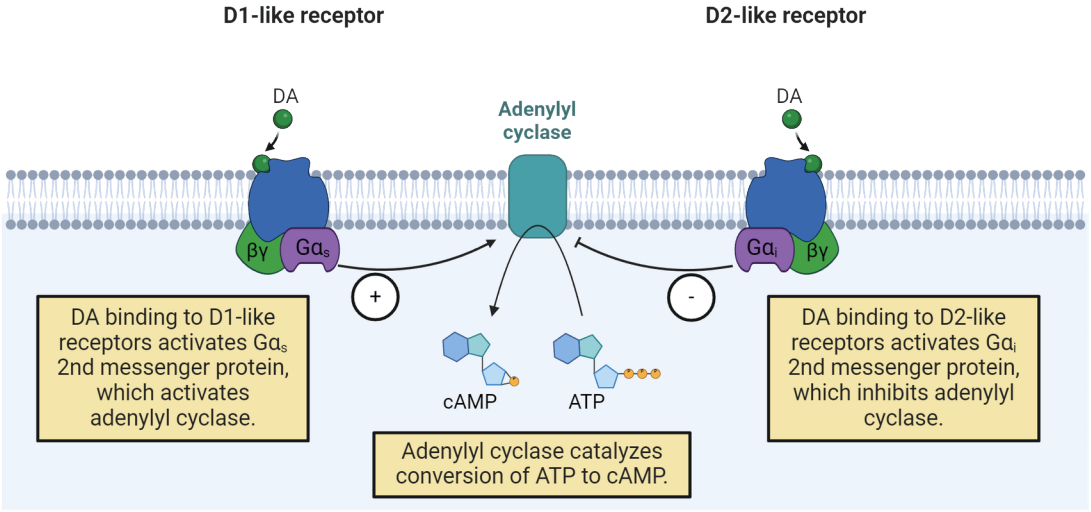

Figure 3.7 Dopamine receptors

Once again, notice that the function of any receptor depends upon which region of the brain the receptor is located and the nature of its second messenger, G-protein-linked systems.

Inactivation of dopamine, norepinephrine, and epinephrine

After dopamine, norepinephrine or epinephrine are released from the axonal terminal, they bind to specialized protein receptors on both the pre- and post-synaptic membranes. Most of the dopamine, norepinephrine, and epinephrine molecules are re-absorbed by the axonal terminal, a process called re-uptake, by low-capacity, high-affinity transporters or by either of the high-capacity, low-affinity organic cation transporters or plasma membrane monoamine transporters. Drugs, mostly anti-depressants, have been developed that selectively target each of these reuptake transporters. These neurotransmitter molecules are then re-packaged in vesicles and re-released again. The dopamine and norepinephrine molecules remaining in the synaptic cleft are catabolized by the enzymes monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT) (Step 7 of Figure 3.6).Under normal aerobic conditions, the dopamine metabolites 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) are transported out of the brain and can be measured in the cerebrospinal fluid and urine as an indirect indicator of the health of these neural systems.

The functions of dopamine, norepinephrine, and epinephrine

The functions of dopamine and norepinephrine depend entirely on the function of the structures in which they are located. Consider the basal ganglia, a collection of nuclei that are responsible for producing normal movement (see Chapter 10 Motor Control). The level of the neurotransmitter dopamine in these nuclei is one hundred times higher than in the surrounding brain regions. Therefore, scientists have concluded that dopamine within the basal ganglia is involved in the control of movement. Furthermore, if we expose your brain to a drug that impairs the function of dopamine or the neurons that produce and release it, then your ability to move will be impaired. However, it would be incorrect to assume that dopamine is only involved with movement—it is not. You can also find dopamine in the retina of your eye and in your hypothalamus, structures that have nothing to do with movement. The nucleus accumbens receives an input of dopamine axonal projections that originate in the midbrain. Drugs that enhance the release of dopamine in the nucleus accumbens induce considerable motor stimulation always toward the rewarding stimulus. Thus, dopamine sometimes has mixed actions that influence movement. The multiple roles played by dopamine in the brain have contributed to difficulty in developing drugs to treat specific psychological and neurological conditions due to unintended effects on other brain circuits that use the same neurotransmitter.

Similar to dopamine, the neurotransmitter norepinephrine influences the function of multiple brain systems. It can be found in the hippocampus, a structure critical for forming new memories. Thus, norepinephrine influences the formation of memories. However, norepinephrine also plays a role in other brain regions that have nothing to do with making memories. The take-away point is that there is no such thing as a specifically unique “dopamine function” or an exclusively distinct “norepinephrine function.” The brain region that the neurotransmitter is found within defines its function, not the neurotransmitter itself. This statement is true for all neurotransmitters. In fact, neurotransmitters exhibit a complex array of actions in different brain regions, and so we can rarely make a single universal statement about their role in brain function.

We know a lot about dopamine and norepinephrine primarily because so many drugs and nutrients have been discovered that can modify their function. Norepinephrine underlies the major components of arousal and behaviors that arise in association with increased arousal; dopamine is intimately related to the control of movement, aspects of consciousness, hormone release, visual image processing and the experience of reward.

In humans, almost all norepinephrine neurons are located within a region called the locus coeruleus (Latin for “blue area” due to the presence of so many copper ions) that lies in the floor of the 4th ventricle (Figure 3.8).

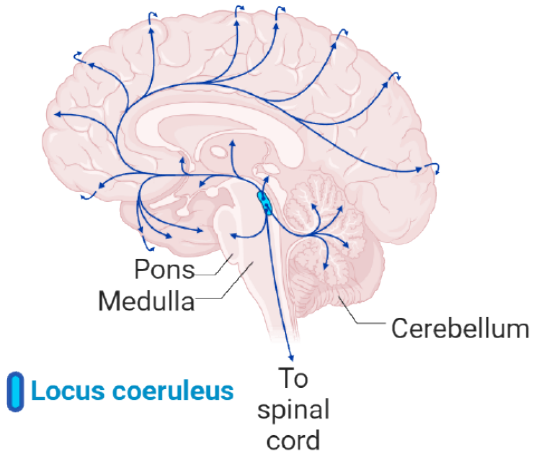

Figure 3.8 Norepinephrine system anatomy

The name of this region is related to the fact that these neurons concentrate copper into the pigmented polymer neuromelanin. Neuromelanin is synthesized from the precursor L-DOPA. Although copper is required for the synthesis of norepinephrine, the concentration of the copper in the locus coeruleus far exceeds what is necessary for neurotransmitter synthesis. Unfortunately, the presence of this metal makes these neurons vulnerable to oxygen, leading to oxidative stress, which poses a particular risk for these neurons. Norepinephrine neurons in the locus coeruleus project throughout the brain, mostly unilaterally. Their diffuse widespread projection into virtually all brain regions allows them to influence your level of arousal and almost every aspect of behavior.

Dopamine neurons are more numerous (by about five times) than norepinephrine neurons. However, they do not project as widely throughout the brain. Instead, these neurons, which originate in the ventral midbrain, send axonal projections forward primarily into basal ganglia and frontal lobes (Figure 3.9).

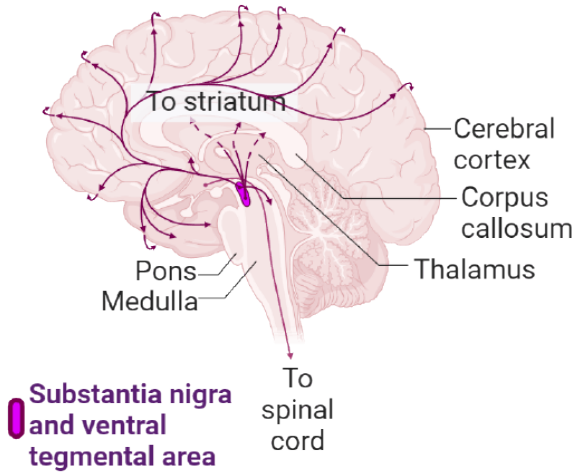

Figure 3.9 Dopamine system anatomy

One major dopamine pathway originates within the substantia nigra, or dark substance, so called because this region concentrates iron into neuromelanin. The oxidation of iron in the neuromelanin (you know this process as rusting) contributes a significant degree to the vulnerability of dopamine neurons to oxygen. Dopamine-containing neurons may be vulnerable to the presence of oxygen due to its original role in plants as an antioxidant; the dopamine molecule may sacrifice its molecular integrity during oxidative stress. Due to the presence of various toxins, mostly insecticides, in our environment and the oxygen that we

require for mitochondrial oxidative metabolism, these neurons are gradually lost with aging. In the US today, the greatest risk for developing Parkinson's disease is growing up in a rural environment around pesticides (Tanner et al., 2011).

Another pair of dopamine pathways originates in a region of the midbrain near the substantia nigra and ascends upward into the brain. One pathway projects to the limbic system, brain regions that are associated with the control of emotion. The other dopamine pathway projects to the frontal lobes and may play a critical role in the generation of pleasure and consciousness. For more than 50 years, scientists have speculated that both too little and too much activity in these pathways underlies the symptoms associated with psychosis (see Chapter 19 Attention and Executive Function). Currently, though, dysfunction of dopamine neurons is no longer considered the direct cause of psychosis. Instead, some recent studies suggest that dysfunction of glutamate NMDA receptors also play a role (Dong et al., 2023).

Generally, in a normal healthy person, the production of dopamine and norepinephrine is not easily affected by dietary supplements but can be negatively affected by a lack of nutrients. The reason is that the first enzyme in the production of dopamine and norepinephrine, tyrosine hydroxylase, is a rate-limiting step in the synthesis pathway. For example, consuming more tyrosine will not induce this enzyme to produce more dopamine.

History of neuroscience: Exciting discoveries that led to misleading conclusions

Sometimes, exciting discoveries lead to misleading conclusions about the function of a particular neurotransmitter. In 1817, James Parkinson wrote the first description of the disease that would be given his name. In the 1920s, scientists identified damage within the substantia nigra in the postmortem brains of Parkinson's disease patients. Then, in the 1960s, came the first reports of reduced dopamine as the cause of the symptoms. Parkinson recommended blood-letting from the neck as a potential therapy. Fortunately, it was discovered that precursor therapy using L-DOPA was considerably more effective, though it did not alleviate all symptoms of Parkinson's disease. This amazing discovery led a generation of scientists and physicians to search for other neurological disorders that could be treated with such simple targeted therapies. Every time this approach was attempted, it failed. The problem is that neurological and psychiatric disorders are far more complex. Even in the case of Parkinson's disease, many symptoms are due to a lack of dopamine, but a few others are due to deficits in other neurotransmitter systems in the brainstem. This may explain why simply replacing dopamine does not produce a removal of all the symptoms. The next time you read or hear someone state that such-and-such disease (for example, depression) is due to the dysfunction of a single neurotransmitter (such as serotonin) because we treat depressed people with serotonin-enhancing drugs, rest assured that those statements are both inaccurate and naïve.

Neurochemistry in the news: dopamine equals sex and love?

Dopamine has also been called the pleasure molecule. Is dopamine the "single chemical in the brain that drives love and sex," as many popular books and new articles claim. No. Such statements are naïve oversimplifications of the truth. Current evidence suggests that dopamine's role in the experience of pleasure is far more complicated. For example, some dopamine neurons cause a hedonic (positive) response to an anhedonic (negative) experience. Each process is regulated by specific dopamine circuits (Der-Avakian and Markou, 2012). In addition, some dopamine neurons become active prior to experiencing the reward. Dopamine neurons in the ventral tegmental area, the classic "pleasure center" of the popular literature, are actually involved in reward prediction. The dopamine neurons in this area facilitate "goal-seeking" behaviors; they fire faster when bigger rewards are expected and alter their firing in characteristic ways when the expected reward is smaller than expected. Furthermore, dopamine is not the only neurotransmitter in the brain that produces pleasure associated with a reward, food or sex. Serotonin, endocannabinoids, endorphins and the neuropeptide oxytocin also play important roles. Finally, as mentioned earlier, you can also find dopamine neurons in the retina of your eye and in your hypothalamus, where it controls release of the hormone prolactin; these actions have little to do with the experience of pleasure.

Serotonin

This section will describe the lifecycle and functions of serotonin (often abbreviated 5HT).

Synthesis

The neurotransmitter serotonin is built from a molecule of the amino acid tryptophan. Tryptophan is actively transported across the blood-brain barrier (step 1 in Figure 3.10). Tryptophan is utilized by all the cells in the brain to produce proteins for a variety of purposes that have nothing to do with neurotransmission. Serotonin neurons produce a series of enzymes that convert a small percentage (less than one tenth of one percent) of the tryptophan absorbed by the brain into serotonin. The process begins inside the cytoplasm of the serotonin neuron with the conversion of tryptophan into 5-hydroxytryptophan by the addition of a hydroxy molecule to the benzene ring via the enzyme tryptophan hydroxylase (step 2 in Figure 3.10). This enzyme is the rate-limiting step in the production of serotonin (Fernstrom, 2013). Unlike tyrosine hydroxylase, which is close to saturated with tyrosine under normal conditions, tryptophan hydroxylase is only half saturated with tryptophan (Young and Gauthier, 1981). Therefore, the entry of additional dietary tryptophan into the brain will lead to the production of more serotonin. Next, also occurring in the cytoplasm, 5-hydroxytryptophan is converted into serotonin by the removal of a carbon dioxide molecule via the enzyme aromatic amino acid decarboxylase, also often called 5-hydroxy-tryptophan decarboxylase (step 3 in Figure 3.10). Notice that the production of serotonin involves the same two chemical reactions, the addition of a hydroxy molecule and removal of a carbon dioxide molecule, that were used to produce the neurotransmitters dopamine and norepinephrine. The enzymes involved are also genetically similar to each other and likely evolved from genetic duplication.

Once produced in the cytoplasm, serotonin can either be stored in synaptic vesicles and released a fashion similar to dopamine and norepinephrine, or, despite having a positive charge, can cross cell membranes through a diffusion-like process (step 4 in Figure 3.10). Multiple low-affinity, high-capacity, sodium-independent transporters, widely expressed in the brain, allow the carrier-mediated diffusion of serotonin into forebrain neurons. The amount of serotonin crossing cell membranes through this mechanism under physiological conditions is considerable (Andrews et al., 2022).

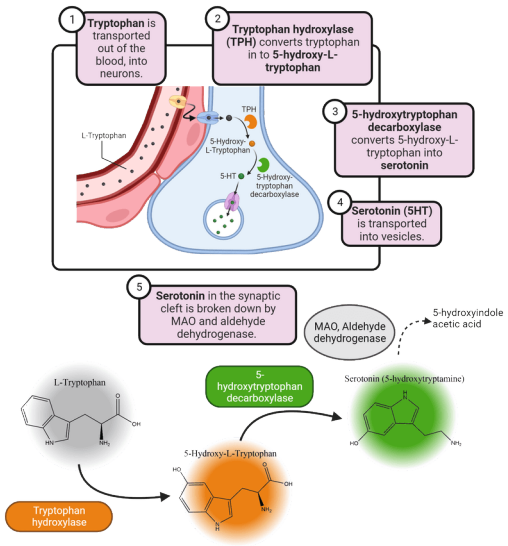

Figure 3.10 Serotonin synthesis

Receptors

Serotonin is one of the most ancient signaling molecules in nature. Bananas, single-celled paramecium, insects, and humans all synthesize it. The first primordial serotonin receptor is related to the rhodopsin protein found in the retina and may have first appeared almost one billion years ago; a time that likely predates the appearance of acetylcholine, dopamine, or norepinephrine. During this time, evolution greatly differentiated the serotonin receptors into a large and diverse group of proteins that are often less than 25% homologous with each other. This long evolutionary history underlies why serotonin plays a variety of roles throughout the brain, including behaviors such as aggression, appetite, sex, sleep, mood and cognitive function.

There are many different serotonin receptors in the brain and body (Table 3.1). It is difficult to assign a specific function to each receptor; once again, it depends on where the receptor is located, and the nature of the biochemical mechanisms activated by the receptor.

Receptor Subtypes	Signaling Mechanism	Distribution	Effects
5-HT_{1A}	Gi,↓cAMP	Raphe nuclei, hippocampus	Regulates sleep, feeding, and anxiety
5-HT_{1B}	Gi,↓cAMP	Substantia nigra, globus pallidus, basal ganglia	Neronal inhibition, behavioral changes
5-HT_{1D}	Gi,↓cAMP	Brain	Vasoconstriction
5-HT_{1E}	Gi,↓cAMP	Cortex, hippocampus	Memory
5-HT_{1F}	Gi,↓cAMP	Globus pallidus, putamen	Anxiety, vasoconstriction
5-HT_{2A}	Gq,↑IP_3	Platelets, cerebral cortex	Cellular excitation, muscle contraction
5-HT_{2B}	Gq,↑IP_3	Stomach	Appetite
5-HT_{2C}	Gq,↑IP_3	Hippocampus, substantia nigra	Anxiety

Table 3.1

Consider one serotonin receptor called 5HT-1A. Studies of genetically altered mice and positron emission tomography studies on humans have been very useful in demonstrating the potential role of this receptor in the regulation of mood and anxiety. For example, mice and humans born with fewer serotonin type 5HT-1A receptors show more anxiety-like behavior (Olivier et al., 2001). Some of the newer anti-anxiety medications stimulate the 5HT-1A receptors. Interestingly, almost all the known hallucinogens stimulate at least two serotonin receptors, the 5HT-1A and 5HT-2A. More will be presented about anti-anxiety medications and hallucinogens in Chapter 14 Psychopharmacology.

Inactivation of serotonin

After serotonin is released from the axonal terminal, and after it has interacted with receptors, one of two things can happen. 1) Most of the serotonin molecules are re-absorbed by the axonal terminal, repackaged into synaptic vesicles, and re-released again. 2) The serotonin molecules that are not removed by re-uptake are catabolized by the enzyme monoamine oxidase (step 5 in Figure 3.10). The product of this catabolism, 5-hydroxyindole acetic acid (5-HIAA), is ultimately removed from the brain and can be measured in the cerebrospinal fluid and urine.

Functions of serotonin

To understand the role of serotonin in the brain, one should first consider the entire body. Ninety percent of the total serotonin in the body is contained within the neurons of the gut. About 8% of the body's serotonin is found in the blood and is localized inside platelets and mast cells; in fact, serotonin was initially discovered in the serum and determined to have tonic (or constricting) effects on the vascular system—hence its name. About two percent of the body's serotonin is found in the pineal gland, which is located inside the skull but not considered part of the brain. The remaining one-half of one percent of the body's serotonin is found in the brain. The nuclei that contain serotonin neurons are in roughly the same anatomical location in the human brain as in every other vertebrate or invertebrate brain which implies a conservation of purpose across time (Berger and Gray, 2009). Despite the relative scarcity of serotonin neurons in your brain, drugs that alter serotonin function can produce profound changes in how you experience the world around you. Serotonin regulates various activities, including behavior, mood, memory, and gastrointestinal homeostasis.

Neurons that produce and release serotonin in the brain are organized into a series of nuclei that lie in a chain along the midline, or seam, of the brainstem; these are called the Raphe nuclei (raphe means "seam" in Latin) (Figure 3.10).

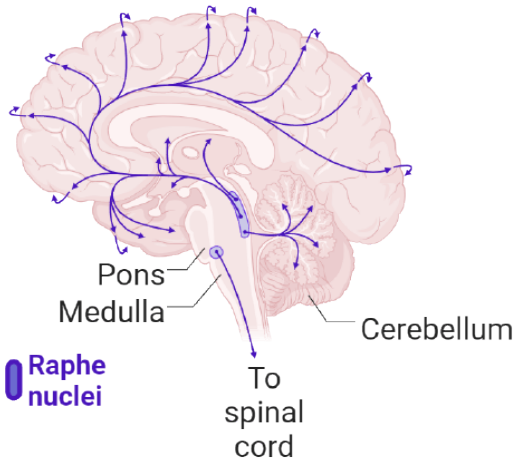

Figure 3.11 Serotonin system anatomy

These neurons project their axons to every part of the brain, and some of these axons form synaptic connections with small blood vessels. Serotonin controls the availability of blood to regions of the brain associated with its function. Another group of serotonin neurons project down-ward into the spinal cord to provide control over the autonomic nervous system and incoming pain signals.

If you were able to insert a recording device into the major raphe nuclei and "listen" to the activity of your serotonin neurons, you would discover that they have a regular, slow spontaneous level of activity that varies little while you are awake. When you fall asleep, the activity of these neurons slows. When you start to dream, these neurons temporarily cease their activity (see Chapter 15 Biological Rhythms and Sleep).

Neurochemistry in the news: getting a good sleep with serotonin

Some over-the-counter products claim that your mood and sleep will improve by consuming the amino acid precursor to serotonin. Consider what happens is you consume a pill containing 500 mg of tryptophan. (Don't bother with turkey meat, it is quite low in tryptophan levels.) First, the thousands of serotonin neurons in your gut feast on most of the tryptophan in the pill. The remaining tryptophan that is transported across the gut-blood barrier is then absorbed by one of the billions of platelets in the blood or by one of the trillions of cells in the body which utilize tryptophan to build proteins or hormones. The very small number of tryptophan molecules that do get transported across the blood-brain barrier are consumed by cells within the pineal gland for the production of melatonin or absorbed by one of the hundreds of billions of non-serotonergic cells that live within the brain. Finally, the few molecules of tryptophan that are still floating around in the extracellular space of the brain may be absorbed by a serotonin neuron in one of the raphe nuclei. Consuming tryptophan may ultimately lead to increased production of serotonin in the cytoplasm of serotonin neurons and improved mood in healthy adults (Asako et al., 2021).

Neuropeptides

The neuropeptide neurotransmitters can be quite small, only four or five amino acids strung together, or quite large, containing hundreds of amino acids folded into complex three-dimensional structures. Neurons that produce and release these neuropeptides are found throughout the brain. Neuropeptides may also be released along with the classical neurotransmitters, such as acetylcholine, dopamine and serotonin, from the same neuron. Which neurotransmitter is released is determined by the firing rate of the neuron; faster firing rates release neuropeptides.

Synthesis

Neuropeptide neurotransmitters are synthesized via a complicated, time consuming (about two to four weeks), and energy-

demanding process of reading the DNA code to produce mRNA that can be translated into a long string of amino acids (step 1 in Figure 3.12). The process utilizes the rough endoplasmic reticulum and Golgi apparatus where the long string of amino acids, called a pre-pro-peptide at this point, is converted enzymatically into intermediate shorter versions called pro-peptides, until finally being enzymatically converted into an active neuropeptide that is then packaged in synaptic vesicles that are transported down the axon to await release (step 2 in Figure 3.12).

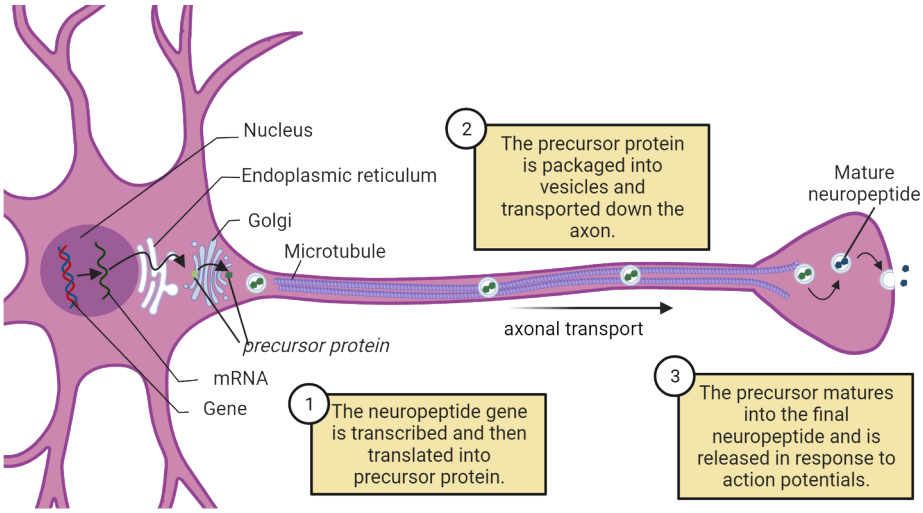

Figure 3.12 Synthesis of neuropeptides

After being released from the terminal axon (step 3 in Figure 3.12), the neuropeptide binds to its specific post-synaptic receptor and is then quickly inactivated by enzymatic degradation that generates not only biologically inactive fragments but also biologically active fragments that can modulate or even counteract the response of their parent peptides. Let's consider two of the best studied neuropeptides with considerable relevance, the endogenous morphine-like peptides called endorphins and oxytocin.

Endorphins

Endorphins are one of 4 families of endogenous opioids (thus, their name): endorphins, enkephalins, dynorphins, and endomorphins. Three of the most studied are shown in Table 3.2.

Family	Precursors	Peptides	Receptors
Endorphins	Proopiomelanocortin (POMC)	α-Endorphin β-Endorphin γ-Endorphin	μ-Opioid
Enkephalins	Proenkephalin (PENK)	Met-Enkephalin Leu-Enkephalin	Δ-Opioid μ-Opioid
Dynorphins	Prodynorphins (PDYN)	Dynorphin A Dynorphin B α-Neoendorphin β-Neoendorphin	κ-Opioid

Table 3.2

Each family has several opioid-like peptides within it. Endorphins have a diverse range of actions in the brain: they modulate the pain signals carried from the periphery to the higher centers of the brain, regulate numerous neuroendocrine or neuroimmune functions, and influence mood. Endorphins interact with families of various receptors. For example, when the "mu" opiate receptor is stimulated, it relieves pain and induces feelings of pleasure or euphoria. Endorphins are released in response to laughing, eating, intense exercising, listening to music, walking in the sunshine (it's the UV light), having sex, and so on. The emotional experience is ephemeral because endorphins have a very short life span once released; they are quickly catabolized by

peptidases.

People behind the science: Candace Beebe Pert and endorphins

Candace Beebe Pert (June 26, 1946 – September 12, 2013) was an American neuroscientist, pharmacologist, and my dear friend, who discovered the opiate receptor, the cellular binding site for endorphins in the brain. Candice told me that she sampled her own blood during her pregnancy to monitor changes in blood-borne endorphins. While the discovery of the elusive endorphin receptor earned the coveted Albert Lasker Award (often a precursor to the Nobel Prize), the prize was awarded to the head of the laboratory, Dr. Solomon H. Snyder, without citing Candace. She wrote a letter to the head of the Lasker Foundation, claiming that her exclusion was due in part to being a woman. Ultimately, Dr. Pert became Chief of the Section on Brain Biochemistry at the National Institute of Mental Health. Candace was as brilliant as she was passionate about advancing women in science.

Oxytocin

Oxytocin is a neuropeptide that is synthesized in magnocellular neurons in the paraventricular and supraoptic nuclei of the hypothalamus. It is synthesized as a large inactive precursor protein and progressively hydrolyzed into smaller fragments and stored in a vesicle. Oxytocin neurons send axons into the posterior pituitary gland as well as throughout the limbic system, olfactory bulb, nucleus accumbens (the brain's principal pleasure center), brainstem (to regulate pain), and cortex (Figure 3.13). Oxytocin receptors are G-protein-linked and are found on the presynaptic and postsynaptic membranes. Oxytocin also acts partially on vasopressin receptors, which complicates understanding its functions. It also indirectly modulates neurogenesis (the birth of new neurons) and synaptic plasticity via these receptors.

Oxytocin has several behavioral functions. In highly social animals, oxytocin, supported by actions of the endocannabinoid system (discussed in 3.3 Neurotransmitters Made from Fats), intensifies social attachment by conveying the social salience of environmental stimuli. Elevated levels of oxytocin via intranasal administration have been linked to a range of cognitive and behavioral effects including within-group conformity, trust, affiliation, and cooperation. Oxytocin also promotes aggression toward threatening out-group rivals and may underlie aspects of racism (Zhang et al.,2019). It appears to play a role in stimulating bonding between mother and child. Other studies have linked exposure to oxytocin with reduced social anxiety. Despite the many popular claims, there is no evidence that oxytocin has an aphrodisiac effect. Experiments with human couples sniffing oxytocin have not shown any increased tendency to fall in love.

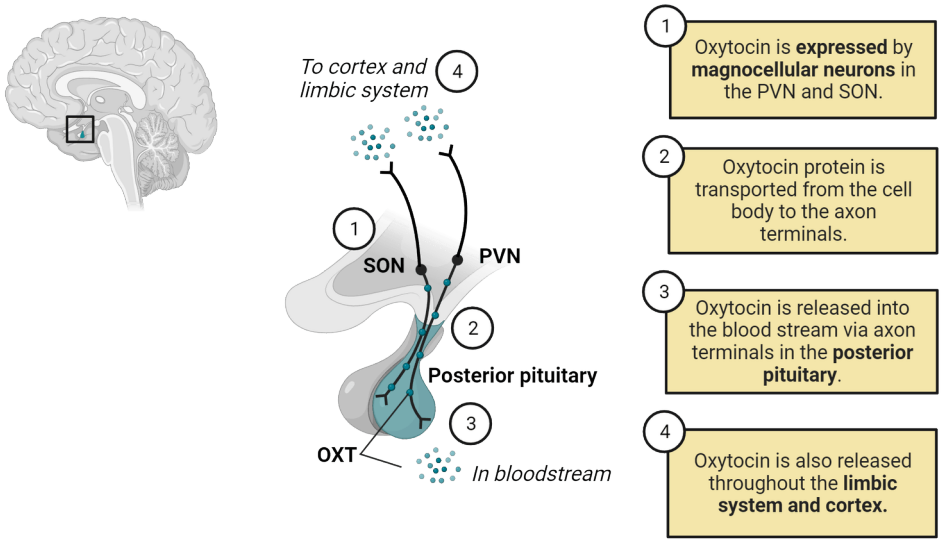

Figure 3.13 Oxytocin networks

Glutamate and GABA

These two amino acids are utilized by more neurons as a neurotransmitter than any other. Glutamate is the principal producer of excitation while GABA (gamma-amino butyric acid) is the principal producer of inhibition. The lifecycle of glutamate is shown in Figure 3.14. The lifecycle of GABA is shown in Figure 3.15. Because these lifecycles overlap substantially, we will discuss them in tandem.

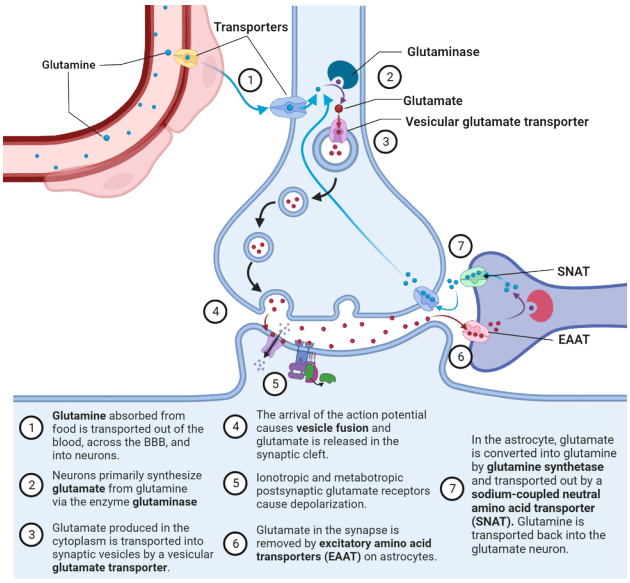

Figure 3.14 Glutamate lifecycle

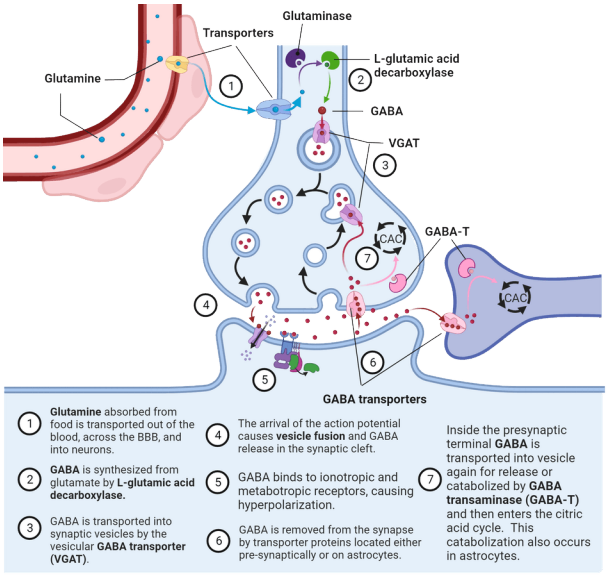

Figure 3.15 GABA lifecycle

Synthesis

The production of both neurotransmitters begins with the amino acid glutamine being transported across the blood brain barrier and requires the participation of an astrocyte (Step 1 in both Figure 3.14 and Figure 3.15). Glutamine is then converted into glutamate by the enzyme glutaminase inside the cytoplasm of both types of neurons (Step 2 in Figure 3.14). It is then packaged into vesicles, if the neuron is glutamatergic (Step 3 in Figure 3.14). If the neuron is GABAergic, glutamate undergoes conversion into GABA by glutamic acid decarboxylase, which requires pyridoxal phosphate (the active form of vitamin B6) as a cofactor and removes a molecule of carbon dioxide (Step 2 in Figure 3.15). The newly synthesized GABA is then transported by the vesicular GABA transporter (VGAT) protein into synaptic vesicles (Step 3 in Figure 3.15). GABA and glutamate are stored in vesicles until

released by their respective neuronal terminals following the arrival of an action potential (Step 4 in both Figure 3.14 and Figure 3.15).

Receptors

Glutamate signaling activates a family of receptors consisting of metabotropic glutamate receptors and ionotropic glutamate receptors (Figure 3.16). Three of these receptors are ligand-gated ionotropic channels: NMDA receptors, AMPA receptors, or kainate receptors. These glutamate receptors were named after the agonists that activate them: NMDA (N-methyl-d-aspartate), AMPA (α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate), and kainic acid. These ionotropic glutamate receptors are nonselective cation channels; they will allow the passage of Na+ and K+, and small amounts of Ca2+. AMPA, kainate, and NMDA receptor activation always produce excitatory postsynaptic responses. All three of these ionotropic receptors are formed from the association of several protein subunits. The metabotropic glutamate receptor, in contrast, is formed from a single protein and functions as a G-protein linked receptor that provides a mechanism for glutamate to modulate cell excitability and synaptic transmission via second messenger signaling pathways.

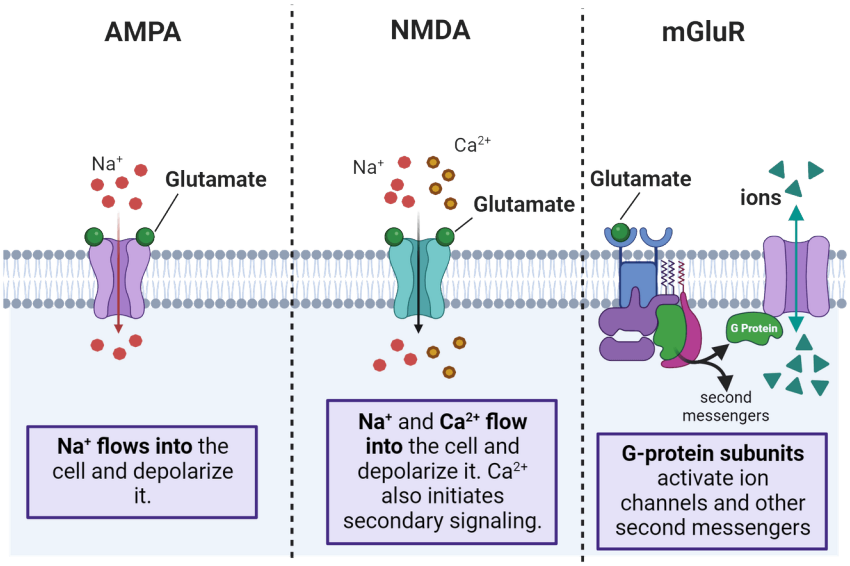

Figure 3.16 Glutamate receptors

GABA receptors are divided into GABA-A and GABA-B (Figure 3.17). Recently a GABA-C receptor was defined. Less is known about its function, but it appears, based on its sequence homology and structure, to have evolved from the nicotinic acetylcholine receptor (see 3.3 Neurotransmitters Made from Fats). GABA-A is a fast-acting ligand-gated ion channel/inotropic receptor. The binding of GABA opens an ion pore to allow negatively charged chloride ions to move across the cell membrane into the cell, increasing the resting negative potential inside the cell. This is also known as hyperpolarization. GABA-A receptors are located throughout the central nervous system with a high concentration in the limbic system and cortex.

The GABA-B receptor is a G-protein linked receptor that leads to the opening of potassium channels, allowing the efflux of positive ions down their concentration gradient leading to the hyperpolarization of the cell membrane. Adenylyl cyclase is also activated, which prevents calcium entry; this action inhibits presynaptic release of other neurotransmitters. GABA-B receptors are slow-acting synaptic inhibitors and are in cortex and thalamic efferent pathways.

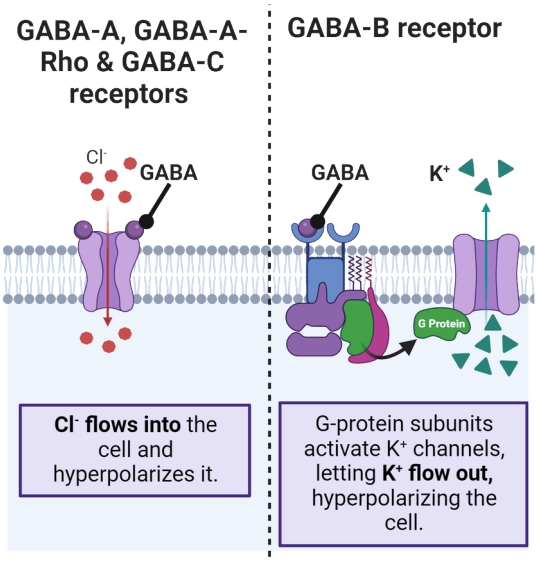

Figure 3.17 GABA receptors

Inactivation of glutamate and GABA

After interacting with their respective protein receptors in the synaptic space (Step 5 in both Figure 3.14 and Figure 3.15), released glutamate needs to be inactivated quickly, otherwise it may overstimulate the post-synaptic neuron and cause local degeneration. Fortunately, there are highly efficient transporters, called excitatory amino acid transporters (EAAT), that remove the glutamate in the synapse into astrocytes. Inside astrocytes, glutamate is converted into glutamine before being released into the extracellular space via the sodium-coupled neutral amino acid transporter (SNAT) (Step 6 and 7 in Figure 3.14). The extracellular glutamine is now available for re-use by glutamate neurons.

Released GABA is inactivated by being transported into astrocytes via GABA Transporters (GAT) (Step 6 in Figure 3.15). Inside the astrocyte, the GABA will be enzymatically converted initially into glutamate, which can then enter the citric acid cycle, or be further converted into glutamine before being released into the extracellular space for reuse by nearby glutamate or GABA neurons (Step 7 in Figure 3.15).

The functions of GABA and glutamate

GABA- and glutamate-releasing neurons are densely located throughout the brain. They tend to function competitively to induce a balance of excitation and inhibition. Neurons spontaneously fire off action potentials due to their tendency to constantly leak potassium ions. The brain takes advantage of this tendency and processes information primarily via the actions of GABA-induced inhibition.

Glutamate neurotransmission is critical for probably the most important physiological process in the brain: learning. This process is mediated through a two-step process shown in Figure 3.18 that begins with the glutamate-induced depolarization of the post-synaptic membrane via the activation of the AMPA ionotropic receptors. At resting membrane potentials, external magnesium (Mg2+) ions enter the NMDAR channel and bind tightly, preventing the influx of any ions. Mg2+ ions are present at millimolar concentrations in the external milieu of neurons, while intracellular Mg2+ concentrations are in the micromolar range, resulting in a net inward driving force for Mg2+ ions at negative membrane potentials. A depolarization of sufficient amplitude and duration by activation of nearby AMPA receptors is required to dislodge the Mg2+ ions from the channel, thereby allowing the influx of sodium and calcium ions. The increase in intracellular calcium ion concentration activates a complex cascade of biochemical changes that ultimately involve the genes of the neuron and that may change how the neuron behaves for the rest of your life. This process underlies the brain's ability to learn (see Chapter 18 Learning and Memory).

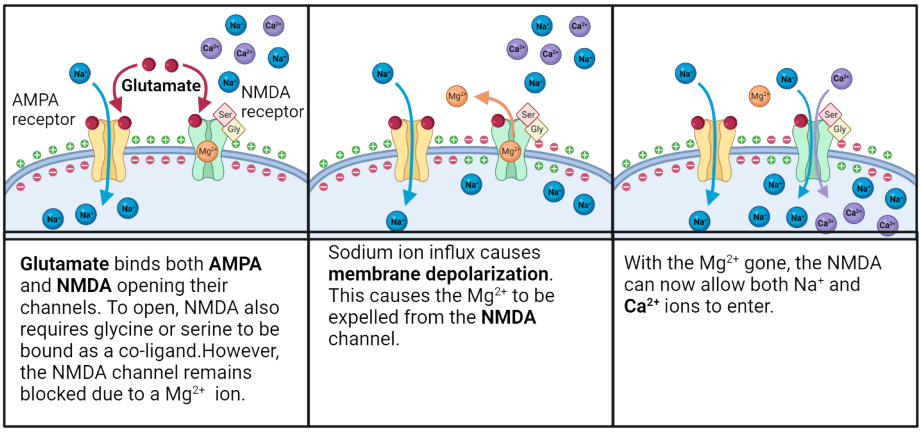

Figure 3.18 AMPA and NMDA functional interaction

Neuroscience in the news: eating GABA to calm the brain

A short search on the internet will uncover many different over-the-counter supplements containing GABA. The advertisements claim that this supplement will reduce stress and anxiety, and help you to fall asleep. Superficially, this makes sense. Anything that enhances GABA receptor function produces an overall decrease in the activity of neurons everywhere in your brain. This property of GABA has led to the development of highly effective anti-anxiety drugs that are GABA receptor agonists. Unfortunately, as is almost always true, the success of such claims about over-the-counter supplements depends upon the placebo effect. You cannot accomplish these effects simply by eating GABA-containing substances to increase the amount of GABA in your brain. While floating in the bloodstream, ingested GABA is mostly metabolized by the liver or consumed by the tissues of the body. Any remaining GABA molecules carry an electrical charge that prevents them from passing across the blood–brain barrier. Recall that the production of GABA begins with the amino acid glutamine being transported across the blood brain barrier, not GABA. Taking a few hundred milligrams of GABA every day, therefore, will not reduce your anxiety or help you sleep.

Histamine

Histamine neurons originate from the tuberomamillary nucleus of the posterior hypothalamus and send projections throughout the brain (Figure 3.19).

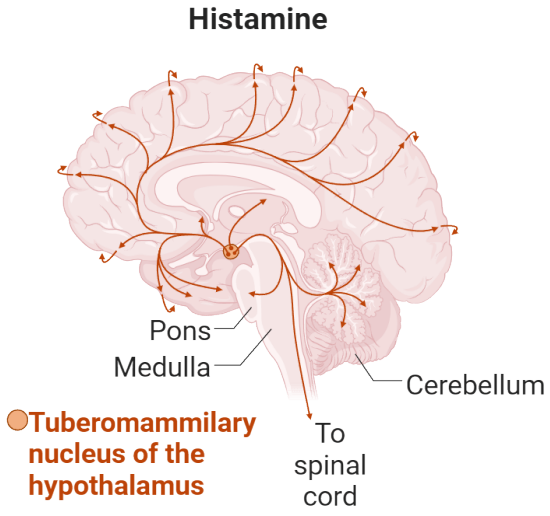

Figure 3.19 Histamine system anatomy

Histamine influences arousal, control of pituitary hormone secretion, suppression of eating and cognitive functions. I have included a discussion of this neurotransmitter because it is the target of so many different over the counter medications that are commonly overused.

Synthesis

Histamine is derived from the decarboxylation of the amino acid histidine, a reaction catalyzed by the enzyme L-histidine decarboxylase (step 1 and 2 in Figure 3.20). Once formed, histamine may be transported in vesicles by a plasma membrane monoamine transporter protein (step 3 in Figure 3.19).

Receptors

Histamine binds to G protein-coupled receptors, designated H1 through H4 (step 5 in Figure 3.20). The H1 and H2 receptors produce neuronal depolarization. The H3 receptor functions as an auto-receptor; it downregulates release of histamine, norepinephrine, acetylcholine, and serotonin (step 6 in Figure 3.20).

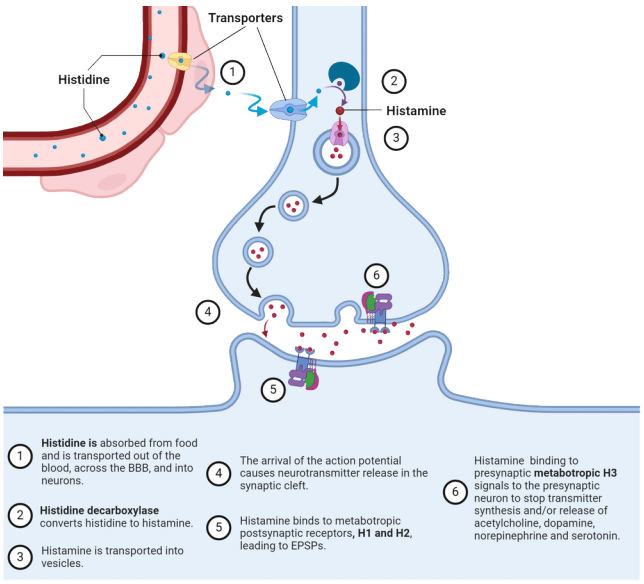

Figure 3.20 Histamine life cycle

Inactivation

Once released by fusion of synaptic vesicles, histamine is primarily catabolized by the enzyme histamine-N-methyltransferase. Unlike the other amino acid-derived neurotransmitters, neurons do not inactivate histamine by re-uptake.

Function of histamine

Histamine neurons, in tandem with neurons releasing norepinephrine, influence your level of arousal during the day. Any drug that reduces the actions of histamine will make you feel drowsy. You probably have taken antihistamines and experienced their adverse cognitive effects.

1.8.4: Neurotransmitters Made from Fats

Learning Objectives

By the end of this section, you should be able to

- 3.3.1 Describe how fat-derived neurotransmitters are produced and inactivated
- 3.3.2 Define the function of each neurotransmitter discussed

The brain contains two important families of neurotransmitters that are physiologically active lipid compounds called either endocannabinoids or prostaglandins. They use related enzymatic systems for their production and inactivation. A third neurotransmitter, acetylcholine, is made from molecules of fat and acetate. Together, these three neurotransmitters influence mood, thinking and the experience of pain. This section will also introduce neurosteroids, a unique class of steroids that are synthesized in the brain and can rapidly modulate neuronal activity.

Endocannabinoids

This section will describe the lifecycle and functions of endocannabinoids.

Synthesis

The two currently best studied endocannabinoid neurotransmitters (there are at least seven) are anandamide and 2-AG (2-arachidonoyl-glycerol); 2-AG occurs at much higher levels in the brain than anandamide (Lu and Mackie, 2016). The production, synthesis and release of anandamide and 2-AG occur independently within the cell, suggesting that 2-AG and anandamide can be recruited differentially from the same postsynaptic neuron depending on the type of presynaptic signaling. The synthesis of both endocannabinoid neurotransmitters begins with phospholipid components of the neural membrane (Figure 3.21). Diacylglycerol (DAG) is produced first followed by enzymatic conversion into 2-AG via the enzyme diacylglycerol lipase (DAGL). A different membrane phospholipid is converted into N-arachidonoyl phosphatidylethanolamine (NAPE) which is then enzymatically converted into anandamide by the enzyme phospholipase D (PLD).

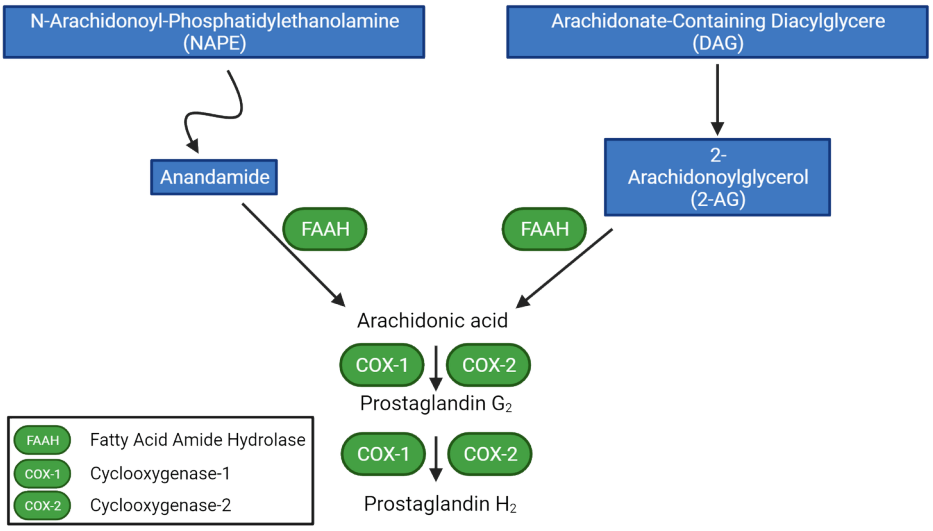

Figure 3.21 Synthesis of arachidonic acid and prostaglandins

Unlike the other neurotransmitters discussed thus far, these two endocannabinoids are not stored in synaptic vesicles. The depolarization of a postsynaptic neuron leads to Ca2+ influx through voltage-gated channels and causes the enzymatic de

novo generation and the release of endocannabinoids such as anandamide. Once produced they are released to flow in reverse direction (retrograde neurotransmission) across the synapse to find their receptors on the pre-synaptic side of the synapse (Figure 3.22).

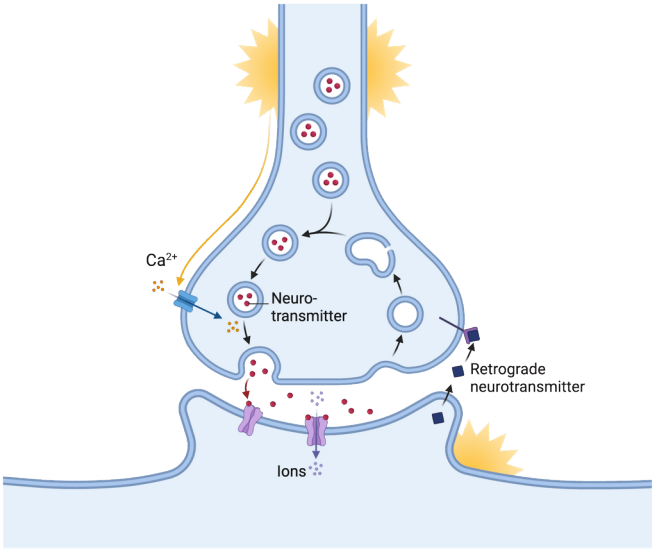

Figure 3.22 Retrograde neurotransmission Retrograde neurotransmitters are not packaged in vesicles. Instead, they are released by the postsynaptic cell and signal on receptors on the presynaptic cell.

Receptors

Two different types of endocannabinoid receptors are located throughout the brain and body. Anandamide binds best to CB1 receptors, while 2-AG binds best with the CB2 receptors (Figure 3.23).

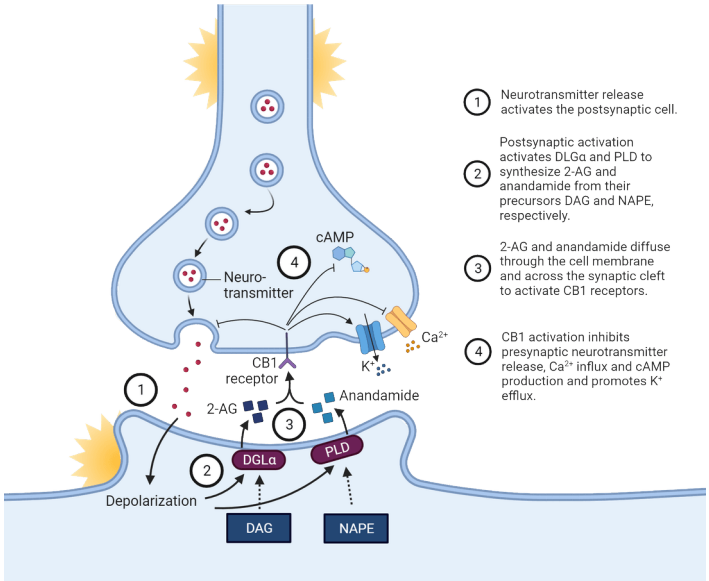

Figure 3.23 Function of endocannabinoid receptors

The type 1 receptors are densely distributed in several brain regions; the type 2 receptor is found at much lower levels in the brain. The type 1 receptor is among the most abundant G protein–coupled receptors in the brain. Anandamide and 2-AG also prevent the release of both glutamate and GABA, thus altering the balance of excitation and inhibition throughout the brain.

Inactivation of endocannabinoids

Anandamide is inactivated by either reuptake or catabolism by the enzyme fatty acid amide hydrolase (FAAH). 2-AG is inactivated by either reuptake or sequential catabolism by both FAAH and monoacylglycerol lipase (MAGL). The major product of this catabolism is arachidonic acid, which can be used to produce prostaglandins (see next section).

The functions of endocannabinoids

At the synaptic level, anandamide and 2-AG act retrogradely on pre-synaptic receptors to inhibit the release of a variety of neurotransmitters by altering the function of potassium and voltage-gated calcium channels. At the systems level, endocannabinoids influence appetite, mood, stress reduction, and the brain's inflammatory response. The endocannabinoids enhance goal-seeking behaviors by augmenting the actions of dopamine within the brain's pleasure centers in the ventral forebrain.

Prostaglandins

This section will describe the lifecycle and functions of prostaglandins.

Synthesis

Prostaglandins are synthesized from the fatty acid arachidonic acid via the enzyme cyclooxygenase (COX). Every prostaglandin contains 20 carbon atoms that includes a single 5-carbon ring. They are found throughout the body and brain. Like the endocannabinoids, prostaglandins are not stored in vesicles; they are produced on demand when they are needed and then released into the extracellular space via a specific protein transporter. Prostaglandins are not reused by the neurons. Prostaglandins are oxidized by NAD+-dependent 15-hydroxyprostaglandin dehydrogenase and then reduced by NADPH/NADH dependent delta13-15-ketoprostaglandin reductase.

Functions of prostaglandins

The variety of prostaglandins that exist and their wide distribution in the brain underlies their variety of functions. Glia release prostaglandins to activate pro-inflammatory cascades. Some prostaglandins are neuroprotective from the effects of hypoxia or ischemia. The sexual differentiation of the brain may depend on the actions of prostaglandins. Acutely, fever-producing agents induce the production of prostaglandins in the hypothalamus, altering body temperature regulation. In contrast, chronic inflammatory processes associated with prostaglandins may underlie the development of depression (Regulska et al., 2021). Generally, the level of most prostaglandins is kept quite low in the brain.

Acetylcholine

This section will describe the lifecycle and functions of acetylcholine.

Synthesis

Acetylcholine (commonly abbreviated ACh) is made by transferring a molecule of acetic acid on to a molecule of choline that is derived from the fatty acid lecithin (steps 1 and 2 in Figure 3.24). This conversion occurs via the action of an enzyme called choline acetyltransferase (Picciotto et al., 2012). The acetyl is derived from a molecule of sugar, usually glucose, that is initially modified inside the mitochondria. The brain needs sugar (usually in the form of glucose) to function normally. Once inside the brain, only a very small percentage of the dietary sugar is used to produce acetylcholine. The brain typically has a constant and ample supply of choline. Choline can be easily obtained from the diet, such as from eggs and baked goods. Despite this fact, many health foods stores sell choline powder to gullible customers, claiming that consuming more choline will somehow enable their brains to make more acetylcholine. Given the vital role of acetylcholine in learning and memory, this is an appealing claim. Regrettably, it has no basis in fact. For adults, the brain responds only to deficits in choline, not surpluses, in the diet. It has a ready source of choline in the diet or stored in the liver and, in fact, never develops a deficit in choline, even in patients with Alzheimer's disease. Thus, consuming extra choline does not induce your brain to make more acetylcholine. Instead, it only results in a gaseous by-product that you exhale and that smells like rotting fish. Rather than enhancing your cognitive abilities, choline

supplements merely generate a terrible case of bad breath.

Once acetylcholine is produced, it is transported into synaptic vesicles (step 3 in Figure 3.24). The vesicles containing acetylcholine fuse with the presynaptic membrane of the axon terminal in response to an action potential (step 4 in Figure 3.24). Each vesicle releases about 10,000 acetylcholine molecules into the synapse. Some of these acetylcholine molecules will bind to protein receptors on the surface of the nearby neuron (step 5 in Figure 3.24). Ultimately, all of them are inactivated by an enzyme.

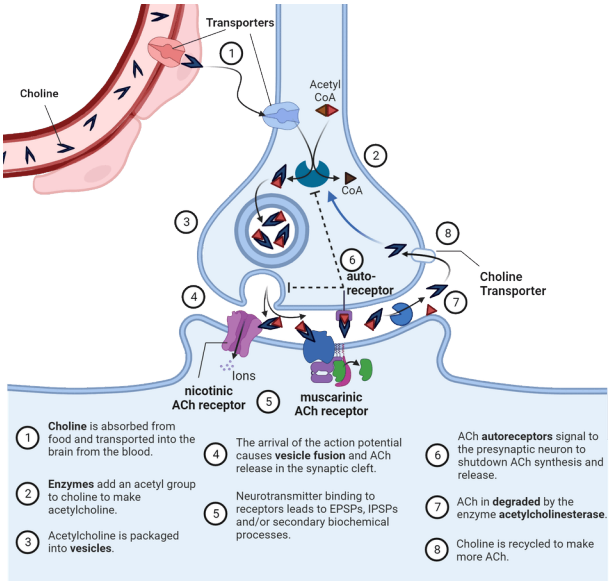

Figure 3.24 Acetylcholine lifecycle

Inactivation of Acetylcholine

Released acetylcholine molecules are quickly inactivated by the enzyme acetylcholinesterase (step 7 in Figure 3.24). Acetylcholinesterase has one of the fastest reaction rates of any of our enzymes, breaking up each molecule in about 80 microseconds (Taylor, 1991). Acetylcholinesterase breaks the acetylcholine into a molecule of acetate and choline. About forty percent of the choline will be reabsorbed into the axon terminal by specialized transport proteins and reused to produce more acetylcholine (step 8 in Figure 3.24). The remaining choline molecules and acetate will diffuse into the extracellular space and ultimately be removed from the brain. Knowledge about the chemistry and function of acetylcholinesterase led to the development of drugs that inhibit the enzyme acetylcholinesterase and greatly increase the amount of acetylcholine in the synapse. Today, acetylcholinesterase inhibitors are common treatments for Alzheimer's disease. In theory, the drugs should compensate for the loss of acetylcholine neurons in these patients; in practice, the drugs provide little clinical benefit because too few healthy acetylcholine neurons are still present in the brain.

Receptors

Once released into the synapse, the neurotransmitter acetylcholine can act on two quite different protein receptors that have been designated, as have most receptors, according to the compounds that were originally used to study them—in this case, muscarine and nicotine (Figure 3.25).

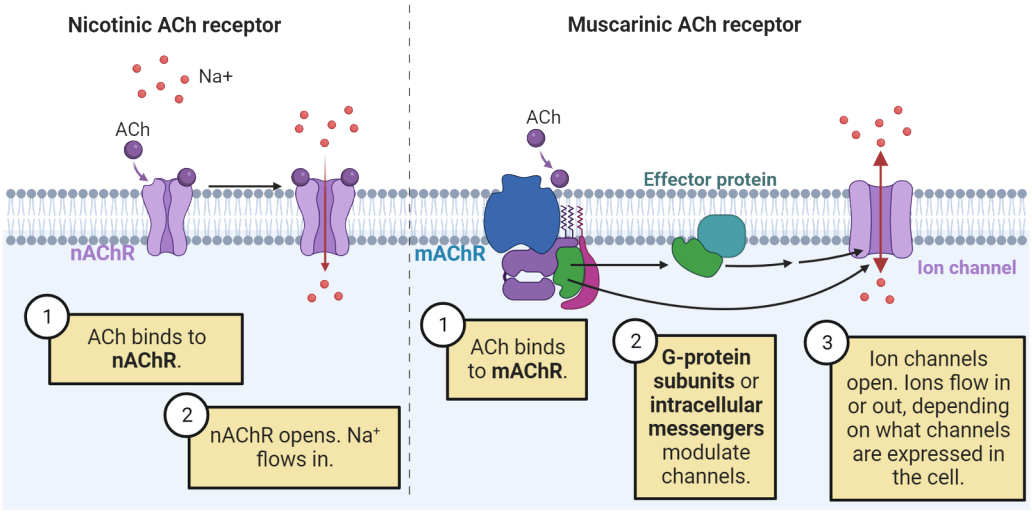

Figure 3.25 ACh channels

Most of the acetylcholine receptors in the brain are the muscarinic subtype, whereas less than 10% are nicotinic. They differ in size, structure, and mechanism of action; yet they both respond to acetylcholine. Nicotinic acetylcholine receptors are simple ligand-gated fast-opening ion channels that are also responsive to nicotine. Most of the nicotine receptors in the body live in the neuromuscular junction (see Chapter 10 Motor Control). Nicotine receptors allow the passage of sodium, potassium or calcium ions and typically produce depolarization. Muscarinic acetylcholine receptors are G-protein-linked receptors that activate other ionic channels via a second messenger cascade. These receptors are responsive to muscarine and can produce either depolarization or hyperpolarization depending on the nature of the ionic channel linked to the G-protein complex.

The functions of acetylcholine

Within the human brain are numerous acetylcholine pathways that influence the function of the cortex, hippocampus, and many other subcortical regions (Figure 3.26).

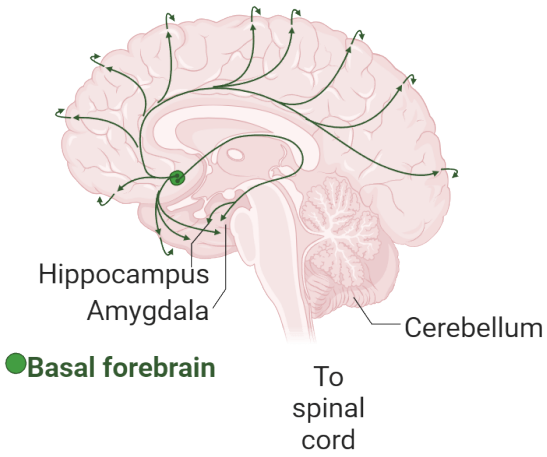

Figure 3.26 Acetylcholine system anatomy

Within these various regions, the actions of acetylcholine enable you to learn and remember, to regulate your attention and mood, and to control how well you can move. Thus, anything that affects the function of acetylcholine neurons has the potential to affect all these brain functions. Sometimes we can learn much about the role of a particular neurotransmitter system by investigating

what happens when it is injured or diseased. In the brains of people with Alzheimer's disease, for example, acetylcholine neurons that project into the hippocampus and cortex degenerate. The loss of normal acetylcholine function in the cortex may be why patients with Alzheimer's disease have difficulty paying attention to their environment. The loss of acetylcholine projections into the hippocampus may underlie the profoundly debilitating memory loss that is the hallmark of this disease (see Chapter 18 Learning and Memory).

History of Neuroscience: Otto Loewi and dreams of neuroscience

In 1902, a young German scientist named Otto Loewi at University College London began working with Henry Dale on how neurons communicate with each other. Loewi began thinking about ways that he might prove, or disprove, the chemical transmission hypothesis. According to Loewi, the idea of a viable experiment came to him in a dream a couple days after Easter Sunday in 1921. Unfortunately, his notes that night were illegible. Fortunately, the following night he had the dream again and he rushed off to the lab to test his ideas. Loewi determined that a substance was released by the vagus nerve that could communicate with other nervous tissues. Several years later this substance was isolated by Dale, who named it acetylcholine. Loewi and Dale shared the Nobel Prize for Physiology or Medicine in 1936 for their work on chemical neurotransmission.

Neurosteroids

Neurosteroids are produced from their precursor steroids by astrocytes and neurons (Maguire and Mennerick, 2024). Dietary cholesterol is converted into pregnenolone, an intermediate necessary for the synthesis of neurosteroids. Pregnenolone is then enzymatically converted into progesterone. Overall, neurosteroids are not themselves active at typical intracellular steroid receptors. They modulate brain excitability primarily by interaction with neuronal membrane receptors and ion channels. For example, progesterone is converted into allopregnanolone, which can enhance the function of GABA receptors and reduce seizure activity, anxiety and stress. Many neurosteroids are broad-spectrum anticonvulsant agents. In contrast, another neurosteroid, pregnenolone sulfate, is a negative GABA receptor modulator and tends to activate general brain activity and induce seizures. Neurosteroids are found at high levels in the cortex, hippocampus, and amygdala. Within these brain regions, neurosteroid synthetic enzymes are localized to glutamatergic principal neurons. Given their role in the control of neuronal excitability, neurosteroid analogs are now being considered for treatment of epilepsy, anxiety, depression, and stress-sensitive conditions.

View this Interactive Content online

The brain obtains lipids, amino acids, and sugars from the metabolism of fats, proteins, and carbohydrates from the diet. Neurons modify these precursor molecules enzymatically into neurotransmitters, store them inside small lipid-walled vesicles and maintain them until the neuron determines that they should be released. The arrival of an action potential induces the neuron to release its neurotransmitter(s) into the synaptic cleft so that it can interact with specialized receptor proteins floating on the surface of a nearby neuron. The production, storage, release and inactivation of neurotransmitter molecules require the contribution of many genes and proteins, and lots of energy. However, these neurotransmitters are the only way that the majority of neurons in the brain can communicate with each other.

3.2 Neurotransmitters Made from Amino Acids

Neurons in the brain absorb metabolites of the food we consume and enzymatically convert them into neurotransmitters. Sometimes the conversion process involves multiple enzymes working together; in contrast, sometimes amino acids become neurotransmitters with little or no modification. The function of these neurotransmitters is determined by the region of the brain they innervate, the type and location of the receptor, and the nature of the mechanisms induced by the receptor. Numerous cognitive disorders and neurological diseases involve dysfunction or degeneration of one or more of these neural systems. An understanding of the chemistry of these neurotransmitters has led to many effective and safe drugs to treat these disorders and diseases.

3.3 Neurotransmitters Made from Fats

Fatty acids obtained from either the diet or pieces of neural membrane are modified into neurotransmitters. In contrast to the amino acid-derived neurotransmitters, two of the fatty acid-derived neurotransmitters discussed are not stored in vesicles; they are produced and immediately released only when needed. Their diffuse distribution underlies the large variety of functions that are assigned to them, including the control of mood, learning and memory and pain. Dysfunction of acetylcholine is well known and studied. In contrast, much less is known about the functions of the endocannabinoid system.

1.8.6: Key Terms

3.1 General Neurochemistry Principles

blood-brain barrier, astrocytes, enzymes, GABA, glutamate, dopamine, norepinephrine, epinephrine, serotonin, neuropeptides, endocannabinoids, prostaglandins, synaptic vesicles, calcium channels, synaptic cleft, synapse, receptor, ionotropic receptor, secondary messenger, G-protein coupled receptor, reuptake, autoreceptor

3.2 Neurotransmitters Made from Amino Acids

Tyrosine, L-DOPA, tyrosine hydroxylase, anemia, aromatic amino acid decarboxylase, dopamine-beta-hydroxylase, copper, Phenolethanolamine-N-methyltransferase, Vitamin C, re-uptake, monoamine oxidase, catechol-O-methyltransferase, 3,4-dihydroxyphenylacetic acid, homovanillic acid, 5-hydroxytryptophan, tryptophan hydroxylase, 5HT-1A, 5-hydroxyindole acetic acid, raphe nuclei, neuropeptide, endorphins, oxytocin, glutamine, glutamic acid decarboxylase, vesicular GABA transporter, NMDA receptors, AMPA receptors, kainate receptors, histamine, L-histidine decarboxylase, histamine-N-methyltransferase

3.3 Neurotransmitters Made from Fats

Anandamide, 2-AG, diacylglycerol, diacylglycerol lipase, N-arachidonoyl phosphatidylethanolamine, phospholipase D, retrograde neurotransmission, fatty acid amide hydrolase, monoacylglycerol lipase, arachidonic acid, cyclooxygenase, acetylcholinesterase, muscarinic acetylcholine receptors, nicotinic acetylcholine receptors, Alzheimer's disease, neurosteroids

1.8.8: Multiple Choice

3.1 General Neurochemistry Principles

1.
Which of the following statements is false?

a. The synaptic communication process often fails because the vesicles are empty.
b. Neurotransmitters become inactive in the presence of oxygen.
c. All neurotransmitters are catabolized after being released.
d. Neurotransmitters may be converted into inactive chemicals while being stored inside synaptic vesicles.

2 .
The fusion of a synaptic vesicle at the axonal terminal requires:

a. the action of voltage-dependent sodium channels.
b. the inhibition of potassium channels.
c. the opening of voltage-dependent calcium channels.
d. an elevation in the intracellular concentration of potassium ions.

3.
G-Protein coupled receptors are _____ that are _____.

a. lipids / ion channels
b. part of a large family of proteins / linked to nearby ion channels
c. mostly limited to limbic brain regions / used to prevent the fusion of synaptic vesicles
d. mostly postsynaptic / responsive to endocannabinoids

3.2 Neurotransmitters Made from Amino Acids

4 .
The production of dopamine begins inside the _____ of the neuron with the production of _____.

a. cytoplasm / L-DOPA
b. synaptic vesicle / L-DOPA
c. cytoplasm / tyrosine
d. synaptic vesicle / norepinephrine

5.
The enzyme tyrosine hydroxylase requires the presence of _____ ions to function properly.

a. calcium
b. iron
c. magnesium
d. potassium

6 .
L-DOPA is converted into _____ by the removal of a molecule of _____.

a. dopamine / carbon dioxide
b. norepinephrine / oxygen
c. norepinephrine / oxygen
d. dopamine / hydroxyl

7.
Dopamine neurons _____than norepinephrine neurons.

a. project to more brain areas
b. are more numerous
c. contain more copper
d. contain more zinc

8 .
The enzyme Aromatic Amino Acid Decarboxylase is active within the _____ and produces _____.

a. cytoplasm / norepinephrine
b. synaptic vesicle / dopamine
c. cytoplasm / dopamine
d. synaptic vesicle / epinephrine

9.
Dopamine-beta-Hydroxylase is found within the _____ and converts dopamine into _____.

a. synaptic vesicle / norepinephrine
b. cytoplasm / norepinephrine
c. synaptic vesicle / L-DOPA
d. synaptic vesicle / epinephrine

10 .
The purpose of ascorbic acid inside of the synaptic vesicles is to:

a. act as a co-factor for dopamine-beta-hydroxylase.
b. act as an anti-oxidizing agent.
c. act as an anti-reducing agent.
d. keep the pH of the vesicle acidic.

11.
The function of any receptor:

a. depends upon the region of the brain the receptor is located.
b. is largely independent of the nature of its second messenger.
c. is determined by the water solubility of its components.
d. is related to the identity of its receptor, e.g., dopamine will always close sodium channels.

12 .
The function of any neurotransmitter depends on:

a. the function of the structures in which they are located.
b. whether the transmitter is lipid or water soluble.
c. the number of amine and carboxyl groups that are on the carbon chain backbone.
d. whether they bind to an ion channel or a G-protein linked receptor.

13.
Dopamine in the substantia nigra contain a dark substance that concentrates _____ makes these neurons vulnerable to _____.

a. copper / insecticides
b. iron carbon dioxide
c. iron / oxygen
d. zinc oxidates / low pH

14 .
Serotonin neurons project _____ to control _____.

a. down-ward into the spinal cord / the autonomic nervous system
b. into the thalamus / incoming pain signals
c. into the cortex / movement
d. into the basal ganglia / learning and memory

15.
The neurotransmitter serotonin is built from a molecule of the amino acid tryptophan by the addition of a _____ followed by the removal of a molecule of _____.

a. amine group / hydroxyl
b. methyl / carbon dioxide
c. carbon dioxide / hydroxyl
d. hydroxyl / carbon dioxide

16 .
Melatonin:

a. is produced from the amino acid tyrosine.
b. influences learning and memory.
c. is released soon after we fall asleep.
d. release increases with age.

17.
Most of the serotonin released from the axonal terminal is:

a. re-absorbed by the axonal terminal, repackaged into synaptic vesicles, and re-released again.
b. catabolized by the enzyme monoamine oxidase.
c. converted into 5-Hydroxyindole acetic acid.
d. removed from the brain.

18 .
Neurons that produce neuropeptides:

a. are found throughout the brain.
b. release on neuropeptides.
c. are only found in the brainstem.
d. tend to have a very slow firing rate as compared to other neural systems.

19.
Which of the following statements is not true of endorphins?

a. They modulate the pain signal carried from the periphery.
b. They regulate numerous neuroendocrine or neuroimmune functions.
c. Because they are naturally occurring humans do not become addicted to them.
d. They are released in response to laughing, eating, and listening to music.

20 .
The two most common neurotransmitters in the brain are:

a. serotonin and dopamine.
b. acetylcholine and GABA.
c. GABA and glutamate.
d. GABA and serotonin.

21.
Released glutamate is:

a. removed from the synapse by excitatory amino acid transporters.
b. removed from the synapse by reuptake into the axonal terminal.
c. removed from the synapse into astrocytes where it will be destroyed and excreted as a metabolite.
d. removed from synapse by reuptake and converted into glutamine before being repackaged in vesicles.

22 .
Most neurons spontaneously fire off action potentials due to their tendency to constantly leak potassium ions. The brain takes advantage of this tendency and processes information primarily:

a. via the control of intracellular calcium-ion levels.
b. via the balance of ion-channel and G-protein linked channels.
c. via the actions of glutamate-induced excitation.
d. via the actions of GABA-induced inhibition.

3.3 Neurotransmitters Made from Fats

23.
Acetylcholine is made by transferring a molecule of acetic acid on to a molecule of choline. The acetic group is derived from _____, the choline is derived from _____ the fatty acid lecithin. Consuming additional choline _____.

a. glucose / lecithin / does not produce more acetylcholine
b. vitamin C / membrane lipids / increases acetylcholine production
c. lecithin / glucose / does not produce more acetylcholine
d. acetyl hydroxyl / glucose / increases acetylcholine production

24 .
Released acetylcholine is inactivated by _____; available choline is _____ while acetate is _____.

a. monoamine oxidase / allowed to passively diffuse away / removed from the synapse by reuptake
b. acetylcholinesterase / mostly removed from the synapse by reuptake / is removed by local astrocytes
c. choline acetyltransferase / allowed to passively diffuse away / removed from the synapse by reuptake
d. choline acetyltransferase / mostly removed from the synapse by reuptake / allowed to passively diffuse away

1.8.9: Fill in the Blank

3.1 General Neurochemistry Principles

1.
Chemicals that allow one neuron to influence the behavior of other neurons are called _____.
2 .
Neurotransmitters are released into the small space between neurons, called a _____.

3.2 Neurotransmitters Made from Amino Acids

3.
Norepinephrine neurons originate primarily within the _____ that is found in the floor of the 4th ventricle.
4 .
Serotonin neurons originate within the _____ and project to every part of the brain.
5.
An increase in intracellular _____ ions activates a complex cascade of biochemical changes that ultimately involve the genes of the neuron.

3.3 Neurotransmitters Made from Fats

6 .
Acetylcholine neurons originate within the _____ and project to the cortex hippocampus, amygdala, and olfactory bulbs.

Our nervous system is the body's command center. It is a well-tuned communication system that transmits signals at the speed of 220 miles/hour to coordinate the body's organs, movements, and sensations. The nervous system connects our 12 body systems and uses a central processing unit, the brain, to coordinate the proper function of the entire human body. The brain has a unique architecture that is partitioned into different regions, totaling billions of neurons, that if put end to end, would total 37 miles. But how does such a complex system emerge? Will an understanding of how the nervous system is built aid in our ability to treat common and rare brain disorders?

In this chapter, we will learn about the early formation of the central nervous system (CNS). We will discuss cell-to-cell communication and movements that ultimately produce an intricate structure with region-specific functions. These structures continue to develop postnatally and are highly influenced by environmental factors/experience, ultimately shaping how we interact with and perceive the world. Throughout the chapter we will provide examples, using clinical case studies and disease discussions, to understand the critical importance of genetics and environment in shaping normal brain development.

1.9.2: Gastrulation and Formation of the Neural Tube (Neurulation)

Learning Objectives

By the end of this section, you should be able to

- 5.1.1 Describe major structural brain defects and their causes.
- 5.1.2 Describe basic principles of gastrulation and neurulation.

Our entire CNS begins from a simple sheet of cells. During development, these cells expand to create the highly patterned and functional units of our brain and spinal cord, giving us the capacity to sense and respond to the environment. In this section, we will introduce you to some of the earliest steps of development. These steps create the foundation for more advanced sculpting of the brain and spinal cord.

Why is brain development important?

CNS abnormalities that cause functional impairment or suffering occur with a frequency of approximately 0.1-0.2% of all live births (Cater et al., 2020). Congenital (those that occur at birth) defects can occur due to environmental toxins (teratogens), as well as other prenatal experiences, such as poor maternal diet, maternal stressors, or genetic mutations. Abnormal brain development that impairs quality of life can also occur postnatally due to the presence or absence of environmental stimuli. For example, a lack of or poor environmental influences postnatally can severely impair cognition years later (Ornoy, 2006). These types of detrimental changes in brain function result because both the prenatal and the postnatal brain have a tremendous ability to sense and respond to the environment by reorganizing its structure, function, or connections. Simply put, the brain is very sensitive to environmental stimulation both pre- and postnatally. The fact that early life experience and brain development can lead to functional deficits well into adulthood underscores a need for research into how the brain develops, how genetics modulates pre-and postnatal development, and how the environment positively or negatively affects overall brain development and function.

How does development begin?

Development of the nervous system requires specific patterning events in the early embryo. These events are summarized in Figure 5.2, which we will elaborate on throughout the sections of this chapter. These events organize the fertilized egg and partition specific units for brain development. Thus, to understand brain development in detail, we must first begin by understanding the mechanisms in place that set up the original partitions.

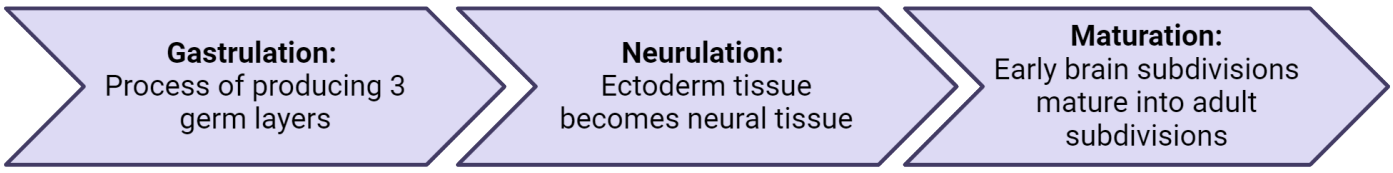

Figure 5.2 Overview of early neurodevelopment

Gastrulation

Development of the nervous system begins with the process of gastrulation, one of the earliest developmental events in the embryo. The goal of gastrulation is to start the subdivision and specialization of cells in the developing embryo. When complete, gastrulation results in the production of 3 primary germ layers. The creation of germ layers can be thought of as the earliest step towards successfully partitioning an organism. Each of the 3 germ layers are made of cells that will give rise to specific tissue

types depending on their location.

Gastrulation begins several days after the fertilization of an egg in species like mice and humans. In those intervening days after fertilization (but before gastrulation), the egg undergoes several rounds of cleavage (cell division) events to produce a sphere of cells called the blastocyst. The sphere of cells surrounds a fluid-filled cavity called the blastocoel (step 1 in Figure 5.3). Reorganization of the blastula will produce two early layers of cells, the inner cell mass and the outer trophoblast layer (step 2 in Figure 5.3). The trophoblast layer will become the mammalian placenta. Through cellular movements, migration, and invagination, the cells of the inner cell mass will produce the 3 germ layers (step 2 in Figure 5.3).

Gastrulation begins after the formation of the primitive streak, which is a long groove that forms across the developing embryo. At the anterior region of the primitive streak is the node (De Robertis, 2006). This node represents the organizing center of gastrulation and is the site where invagination of cells begins. Figure 5.3 step 3 demonstrates an example of early invagination. After the cellular movements are complete, the gastrula contains 3 germ layers: the endoderm, mesoderm, and ectoderm (Figure 5.3). They are named based on where they are located within the developing embryo: the endoderm is the innermost layer, the mesoderm is in the middle layer, and the ectoderm is the outermost layer. The CNS is produced from the ectoderm, although all layers communicate with one another to coordinate development.

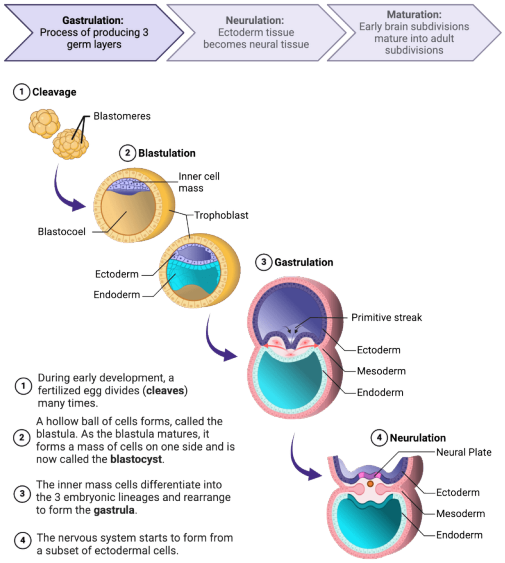

Figure 5.3 Gastrulation

Neuroscience Across Species

Compare and contrast: gastrulation in other species

Gastrulation is highly conserved across species. However, some anatomical names and regions differ. Many of the cellular movements and signaling events that regulate gastrulation were originally identified in other embryos such as amphibians. In some species such as frogs and zebrafish, the egg is externally fertilized, and the events of gastrulation occur external to the mother. Despite differences in species and location, similar structures arise and organize gastrulation in amphibians and other species. For example, the mammalian blastocyst is akin to a structure called the blastula, which contains a primitive streak-like structure called the blastopore. The dorsal end of the blastopore is an organizing center called the blastopore lip, equivalent to the node. Observable comparisons can be viewed in Figure 5.4 of mouse (mammalian) and zebrafish development.

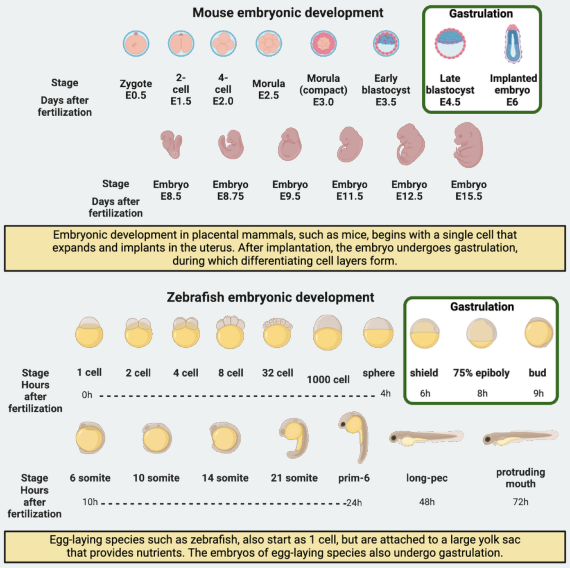

Figure 5.4 Prenatal development across species

The early embryo in both species undergoes cleavage events, rapidly increasing the number of cells. In zebrafish, the cells are located above a large extra embryonic structure called the yolk sac. The human yolk sac is essential for the early production of blood and germ cells. For example, it is the site of production of microglia, the immune cells in the brain (see Chapter 17 Neuroimmunology). In humans, gastrulation occurs in the 3rd week of development and begins with the formation of the primitive streak. In mice, the blastocyst is formed by embryonic (E) day 3 and gastrulation begins at embryonic day 6.5. This is equivalent to approximately 6 hours post fertilization in zebrafish. In both species, the end of gastrulation produces the gastrula, which contains three complete germ layers (Figure 5.3). Gastrulation in chick embryos is very similar to the process in humans. The epiblast layer will produce the 3 germ layers and cells will migrate through the primitive streak as in higher vertebrates. The movements are organized at Hensen's node which is the equivalent of the node in mammals.

Neurulation

Completion of gastrulation lays the foundation for a process called neurulation, which will generate the early brain and spinal cord tissues via the formation of a structure called the neural tube (summarized in Figure 5.5). Of the 3 germ layers, the ectoderm, or outer layer, will generate cells that become neural tissue or epidermis: two vastly different tissues. To make neural tissue (instead of epidermis), a portion of the ectoderm called the neural plate must undergo neural induction.

The neural plate is a single layer of cells located in a small, central region of the ectoderm (Figure 5.5, step 1). It is induced to become neural tissue by the expression of molecules we call neural inducers. These are secreted factors that direct the surrounding tissues through neurulation (Harland and Gerhart, 1997). One example of a neural inducer is noggin (Valenzuela et al., 1995). Localized expression of noggin induces the neural plate to invaginate (step 2 of Figure 5.5). Invagination can be described as the process of folding cells inward, to produce a small cavity. In step 2 of Figure 5.5, the cells of the neural plate that are pushing down into the tissue beneath them are migrating and growing towards cells that are secreting noggin (and other factors). This migration of neural plate cells into the underlying tissue results in the formation of the neural groove (Figure 5.5, step 2), a center region that is surrounded by indentations that form the neural folds. Ultimately by cellular movements, the two neural folds connect producing a neural tube that sits ventral to the outer epidermis (Figure 5.5 steps 3 and 4). The inner region of the newly closed neural tube develops into the central canal of the spinal cord and what will eventually form the ventricles of the brain.

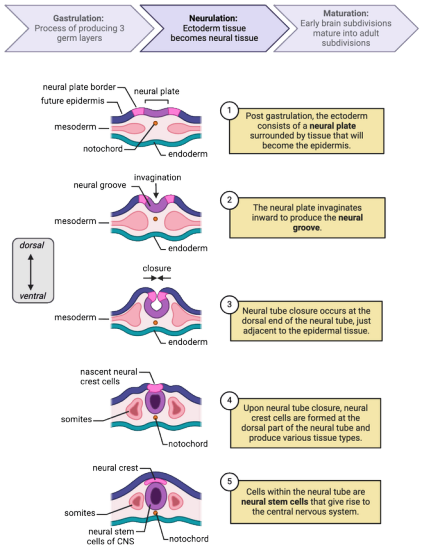

Figure 5.5 Neurulation

Environment and Bidirectional communication: Neural tube defects and folic acid

Neurulation is a critical step in early brain development and if this process does not occur properly a class of disorders called neural tube defects arise. The most common neural tube defects are the result of abnormal neural tube closure, which can be affected by environmental and genetic influences. These defects fall into different classes based on type and severity. In the severest forms such as anencephaly, the neural tube does not close at the anterior end and causes missing regions of the skull and brain. Other examples include encephalocele, when the brain protrudes through the skull, and hydrocephalus, which is characterized by an accumulation of cerebrospinal fluid in the brain. Spina bifida is one of the most well-known examples of a neural tube defect and occurs when the posterior end of the neural tube does not close fully. Spina bifida can range in severity, causing either a complete opening along the vertebrae of the back or a minor separation in the bones of the vertebrae (Figure 5.6).

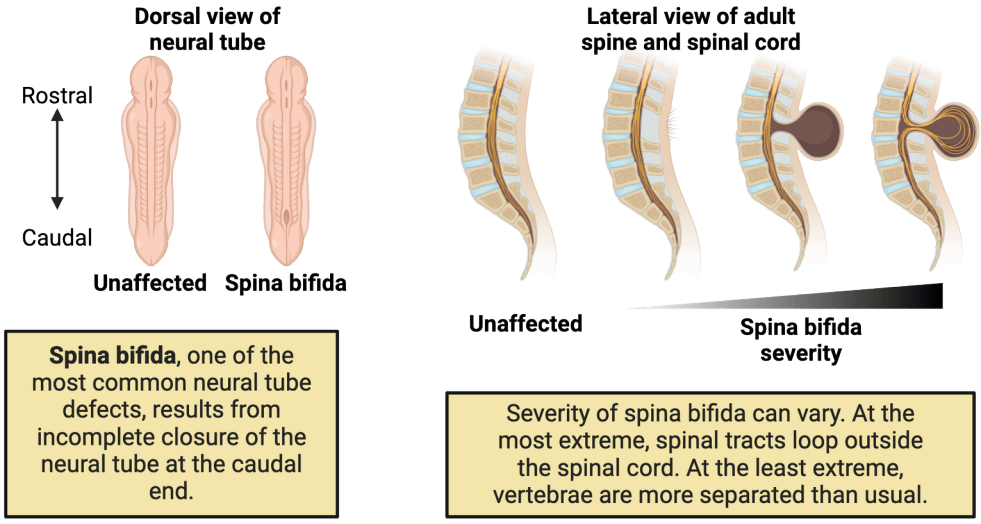

Figure 5.6 Defects of neurulation

Interestingly, the different types of neural tube defects observed occur at the extreme ends of the neural tube (not in the middle) as a result of how the neural tube closes. The neural tube begins closure in the middle and slowly closes on either end. Spina bifida is localized to the posterior regions of the neural tube, while anencephaly, encephalocele, and hydrocephalus occur in the anterior regions of the neural tube.

It is predicted that approximately 70% of neural tube defects occur due to genetic factors. There have been over 240 genes associated with neural tube defects (Harris and Juriloff, 2010), which strongly supports the link between genetic predisposition and neural tube abnormalities. However, genetics do not solely determine the presence of neural tube defects, as a huge proportion of neural tube defects can be prevented with the nutritional supplementation of folic acid in the mother's diet. Folic acid is a water-soluble B-vitamin and deficiencies in folic acid have been associated with an increased risk of neural tube defects (Wallingford et al., 2013). Many foods including orange juice and some cereal grains are fortified with folic acid. The addition of folic acid to specific food products of general consumption has had an immediate impact on the prevalence of neural tube defects. Despite the efficacy of folic acid supplementation, it is still unclear how folic acid directly prevents neural tube defects.

Neuroscience in the Lab

Identifying Neural Inducers

In 1924, Hans Spemann and Hilde Mangold performed transplantation assays using newts, which are salamanders. They demonstrated that creation of a neural tube is controlled by a regional organizing center, or a small cluster of cells that direct the surrounding cells to form neural ectoderm and subsequently, the CNS (Spemann and Mangold, 2001). The design of this renowned study is diagrammed in Figure 5.7. In Step 1, they removed the dorsal blastopore lip (the organizing center) from a pigmented newt. The blastopore lip is normally located on the dorsal side of the embryo and in this case, because it is from a pigmented newt, it should generate pigmented cells. In Step 2, they transplanted the pigmented blastopore lip on the ventral region of a non-pigmented host newt. During normal development, the ventral side of the embryo is usually restricted to epidermal tissue while the dorsal region produces nervous tissue.

Upon transplantation of the pigmented dorsal blastopore lip, a complete secondary body axis was produced on the ventral side of the non-pigmented embryo. Interestingly, the secondary body axis was primarily produced from the non-pigmented host. As shown in Step 3, the ventral body included a complete secondary body axis with brain and spinal cord, as well as non-neural structures. The major conclusion from this experiment was that the host's (non-pigmented) ventral ectoderm, which usually would only form epidermal tissue, was induced to form neural tissue. These data suggest that the dorsal blastopore lip forms an organizer, which is termed the Spemann-Mangold organizer and emphasizes the presence of a neural inducer.

1.9.3: Growth and Development of the Early Brain

Learning Objectives

By the end of this section, you should be able to

- 5.2.1 Define major structural regions of the early brain.
- 5.2.2 Describe the creation and maintenance of neural stem cells.
- 5.2.3 Describe differentiation of neurons and glia.
- 5.2.4 Describe radial migration of the cortex.
- 5.2.5 Describe tangential migration.

The early maturation of the CNS entails subdividing sections through a process called segmentation. During this time, the brain undergoes massive cellular expansion producing neural stem cells that will ultimately give rise to neurons and glia (not microglia). Here, we will describe the segmented regions of the early brain and the mechanisms that regulate neural stem cell function and differentiation alongside a discussion of the types of migration that organize neurons to their final destination.

Segmentation of the early brain

The enclosed neural tube contains almost all the components needed to produce the brain and spinal cord. The tube itself will now morph into a region-specific structure that includes the forebrain, midbrain, hindbrain, and spinal cord (Figure 5.8). (See Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy.)

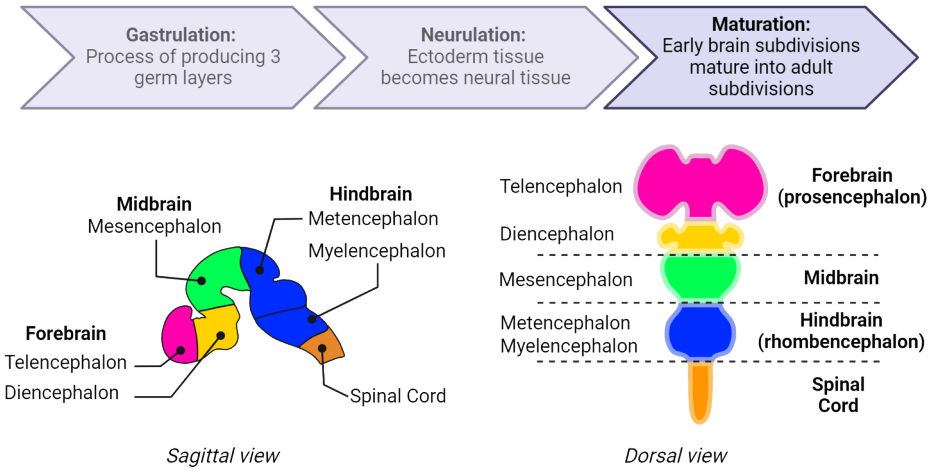

Figure 5.8 Early segmentation of the brain

This process is called segmentation (Hirth et al., 1995; Millet et al., 1996; Nomura et al., 1998; Krumlauf and Wilkinson, 2021) and includes the process of bending and folding regions of the neural tube. The anterior region of the neural tube will bend forward with the anterior most region forming the prosencephalon (forebrain) and the mesencephalon (midbrain), which is adjacent to the cephalic flexure. A flexure is a term used to describe a bend or fold. The cephalic flexure is distinguished as a curvature located at the junction between the brainstem and spinal cord. It is a critical anatomical adaptation that helps support the body to walk on two legs, opposed to four like cats or dogs. The body is able to do this by balancing the weight of our heads on top of the spinal cord, while keeping our eyes forward to gather spatial awareness as we walk on two feet.

The cephalic flexure is anterior to the rhombencephalon (hindbrain), which is located in between the cephalic flexure and the cervical flexure, the bend that will divide the hindbrain and spinal cord (Figure 5.8). The prosencephalon is further subdivided

into the telencephalon and the diencephalon. The rhombencephalon is divided into the metencephalon and myelencephalon. The telencephalon will produce the cerebral cortex, while the diencephalon will generate the thalamus, and hypothalamus. The midbrain and hindbrain will produce parts of the brainstem, pons, and cerebellum, collectively (see Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy). Posterior to the hindbrain region, the neural tube becomes the tissue of the spinal cord. These divisions are all specified early in development, even though their full functional maturation will take months (and sometimes years).

Environment and Bidirectional communication: Genetic diseases of development with environmental influence

Disorders that lead to structural damage or malformations which impair lifelong function are the most common forms of congenital brain disorders. While there are a variety of environmental teratogens that can alter brain development, a significant number of congenital brain malformations are associated with a genetic mutation. For many of these disorders, a gene of interest has been assigned or associated with the disease, but how a specific mutation disrupts overall brain development is still a puzzle. These mysteries persist most likely because, in many cases, genes interact with environmental influences to determine their final effect on the brain. For example, holoprosencephaly is a congenital brain disorder characterized by abnormal separation of the forebrain (Weiss et al., 2018). This occurs prenatally and mutations in various genes have been shown to cause holoprosencephaly (Geng and Oliver, 2009). However, the degree of illness is often variable amongst individuals (Figure 5.9). Severe forms of the disease exhibit cyclopia (a single eye) and the brain does not divide into two hemispheres whereas some individuals diagnosed with holoprosencephaly can present with semilobar holoprosencephaly, in which the brain has a small separation between each hemisphere (Figure 5.9). It is generally accepted that environmental exposures in combination with genetic mutations ultimately dictate the presence and severity of holoprosencephaly. For example, some environmental teratogens such as ethanol are known to exacerbate the phenotypes of holoprosencephaly (Hong and Krauss, 2012). Additional environmental interactions include maternal diabetes and prenatal exposure to specific pharmaceutical drugs (Cohen and Shiota, 2002).

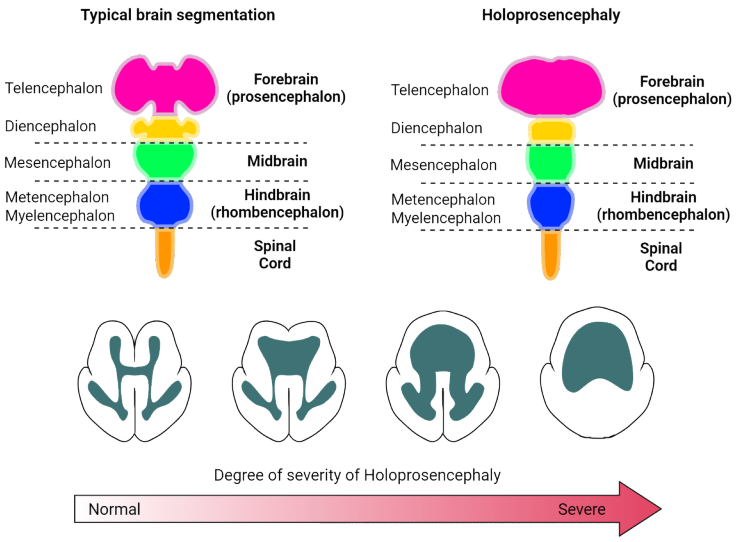

Figure 5.9 Holoprosencephaly

Proliferation and differentiation: how are neurons and glia formed?

This section will cover the generation of neurons and glia in development.

Neural stem cells and proliferation

As the neural tube forms, we see the emergence of a special class of cells that will proliferate (divide) to create numerous daughter cells that go on to become neurons and glia of the CNS, except for microglia which are formed in the peripheral yolk sac. These cells are committed to become nervous system cells and are referred to as neural epithelial cells or neural stem cells. In the very early stages of neural tube formation (Step 1 in Figure 5.10), these cells divide rapidly to create identical daughter cells, thereby

expanding the neural tissue and growing the neural tube. Some of these daughter cells go on to become a type of cell called a radial glial cell (RGC).

RGCs are a class of neural stem cells located in a proliferative region called the ventricular zone, the thin layer of tissue surrounding the fluid-filled central cavity of the neural tube (i.e., the future ventricular system). RGCs have a unique, bipolar shape, shown in Figure 5.10, where they extend one process medially, to contact the ventricular space, and another laterally, to contract the edge of the developing neural tube (known as the pial surface). Within the ventricular zone, RGCs divide (proliferate). The goal of this expansion is to create enough RGCs to produce the neurons and glia required for a fully formed brain.

RGCs are unique in that they have the ability to self-renew, which means they produce more of themselves through symmetric cell divisions where one cell produces two independent identical cells. RGCs also have the ability to divide asymmetrically, which means they can produce one cell that is identical to themselves, but at the same time produce a different, more committed cell that we call an intermediate progenitor (IP) (Step 2). IPs migrate along the radial processes of the RGCs into the subventricular zone (Step 3 and detailed location on the y-axis) where they will undergo symmetric cell divisions to produce neurons (Step 4 and 5). We call this process of creating new neurons neurogenesis. Later, RGCs will switch towards the development of daughter cells that go on to become astrocytes and oligodendrocytes, processes referred to as gliogenesis (Step 6). Gliogenesis occurs well after neurogenesis and closer to birth, with production of astrocytes occurring first followed by production of oligodendrocytes.

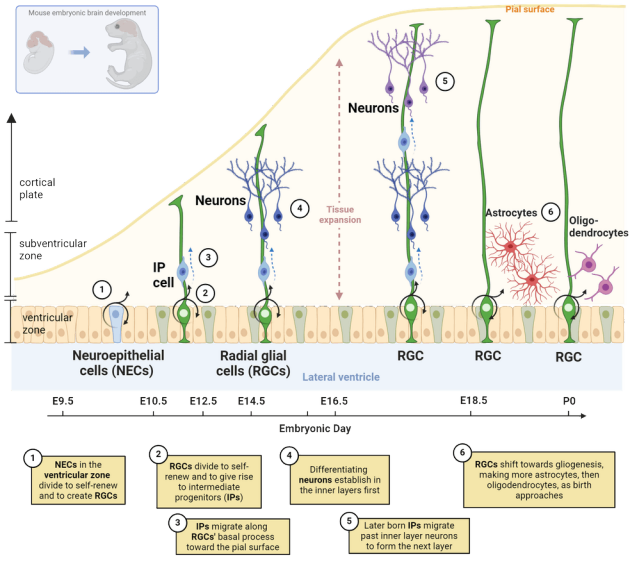

Figure 5.10 Embryonic corgical neurogenesis

As neurogenesis and gliogenesis progress, the brain, of course, grows. For humans and several other highly intelligent mammals, our brain growth presents an exceptional challenge. In short, we need to fit a lot of brain, particularly a lot of cortex, into a small space, otherwise our heads would be too big for our necks to support. All mammalian species have a cortex, but it differs in size and texture (see Chapter 4 Comparative Neuroscience). In smaller mammals such as mice, the cortex is smooth and smaller relative to skull size. However, in higher mammals, the cortex is much larger. It has a surface area the size of a pillowcase, approximately 40 by 62.5 centimeters. This size difference can be attributed to increased proliferation and production of neurons. To accommodate the increase in cell number, the human brain produces cortical folding, which is the formation of gyri and sulci. In rare instances, the human brain lacks the formation of gyri and sulci, this condition causes lissencephaly, or smooth brains. Lissencephaly is associated with intellectual disability.

As the human brain grows during development, we see it go from a relatively smooth structure to one with many sulci and gyri. Figure 5.11 shows how during development the large cortical lobes curl over on top of the lower brain regions, expanding to cover and surround mesencephalic regions. This curling over during development helps explain why many of our subcortical structures (hippocampus, thalamus, basal ganglia, and lateral ventricles) have a curved shape. To get an idea of how brain folding occurs during brain development, take out four sheets of paper. First take one sheet and crumple it tightly. The paper will slightly expand then settle into a crumpled state. Now get the remaining three sheets of paper and crumple all three together. Notice how thicker paper leads to fewer folds. The crumpled pieces will be much larger and harder to fold. Now apply that logic to the growing brain. Thicker cortices fold less and end up with less cortical material hiding below the surface.

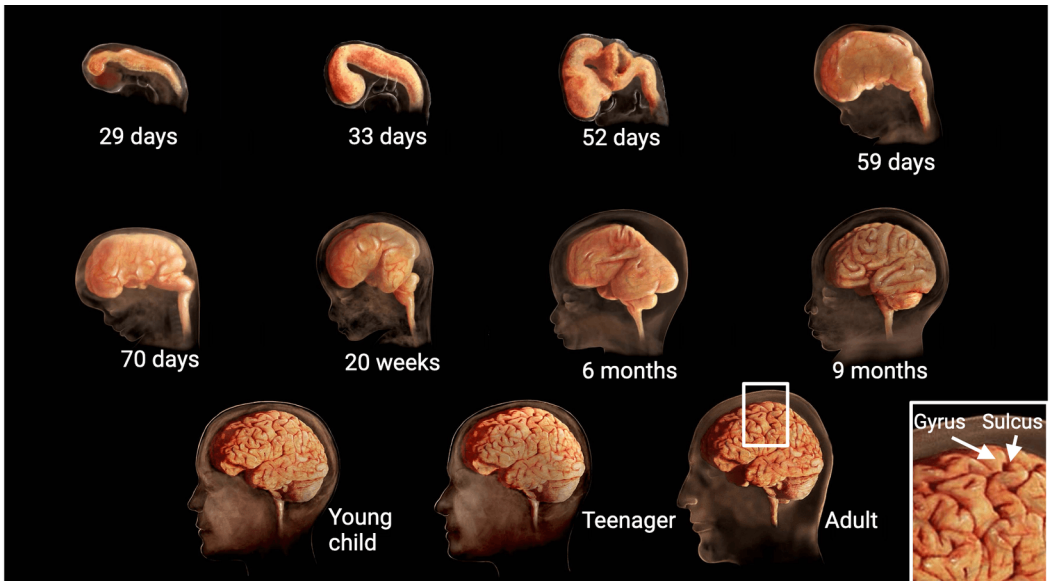

Figure 5.11 Brain growth and folding As the human brain grows, it develops sulci and gyri and curves around within the expanding skull. These adaptations help humans fit a large surface area in a small space. Image credit: Brain images by ScienceSourceImages.

Zika virus infection of neural stem cells

Zika virus is an arbovirus that is transmitted through the bite of the mosquito, Aedes aegypti. The most recent outbreak of Zika virus was in 2016. While the disease is relatively mild or asymptomatic in most individuals, it has been associated with microcephaly or smaller head size in newborns exposed to viral infection during prenatal development (Mlakar et al., 2016). The probability of a fetus to be born with microcephaly after Zika infection of the mother is between 1-13% (Antoniou et al., 2020). Such an association prompted scientists to study the effects of Zika viral infection on neural stem cell function, survival, and differentiation. In 2016, at the height of the Zika virus outbreak, Garcez and colleagues used organoid culture to study the effects of Zika virus on neural stem cell function. Organoids are stem cells that are grown in a culture dish but take on the 3-dimensional structure of an organ (see Chapter 4 Comparative Neuroscience). Using this system, it was demonstrated that infection of neural stem cells with Zika virus causes increased cell death and reduced the growth of the organoid (Garcez et al., 2016). These studies confirmed that Zika virus directly infects neural stem cells and hinders their development. They also demonstrate how proper neural stem cell function is critical for building a healthy, functional brain.

Differentiation of neurons and glia

As mentioned previously, asymmetric cell divisions produce neurons first, and later in development they produce glial cells. Thus, the same neural stem cell has the capacity to produce neurons and glia, two vastly different cell types (Figure 5.12).

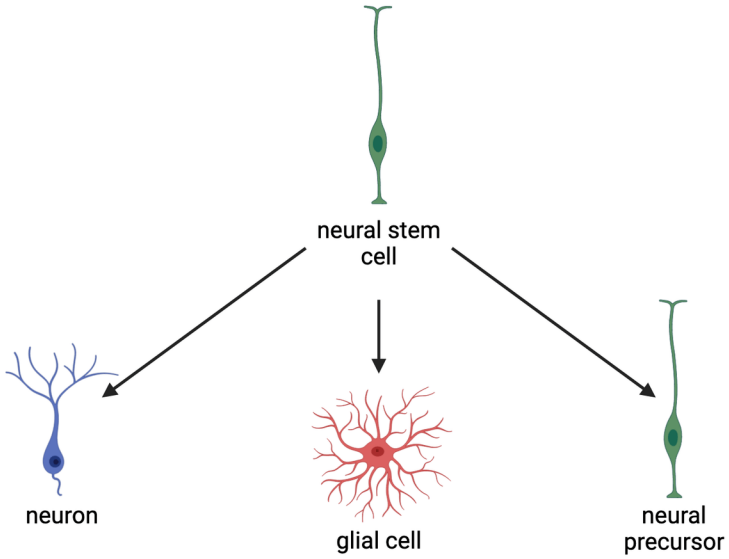

Figure 5.12 Neural stem cells are the multi-potent progenitor of the central nervous system and give rise to all the neurons, and glia (astrocytes, oligodendrocytes) of the adult brain.

This capacity to make more than 1 cell type is referred to as multipotency. The process by which the daughter cells mature in their final functional form (neuronal or glial) is called differentiation. Differentiation of neurons and glia are separated by time. Their formation is regulated by the promotion or repression of gene expression. For example, the expression of proneural genes promotes the differentiation of daughter cells into neurons. During this time, the expression of proglial genes are inhibited. Thus, proneural genes have the capacity to suppress gliogenic signals (Bertrand and Guillemot, 2002). Later, proneural genes are repressed and proglial genes turn on, allowing daughter cells to mature into glia.

But what causes these genes to turn on and off? Expression of proneural or proglial genes, and therefore differentiation, is highly influenced by neighboring cells in the environment. Cells usually interact and communicate by secreting soluble signals that bind receptors expressed on the cell surface, or by cell contact, which allows cell-surface proteins on each cell to bind each other directly. Either kind of interaction (soluble, cell contact) can initiate intracellular signaling that drives changes in expression of the neural/glial driving genes. As the brain matures, these environmental signals change, different genes are turned on and off, and the balance between neuro- and glio-genesis therefore shifts.

Neuronal Migration Patterns

Neurogenesis occurs whilst the neural tube is expanding into multiple layers. A key step in neurogenesis is for these new cells to migrate to the right spot, where they can eventually become part of functional circuits. The neural tube contains a mixture of neural stem cells and IPs. Dividing IPs are produced in a sub-region called the subventricular zone, from an asymmetrically dividing population of RGCs. IPs will eventually produce neurons that travel along the two outstretched processes of the RGC. Newly born neurons migrate along the glial projections of RGCs towards the pial surface (Step 3 in Figure 5.10). As development proceeds, subsequent waves of neurons will migrate past the existing newly differentiated neurons. This process results in the neural tube becoming partitioned into different layers as it expands. In the mammalian cortex, the remnants of this process can be seen in the distinct cell layers that contain different subtypes of neurons (Rakic, 1974). Not all neurons migrate along RGCs. Inhibitory GABAergic interneurons migrate tangentially from zones called ganglionic eminences. There are 3 ganglionic eminences from which many different neurons arise and undergo tangential migration. Figure 5.13 diagrams tangential versus radial migration, showing how the two differ.

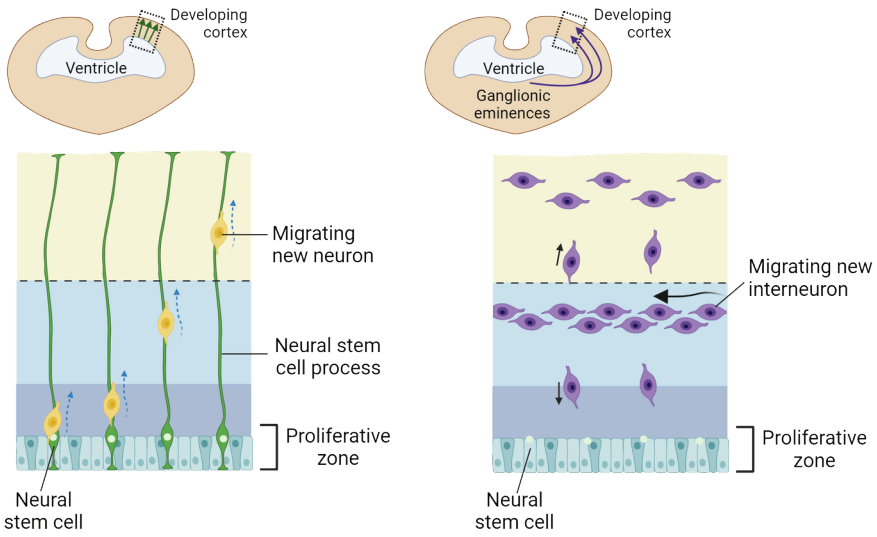

Figure 5.13 Radial versus tangengial migration

Developing layers of the cerebral cortex

The mammalian adult cortex is composed of 6 layers with a unique composition of cell types. The image on the left side of Figure 5.14 is a drawing by Ramon y Cajal, showing how these layers look in a cross-section of an adult brain where neurons have been stained a dark color. Over the course of time, scientists have asked, how are the layers of the cortex formed? Which layers (1-6) are formed first? In other words, can experiments be designed to determine which neurons from each layer are born first? The right side of Figure 5.14 shows one classic experiment that was used this way.

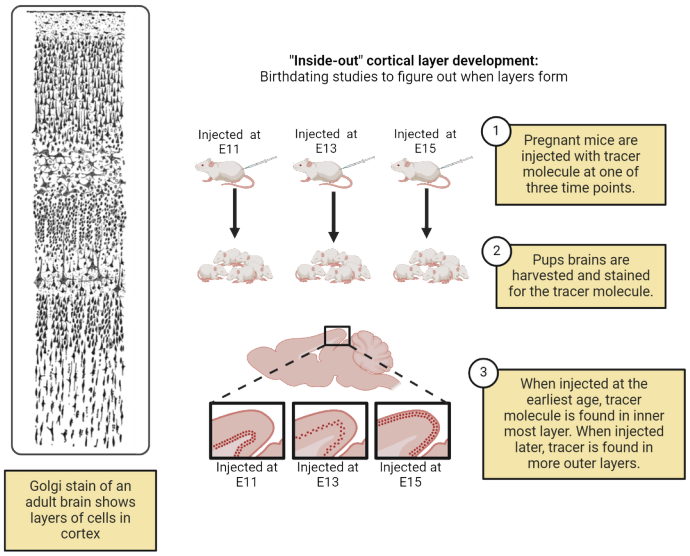

Figure 5.14 Cortical layer formation Image credit: Santiago Ramón y Cajal, "Comparative study of the sensory areas of the human cortex"; published 1899, ISBN 9781458821898, Public Domain, https://commons.wikimedia.org/w/inde...?curid=8513016

To determine which neurons are born first and in what location, a tracer molecule was injected into pregnant female mice at different embryonic stages of pregnancy (E11, E13, or E15) (step 1 of Figure 5.14). The tracer molecule labeled the neurons produced (via cell division) right around the time of its injection in developing pups. The pups were then euthanized after birth and researchers looked in their brains to see where the marker-labeled neurons could be found (step 2 of Figure 5.14). The early injection of the tracer molecule at E11 was associated with tracer-labeled neurons in the innermost layer of the cortex (Layer 6) while injection at E13 and E15 were associated with tracer-labeled neurons in the middle layers and more superficial layers, respectively (step 3 of Figure 5.14). Hence, the earliest born neurons are present in the innermost layers and later born neurons

are in the superficial layers, producing an inside-out development of the cortex.

The neural crest

So far, we have discussed how the CNS develops. But what about the neurons and glia of the peripheral nervous system? During early development, upon neural tube closure, a transient population of cells called neural crest cells (NCCs) is produced at the dorsal end of the neural tube. NCCs are a multi-potent population of cells that give rise to various tissue derivatives including neurons of the peripheral nervous system (PNS), melanocytes, chondrocytes of the cranial region, and ganglia of the autonomic nervous system. There are 5 main subsets of NCCs. These include cranial, trunk, vagal, sacral, and cardiac NCC. The top of Figure 5.15 illustrates the migratory pathways these cells take during early development in humans and mice. Some of the fates of the cranial NCCs are diagrammed in the bottom of Figure 5.15; they include cartilage, bone, cranial neurons, and connective tissue of the face, among others. Other subsets of NCCs produce melanocytes (trunk and cardiac) and dorsal root ganglia (trunk), enteric ganglia (vagal and sacral), and large artery connective tissue (cardiac).

1.9.4: Synapse Formation and Maturation

Learning Objectives

By the end of this section, you should be able to

- 5.3.1 Explain neurite outgrowth and the structural components of a growth cone.
- 5.3.2 Describe polyneuronal innervation and experience related innervation modifications.

The creation of neurons and glia is only the first step in creating a functional brain. For neurons to function in meaningful ways, they have to connect to each other. Making (and keeping) these connections requires several steps. Here, we will discuss the formation of the growing axon (neurite) and major influences guiding final contact and synapse formation. We will end by describing polyneuronal innervation, our first window of opportunity to observe the potential for synaptic plasticity.

Communication by electrical impulse

The anatomist Santiago Ramón y Cajal was the first to describe fibers radiating from individual neurons (Cajal, 1995). He postulated that neurons were separate entities and used long fibers and connections to communicate. How the brain communicates through synapses was previously discussed in Chapter 2 Neurophysiology. Here we will provide a short review of this process because it is integral to the formation of synaptic connections early in development. Neurons communicate with each other via the synapse which can be seen in Figure 5.16.

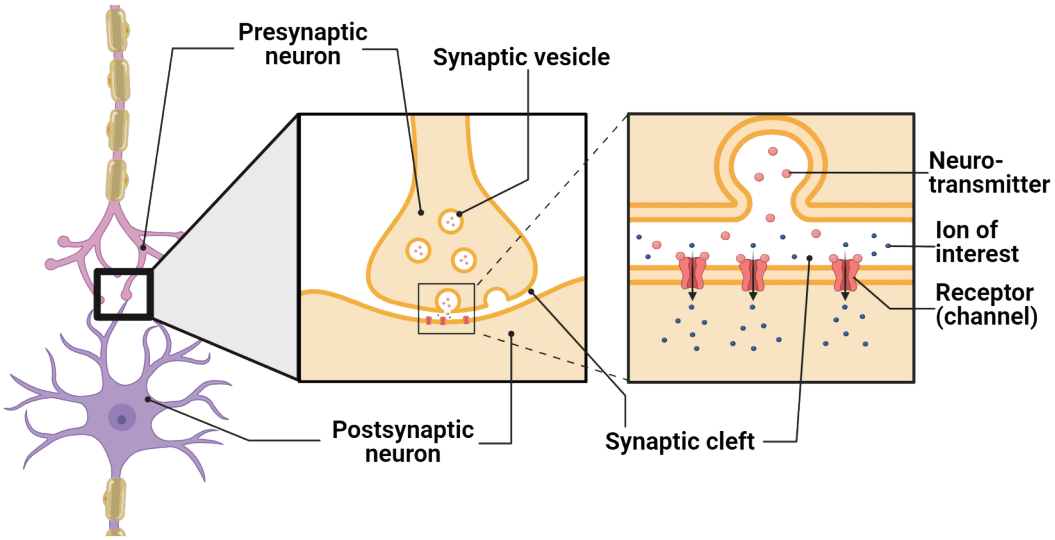

Figure 5.16 Reminder of synaptic transmission

The presynaptic neuron (sending the signal) is in close proximity with the postsynaptic neuron (receiving the signal) and can use signaling molecules and neurotransmitters to either increase or decrease the probability that the postsynaptic neuron fires an action potential. This communication occurs at the synaptic cleft (Figure 5.16). Complex mechanisms are required to ensure that the correct presynaptic neuron pairs with the appropriate postsynaptic neuron/tissue during development. Neurons extend and grow their axon using multiple cues and once they encounter their partner, they will test their match using temporary junctions, cell signaling and adhesion molecules, combined with electrical activity. Such signals, if positive, will then promote formation of a mature synapse.

During development, neurons extend a specialized structure from the tip of a growing axon or dendrite. This structure was first described by Ramon y Cajal and was coined the growth cone (Figure 5.17). Growth cones are dynamic, in that they sense and respond to the environment in search of a target tissue to innervate (connect to via a synapse). Growth cones change shape

by extending outward a leading edge (Figure 5.17), which interacts with the environment. The leading edge of the growth cone appears as a hand with fingertips. The outstretched fingertips are called filopodia (plural). Each filopodium (singular) samples the environment for attractive and repulsive signals that help to determine the direction of growth. In between each filopodium is a flat structure called the lamellipodium (Figure 5.17). Growth cones express various molecules on their surface that interact with the environment. Therefore, two unique growth cones may respond differently to the same environment.

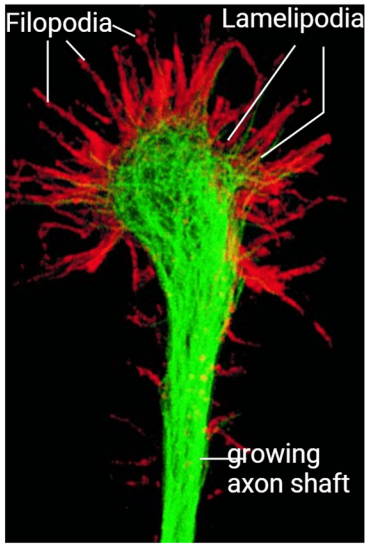

Figure 5.17 Growth cones Image credit: Microscopy image Public Domain, https://commons.wikimedia.org/w/inde...?curid=1321398. Labels added.

The growth cone is dynamic, and when it meets attractive cues, a structural protein inside the budding growth cone called actin facilitates changes in the direction of the growth cone. Actin subunits can come together in a process called polymerization to move the growth cone. Actin filaments are primarily located in the filopodia.If a repulsive signal is detected, in contrast, actin subunits detach from each other, which is commonly referred to as depolymerization. Actin subunits are essential for growth cone movements, but the axon itself is not made of actin. It is produced from a more rigid protein called tubulin. Tubulin subunits come together at the opposite end of the leading edge of the growth cone to elongate the axon.

Types of receptors expressed on the growth cone

There are several different classes of molecules expressed on the surface of a growth cone. Figure 5.18 shows three of these major classes.

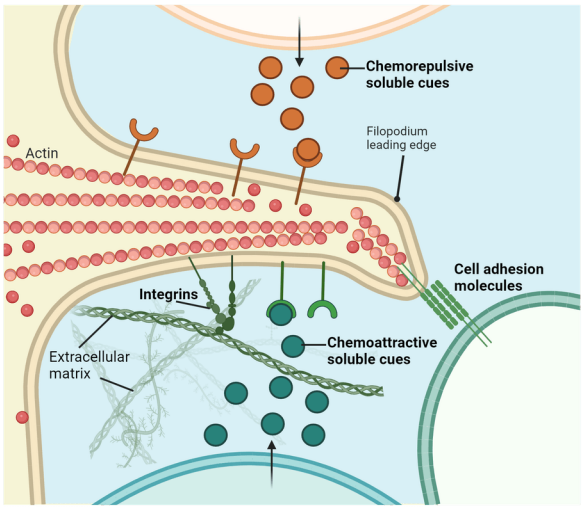

Figure 5.18 Signals guiding the growth cone

Cell adhesion molecules (CAMs) such as neural cell adhesion molecule (NCAM) bind to other CAMs on neighboring cells. These molecules can bind to each other in a process called homophilic binding (bind to the same receptor on another cell) or can bind to other CAMs through heterophilic binding (binding to a different receptor on another cell). CAMs are unique from calcium dependent cell adhesion molecules (cadherins) because cadherins require calcium for an interaction and bind via homophilic binding. Cadherins are similar to CAMs because they are receptors present on adjacent cells which interact. Both CAMs and cadherins are unique from a third class of membrane bound receptors called integrins. Integrins bind and interact with components of the extracellular matrix. These components include laminin, fibronectin, and collagen.

Additional cues can be received through ephrins, semaphorins, and netrin. Ephrins bind to Eph receptors while semaphorins bind to plexin or neuropilin receptors. Netrins are secreted factors that bind to the Unc-5/DCC receptor. Semaphorins are mostly inhibitory but under some circumstances can present attractive signals to the growing axon. There are two classes of ephrins, A and B, class A ephrins are anchored into the membrane and class B are transmembrane receptors that have an intracellular and extracellular domain. In vertebrates, netrin binds to the receptor DCC, which is expressed on the growth cone. The interaction between DCC and netrin is an attractive signal for the growth cone. Interestingly, netrin can also bind to the UNC5 receptor and when it does, it provides a repulsive cue. Thus, netrin can provide both attractive and repulsive cues.

Mechanisms of axon guidance at the midline: lessons from invertebrates

Much knowledge has been gained by studying axon guidance in the spinal cord of invertebrates. One particular piece of development that has revealed many insights into how axons find their way through the developing nervous system is how developing spinal axons in the neural tube decide whether to cross the midline in flies (Drosophila, specifically). Interneurons of the spinal cord are produced at the dorsal side of the neural tube. The growing axons of these cells are observed to first extend ventrally, toward the floor plate on the most ventral side of the developing spinal cord (Figure 5.19). Once at the floor plate, the axons must make a choice: some must stay on that side of the midline (ipsilateral) while others must cross the midline to the opposite side. Axons that cross the midline form a commissure and we refer to them as the commissural neurons. Both types of axons are needed for proper circuit formation and the balance between them is critical to later function.

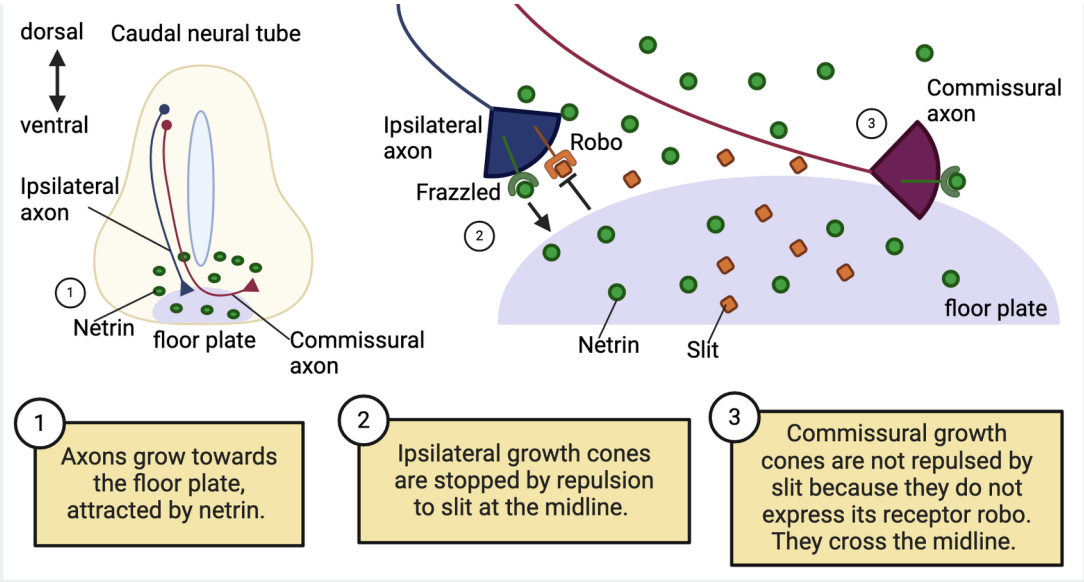

Figure 5.19 Growth cone signaling in the developing fly neural tube

Studies in Drosophila, the fruit fly, have helped us understand the signals that guide these movements of the spinal interneuron axons. First, researchers found that growth cones grow towards the floor plate through interactions between netrin and frazzled receptors. Frazzled receptors are the fruit fly equivalent to vertebrate DCC. The expression of frazzled attracts axons to the midline. However, this interaction alone does not fully describe the decision of an axon to cross the midline.

In Drosophila, the floor plate in the midline also secretes another protein, called slit. Slit provides a repulsive signal. Slit binds to the receptor robo, which is expressed on the growth cone. When slit binds to robo, axons that arrive at the floor plate due to their attraction to netrin are repelled from the midline and will not cross the midline. Mutations in slit or robo lead to an abnormal number of crossings. But if slit-robo interactions repel the growth cone, how do any axons cross-the midline? Robo expression at the growth cone must be suppressed in order for an axon to cross the midline. In the fruit fly, a protein called comm regulates the expression of robo at the surface of the growth cone. Comm suppresses robo just long enough for axons to cross the midline. A very analogous process occurs in higher vertebrates except that the Robo-like receptor Rig1, when expressed in the proper form, will allow crossing of the midline.

Synaptogenesis

Ultimately, the growth cone is directed by those attractive and repulsive signals to a putative target cell to form a mature synapse. The mature synapse has basic structural components that facilitate neuronal activity. The mature synapse contains vesicles of neurotransmitters, ionic channels (calcium channels), components to release neurotransmitters, a synaptic cleft, and a postsynaptic density (PSD) (Figure 5.16). These are all features that develop as a result of the pre- and postsynaptic cells interacting to help each other mature. When the presynaptic cell first meets the postsynaptic target, the synapse has immature characteristics, exemplified in Figure 5.20.

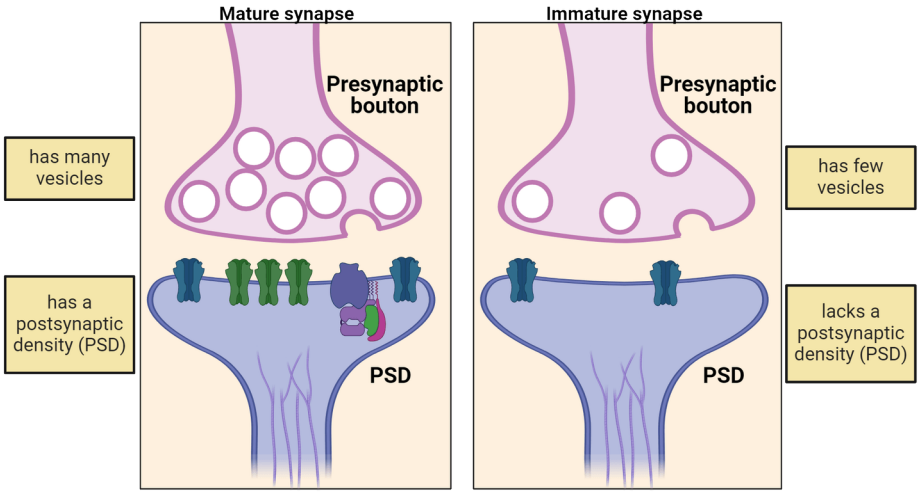

Figure 5.20 Immature v. mature synapses

There are two major classes of synapses: electrical and chemical (see Chapter 2 Neurophysiology). Chemical synapses communicate through the release of neurotransmitters, which are located in vesicles within the presynaptic neuron. The early immature chemical synapse lacks a PSD and has only very few vesicles in the presynaptic neuron. This immature chemical synapse has the ability to signal via neurotransmitter release, though it is not as robust as a mature synapse will eventually be (Figure 5.20). Rudimentary neurotransmitter release is required for chemical synapse maturation. Electrical synapses are fewer in number relative to chemical synapses and function through gap junctions that allow the electrical current to move from one cell to the next. Recent studies have shown that the components of an electrical synapse (i.e. gap junctions) are required for the development of chemical synapses (Todd et al., 2010). Thus, there is evidence that neurons first form transient electrical synapses before chemical synapses develop.

Developing a synapse entails 3 main steps. The growing axon must 1) detect a postsynaptic target and defasciculate, 2) form temporary contact with the target cells, and 3) undergo matching between the neurotransmitters of the presynaptic cell with the receptors on the target postsynaptic cell. During axon outgrowth, like-minded axons, those with similar growth trajectories, form bundles called fascicles (Stoeckli and Landmesser, 1995). Therefore, when an axon recognizes a potential postsynaptic match, the axon must undergo defasciculation. Defasciculation is when the axon breaks away from the bundle of axons to encounter its target cell. After detachment, the axon will undergo a matchmaking process that relies on cell adhesion. Cell adhesion is a process of connecting to neighboring cells in the environment using cell surface receptors. Cell contacts between the pre and postsynaptic neuron hold the two cells together long enough to initiate synaptogenesis. Subsequent signaling between the two cells ensures that the presynaptic cell synthesizes, packages, and releases an appropriate neurotransmitter that the postsynaptic cell can respond to via expression of appropriate receptors in its PSD.

Neuronal survival and cell death

The developing brain undergoes significant expansion of neural stem cells, which are required for the development of neurons and glia. Interestingly, the developing brain initially produces too many neurons, meaning that the number of cells produced is more than what is needed for adult function. How does the brain compensate for this overproduction of neurons? As it turns out, the developing brain undergoes a process called programmed cell death, or apoptosis. Through apoptosis, excess neurons die, and the developing brain is refined.

Neuronal survival is regulated by multiple mechanisms, one of which is the size of the target tissue which a neuron will innervate. In 1909, Marian Lydia Shorey first demonstrated that there was a correlation between target tissue size and the number of surviving neurons (Shorey, 1909). Removal of the budding limb from chick embryos led to a decrease in the total number of neurons innervating the tissue whereas adding an extra limb tissue increased the total number of neurons. Subsequent experiments by Viktor Hamburger (1934) later revealed that neurons underwent cell death after the target tissue was removed (Hamburger, 1934). Figure 5.21 shows an example of this kind of experiment and the resulting loss of motor neurons in the lumbar spine of developing chicks.

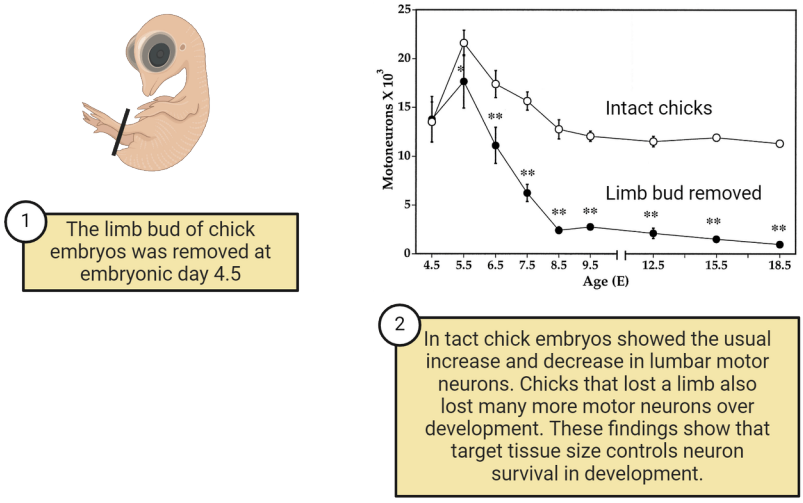

Figure 5.21 Tissue size and neuronal survival in development Data from: Peripheral Target Regulation of the Development and Survival of Spinal Sensory and Motor Neurons in the Chick Embryo. Jordi Calderó, David Prevette, Xun Mei, Robert A. Oakley, Ling Li, Carol Milligan, Lucien Houenou, Michael Burek, Ronald W. Oppenheim. Journal of Neuroscience 1 January 1998, 18 (1) 356-370; DOI: 10.1523/JNEUROSCI.18-01-00356.1998 (c) Journal of Neuroscience

These studies show that neuronal survival is not a random process and is influenced by the ability of tissues to form connections. How might the embryo decide which neurons die and which should survive? Neuronal survival is mediated by a class of molecules called neurotrophins that bind to a family of cell surface receptors called Trk receptors. Neurons that have inadequate signaling between neurotrophins and Trk receptors ultimately undergo apoptosis. Neurons have to compete with each other for access to these neurotrophins (Figure 5.22). Tissues producing less neurotrophins will support the survival of fewer neurons. This competition will also favor the survival of neurons that start to make better connections with sources of neurotrophin. In the chick limb bud removal experiments, the loss of the limb bud tissue removed a major source of neurotrophins, causing motor neurons headed towards that tissue to die off while others that found more neurotrophin-abundant targets in other tissues survived. This selection is one of the reasons we refer to this step as part of nervous system refinement. It is not random which neurons die and which survive, but rather driven by the connections the neurons are starting to form.

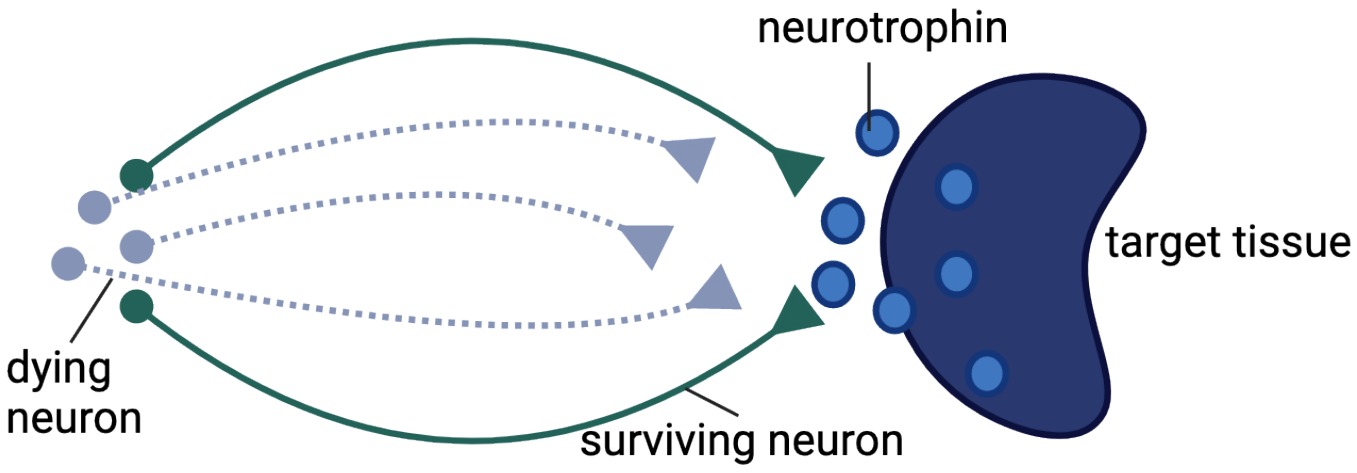

Figure 5.22 Neurotrophin and cell survival Neurons that make the strongest connections get best access to neurotrophins and survive. Others with poorer connections die.

People behind the science: Discovery of nerve growth factor (NGF)

In the 1940s, studies from the laboratory of Viktor Hamburger began exploring the use of tumor transplants in the chick embryo as a means of identifying and characterizing the factors that promote neuronal survival. As part of these studies, Rita Levi-Montalcini (Figure 5.23), a research associate in the Hamburger lab, transplanted tumor cells on one side of the body wall of the chick embryo. When comparing the transplanted side with the non-transplanted side of the embryo, Dr. Levi-Montalcini found that the presence of the tumor increased the number of nerve fibers innervating the tumor and the size of the adjacent dorsal root ganglia. Dorsal root ganglia are clusters of cell bodies found at the base of a spinal nerve. Thus, the tumor secreted a factor that promoted survival of the nerve fibers. Subsequent experiments ultimately used ganglion explants that were cultured at a distance from the tumor. She used various types of tumors and tissue to find that sarcoma tumors could promote neurite outgrowth.

Figure 5.23 Rita Levi Montalchini "Image credit: Photo by Diario de Madrid - Diario de Madrid - La científica y premio Nobel Rita Levi, vista por su sobrina nieta, CC BY 4.0, https://commons.wikimedia.org/w/inde...curid=99838777

The experiments performed ultimately paved the way for the discovery of nerve growth factor, a protein that we now know binds to TrkA receptor. Dr. Levi-Montalcini was awarded the Nobel Prize in 1986 alongside her colleague Stanley Cohen. Her story is particularly inspiring because in 1938 laws against those of Jewish descent prevented her from working in university laboratories. She spent her early career conducting experiments in her bedroom, which she later published, providing her the opportunity to work in the laboratory of Dr. Hamburger. She worked in the Hamburger lab for many years before establishing her own laboratory.

Synapse refinement

Early prenatal brain development combines coordinated control of various signals to produce an elaborate foundational unit capable of precise control of the human body. However, it is important to note that this unit represents only a foundation and is subject to refinement. We discussed refinement above in terms of which neurons survive. Synapse refinement is also a prominent feature of the developing nervous system. Synapse refinement is the process by which the early synapses are modified or eliminated because of specific signaling events.

The neuromuscular junction (NMJ) is a well-defined example of synapse refinement after birth (Bishop et al., 2004). We have learned a great deal about the capacity for refinement by studying the NMJ. The NMJ represents the synapse between the axon of a motor neuron and a muscle fiber (Chapter 10 Motor Control). Muscle fibers are regulated by a single motor neuron in adults, but it has been established that in newborn rats, muscle fibers are innervated by a minimum of 2 different motor neurons. This type of innervation is called polyneuronal innervation. After birth, motor neuron innervations are reduced, but not because of neuronal cell death. Rather, the branches are eliminated or refined to target only a single muscle fiber (Figure 5.24) (Brown et al., 1976).

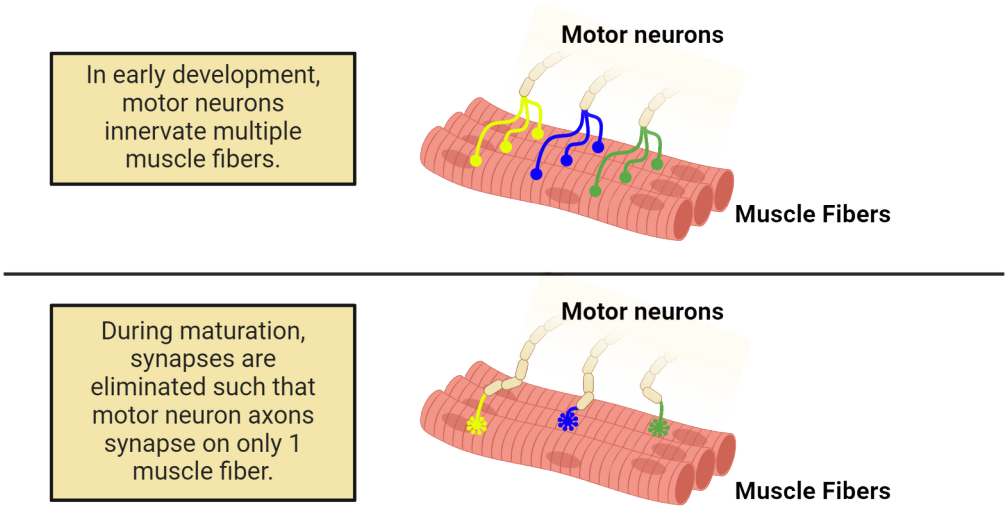

Figure 5.24 Muscle innervation development

The process of transitioning from polyneuronal innervation to mono-neuronal innervation is dependent on electrical activity and competition between two innervating neurons. It is critical for the precise recruitment of the motor unit during force and contraction generation (Lee, 2020). Should it be dysfunctional, more than one neuron would control the activity of a muscle cell. This phenomenon is not limited to the NMJ and has been demonstrated in the CNS. For example, Purkinje cells of the cerebellum that are innervated by climbing fiber inputs of the inferior olive are poly-innervated at birth, but by 2 weeks of age, the synapses are refined to a single innervation per Purkinje cell (Mariani and Changeux, 1981).

Synapse refinement in the CNS

We have discussed synapse refinement at the NMJ as a model for how synaptic connections are reorganized postnatally. Similar processes are occurring in the CNS, but what drives this process in the CNS? It turns out that, similar to how neurons must compete for neurotrophin survival cues, competition is also critical to synapse survival.In short, synapses that get used more get strengthened and those that are not used are lost. The most effective synapses are those that have a strong association between presynaptic neurotransmitter release and postsynaptic firing. Presynaptic neurons that fire in unison are especially effective at competing as a team to maintain strong connections that cause the postsynaptic neuron to fire. Figure 5.25 shows a representation of this principle. Early in development, a postsynaptic neuron may receive multiple inputs (# 1), some of which fire together (# 2) and others of which do not (# 3). The correlated inputs are much more likely to cause the postsynaptic cell to fire, because they are working together. As development proceeds, those correlated connections get stronger (# 5) and uncorrelated ones get weaker.

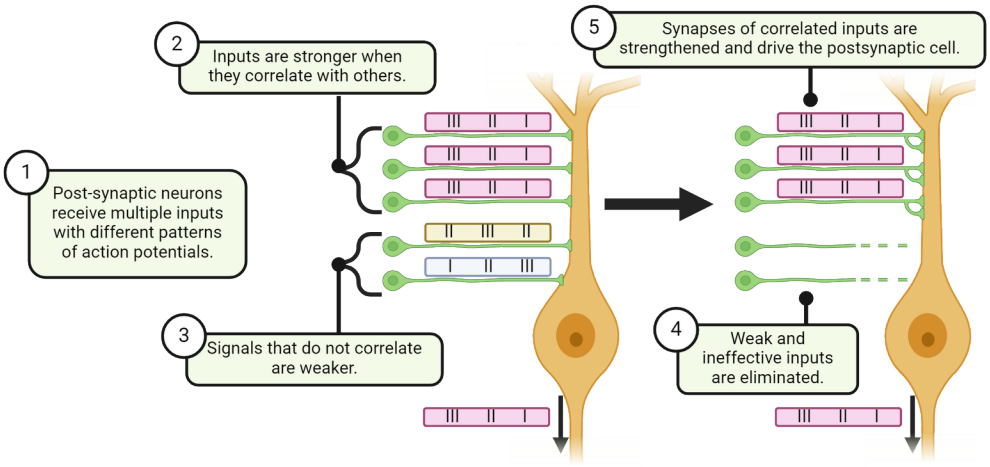

Figure 5.25 Synaptic correlation

What happens to those "weaker" synapses? Rival synapses that cannot fire synchronously with a neuron or a target cell and receive little input eventually lose synaptic connection and are eliminated through pruning (# 4 in Figure 5.25). Why do we need to eliminate synapses? Consider it like how tree roots compete for water in the rainforest. To survive and strengthen, the roots that branch out towards areas which fortify the livelihood of the tree will grow stronger, and those that fail in this sense weaken and die. Synapse numbers tend to peak during childhood in humans, with pruning then extending from late childhood through adolescence (Figure 5.26).

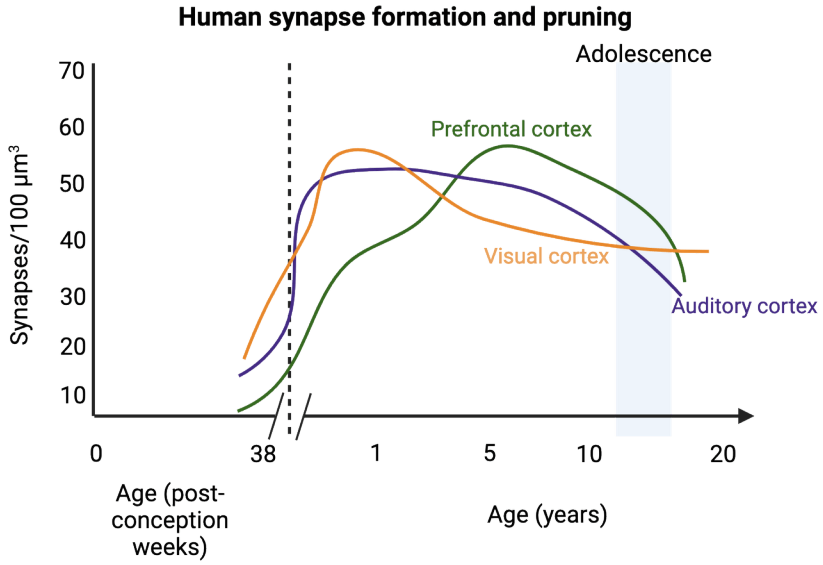

Figure 5.26 Synapse formation and pruning Synapses are over-produced and then pruned. Less active synapses are pruned while active synapses are preserved.

Pruning requires a balance; too little or too much can reduce the efficiency of brain function. Aberrant pruning can result in cognitive disorders due to faulty wiring in early life stages (Johnston, 2004; Sakai, 2020). For example, patients diagnosed with schizophrenia, a debilitating psychiatric illness with a myriad of hallucinogenic symptoms, show fewer synapses (over pruning) in brain scans relative to healthy individuals (see Chapter 19 Attention and Executive Function). The loss of synaptic connections is pronounced in the prefrontal cortex, a region where pruning peaks during adolescence, an active period of synapse elimination, coinciding with the onset of the disorder. In contrast, disorders such as autism have shown an excess in connections, suggesting failure to eliminate synapses. Findings like these suggest that CNS disorders can result from excessive or insufficient pruning during childhood and adolescence.

Myelination and plasticity

Myelin is a sheath that surrounds axons to promote the rate of electrical signaling. It is made of proteins and lipids and deposition of myelin on axons begins 1-2 months before birth. This makes myelination one of the later steps in nervous system development (Figure 5.27).

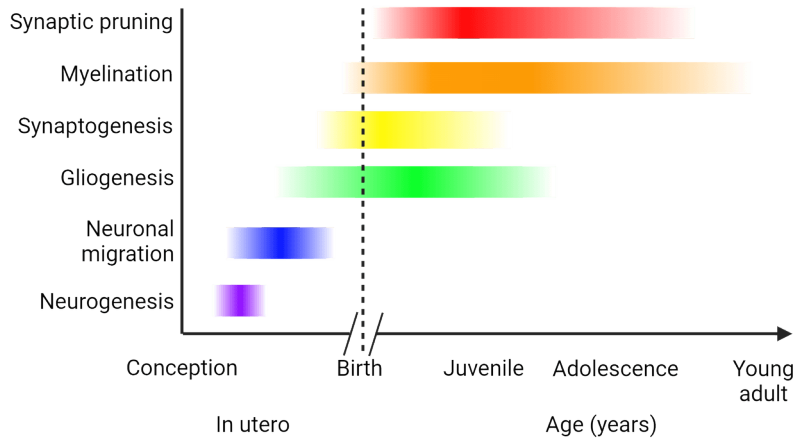

Figure 5.27 Primate neurodevelopment

Myelin is produced by oligodendrocytes in the CNS and Schwann cells in the peripheral nervous system (see Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy). Both of these are glial cells produced during gliogenesis. Myelination does not occur all at once, but rather in a progression. Generally, axons in the peripheral nervous system are myelinated first, followed by spinal cord axons and finally axons in the brain. Figure 5.28 shows MRI images of the brain during the first year of life, showing rapid accumulation of myelin (pseudocolored red) in the brain. This first year is when the peak of myelination occurs in humans. A parallel in the first month of life in rodents can also be seen in the bottom panel of Figure 5.28, where myelin has been stained dark in brains from rats aged postnatal day 7 to 35.

Figure 5.28 Myelination in the developing brain Images from: Erik van Tilborg , Caroline G M de Theije, Maurik van Hal, Nienke Wagenaar, Linda S de Vries, Manon J Benders, David H Rowitch, Cora H Nijboer. 2018. Origin and dynamics of oligodendrocytes in the developing brain: Implications for perinatal white matter injury. Glia, 66(2): 221-238, doi: 10.1002/glia.23256. CC BY 4.0

Though the first year is when most myelination happens in humans, myelination continues in the forebrain well into childhood

and adolescence and accounts for some degree of plasticity during these time periods. Interestingly, extensive piano playing is associated with increased myelination (Fields, 2005). In adolescence, increased risk-taking behavior can be the result of incomplete development of the forebrain, which includes reduced white matter (myelination) development (Beckman, 2004). But how does the environment affect myelin deposition? For the CNS, the answer probably lies in how sensitive developing oligodendrocytes are to environmental stimuli. Oligodendrocytes are glial cells of the CNS that produce and deposit myelin. For example, when rats were raised in an enriching environment, with toys and other rats to play with, the number of oligodendrocytes in their cortex actually increased (Szeligo and Leblond, 1977). Consistent with the increase in the number of oligodendrocytes, an enriching environment is also associated with an increase in the number of myelinated axons (Juraska, 1988). These studies were performed in rats, but there is also evidence for white matter developmental plasticity in humans. For example, neglect during childhood has been shown to decrease white matter by 17% in the corpus callosum (Teicher et al., 2004). We will discuss more about experience-dependent plasticity in neurodevelopment, but these examples help to highlight how development is not a simple series of steps but a constant interplay between developing systems and their environment.

1.9.5: Experience Dependent Plasticity

Learning Objectives

By the end of this section, you should be able to

- 5.4.1 Describe and provide examples of experience-dependent plasticity during development.
- 5.4.2 Describe effects of environmental toxins and early experience during critical periods.

Early embryonic development provides the foundational unit of a brain with immature connections, but sensory cues can dramatically alter how brain maturation occurs. These sensory cues play a significant role in how neurons differentiate, how dendrites sprout, how neurons form and maintain synaptic connections, and how the brain produces final neural networks. At the early stages of development, our brain has a high degree of neural plasticity. Neural plasticity is the ability to adapt and reorganize in response to environmental stimuli. In fact, during certain periods of development called critical periods, environmental stimuli can lead to long-term positive or negative effects.

The brain's plasticity for refinement during critical periods can be either beneficial or detrimental. As an example of a beneficial experience, in rodent studies, enriched environments improve function of several brain regions when compared to animals homed in standard cages. These “enriched” living spaces provide settings that encourage exploration, cognitive engagement, social interaction, and physical activity in animals, enhancing plasticity. Rats raised in enriched environments show enhanced plasticity in several brain regions, even including sensory areas like the visual cortex, which shows an increase in connections and stronger circuits. Detrimental effects of negative environmental experiences are also, of course, possible. Monkeys and cats raised in restricted visual conditions, such as suturing an eye shut at a critical period of visual cortex growth or rearing in conditions without light, suffer permanent impairments in their visual abilities (Tian and Copenhagen, 2001; Vistamehr and Tian, 2004; Levelt and Hübener, 2012; Berry and Nedivi, 2016). These impairments include overcompensation in the plasticity to the eye receiving stimuli. Unfortunately, as we reach adulthood, the brain’s ability to reshape and grow new connections declines. At the same time, other factors can hasten the decline of cognitive plasticity, including environmental factors, hormones, and neurodegenerative diseases (Voss et al., 2017).

Embryonic and fetal period

Figure 5.29 defines critical periods in prenatal development. These periods are timepoints in prenatal development when specific organ systems of the embryo or fetus are particularly susceptible to environmental stimuli, meaning that negative stimuli can result in structural or functional brain malformations that impair function lifelong. CNS development begins embryonically at 3 weeks post-fertilization. The embryonic period lasts until 10 weeks, and encompasses neurulation, a critical period we have previously discussed as it relates to neural tube formation and closure. CNS development continues from 10 weeks to 38 weeks, which is defined as the period of the fetus.

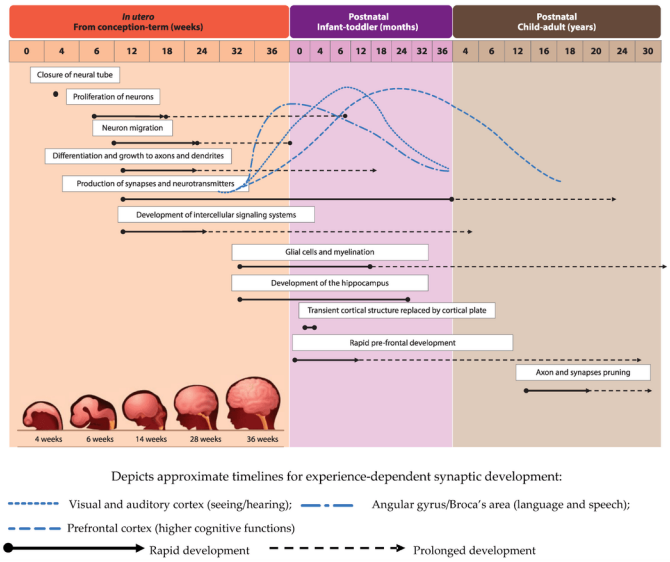

Figure 5.29 Developmental sensitivity to defects Image credit: Image credit: Cohen Kadosh, K.; Muhardi, L.; Parikh, P.; Basso, M.; Jan Mohamed, H.J.; Prawitasari, T.; Samuel, F.; Ma, G.; Geurts, J.M.W. Nutritional Support of Neurodevelopment and Cognitive Function in Infants and Young Children—An Update and Novel Insights. Nutrients 2021, 13, 199. https://doi.org/10.3390/nu13010199. CC BY 4.0

The pioneering work of Charles Stockard and Hans Spemann has shown that there are stages that are particularly sensitive to environmental exposure and/or manipulation (Stockard, 1921; De Robertis, 2009). Stockard is known for his work with fish embryos, in which he found that introducing chemical agents at a specific stage would create what he called "monsters". Figure 5.30 shows a drawing by Stockard of one of these fish after exposure to a teratogen during the critical embryonic period. This damage was permanent, and when replicated at other stages of development, there was essentially no similar defect seen, suggesting that there are specific prenatal stages that are very sensitive to teratogens. The reason for this susceptibility is that the fetus is experiencing rapid growth in size, weight, and muscle at early stages. Below we detail two common environmental exposures during fetal development that result in abnormal nervous system development, causing lifelong impairment in function.

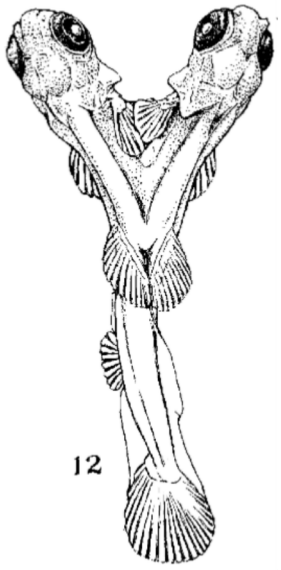

Figure 5.30 Stockard's drawings This drawing by Stockard represents one of the phenotypes he observed following exposure to teratogens during critical periods in development. Exposure to the same teratogen outside of the critical period had little effect. Image credit: Drawing from: Stockard, C.R. (1921), Developmental rate and structural expression: An experimental study of twins, 'double monsters' and single deformities, and the interaction among embryonic organs during their origin and development. Am. J. Anat., 28: 115-277. doi.org/10.1002/aja.1000280202. Public Domain.

Fetal alcohol syndrome

Exposure to alcohol during the fetal period can result in fetal alcohol syndrome (FAD) and fetal alcohol spectrum disorders (FASD). Alcohol is a teratogen, and its effects can lead to growth retardation, abnormal brain development, intellectual disability, and craniofacial abnormalities, which include a narrow forehead, flat midface, narrow eyelid openings, shortened nose, a long upper lip, and an absent philtrum (Figure 5.31; Sulik et al., 1981).

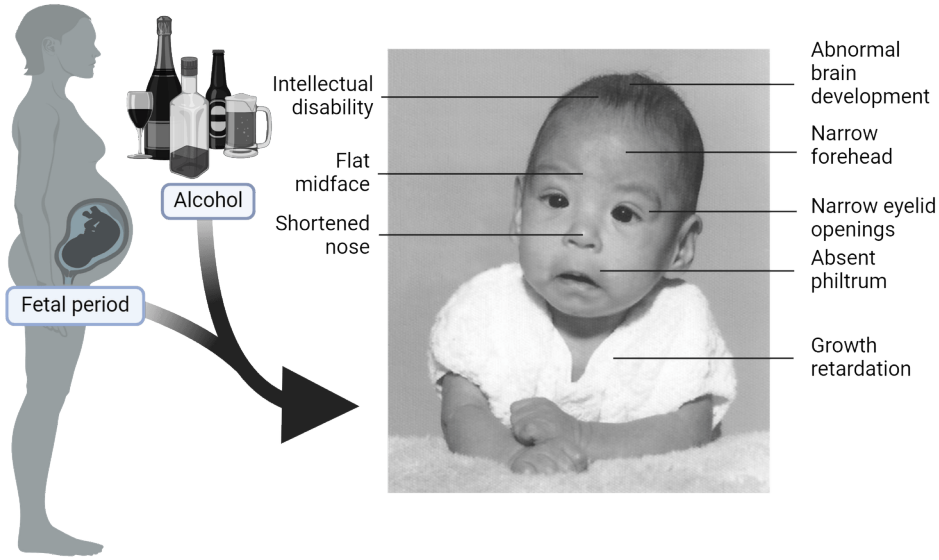

Figure 5.31 Fetal alcohol syndrome Image credit: Teresa Kellerman - http://www.come-over.to/FAS/fasbabyface.jpg, CC BY-SA 3.0, https://commons.wikimedia.org/w/inde...curid=11896203

FASD is the most common non-genetic form of intellectual disability, with broad symptoms, including poor cognition and behavioral phenotypes (Denny et al., 2017). The effects of FAD on growth and development can be observed in Figure 5.31. While the term "fetal" in FAD/FASD implies the effects of alcohol are focused only on the fetal period, alcohol can also have a negative impact earlier in pregnancy. When mice had a brief exposure to alcohol during embryonic development, they presented with severe facial malformations (Sulik et al., 1981). This period of embryonic development in mice is equivalent to approximately the third week of human gestation, a time point when many women aren't aware of their pregnancy (Sulik et al., 1981). This is why it is recommended that individuals planning to become pregnant refrain from alcohol consumption.

Retinoic acid as a teratogen

Retinoic acid (RA) is a steroid hormone produced from vitamin A. Upon production, RA has several developmental responsibilities and can bind to RA receptors that together bind to DNA and change the genes that are expressed inside of a cell. Controlled levels of RA are essential for development, but excess intake of vitamin A or RA by pregnant women can lead to birth defects. These birth defects include microcephaly, spina bifida, hydrocephalus, and exencephaly. Importantly, drugs that contain forms of RA are frequently used to treat dermatological conditions including acne. Exposure to these drugs during pregnancy can predispose the fetus to CNS defects, as well as craniofacial abnormalities and shortened limbs (Berenguer et al., 2021).

2: Perinatal period

The perinatal period encompasses the time frame from childbirth up to 24 months. During this time, the CNS possesses tremendous plasticity, defined as the ability to remodel or reorganize based on experience. Such plasticity is very robust from birth to 3 years and gives rise to developmental critical periods. While the early brain maintains a high degree of plasticity, it is important to note that plasticity is maintained into adulthood, although it does decrease as we age. As discussed previously, significant synapse refinement occurs in the form of loss of poly-innervation and pruning during this period of development. Below, we will discuss several examples of how long-term brain function can be shaped by experiences during this perinatal period.

Perinatal brain development and parental care

One of the most tragic consequences of the perinatal critical period for CNS development is the long-term and severe impact that neglect or abuse during this time can have. Figure 5.32 highlights some of the major brain regions where disrupted growth is evident years after childhood abuse/neglect. They include regions important for emotion (amygdala), memory (hippocampus), and executive function (prefrontal cortex). These kinds of extreme examples show how experience in early life can disrupt the structure of the brain long-term.

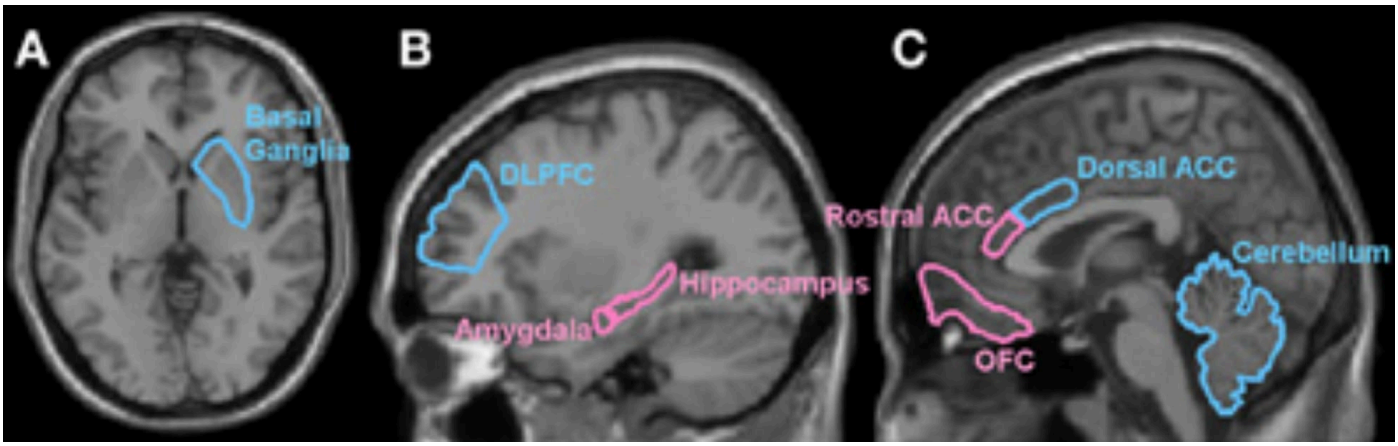

Figure 5.32 Brain symptoms of neglect Brain MRI highlighting the brain regions where functional and structural changes are prominent as a result of mistreatment. The pink areas are regions that mediate emotion and motivation. Blue areas support higher order functions such as working memory and attention. Image credit: Hart H and Rubia K (2012) Neuroimaging of child abuse: a critical review. Front. Hum. Neurosci. 6:52. doi: 10.3389/fnhum.2012.00052. CC BY 4.0

Neuroscience in the lab: Uncovering mechanisms of parental care effects on brain development

The importance of perinatal care experiences on brain development cannot be underemphasized. But how do these nurturing events (or their absence) in infancy and childhood affect our adult behavior? Studies in rats have provided some insight into how early life care can affect adult behaviors by shaping the stress response. Maternal rats provide nurturing to their offspring through licking and grooming. Rat moms are not all equal and some provide more licking and grooming than others, even in the controlled conditions of the lab. Meaney and Szyf (2022) took advantage of this natural variation to study the consequences of maternal behavior on the long-term development of their pups. Remarkably, they found that adult rats that received more grooming attention as pups responded better to stressful events later in life (Liu et al., 1997) (see Chapter 12 Stress). Specifically, they secreted less stress hormones in response to a stressor created by the researchers. The key to their reduced hormonal response was a long-lasting increase in stress hormone receptors. A high number of these receptors inhibits the excessive production of stress hormones leading to reduced hormonal stress response. This example shows one mechanism by which perinatal experience can lead to life-long changes that impact brain function, in this case the response to stress.

Perinatal critical period for language development

Language development is particularly sensitive to input during the perinatal and juvenile time period. An infamous story of neglect, given the pseudonym “Genie”, has helped further understand the importance of language development during critical periods (Salus and Curtiss, 1979; Rymer, 1993). The unfortunate events this child endured were extreme deprivation of sensory experience. Genie was confined to a small room, isolated, and tied to a potty seat, every day up to 13 years of age. The child was severely deprived from receiving any sensory stimuli, to the point where her father prohibited that anyone talk to Genie, instead only barking or growling at her was allowed. For many years after she was found, Genie received help among many therapists to aid in her development. Through extensive therapy, she was able to learn basic words and word combinations, but she still lacked the ability to speak in full sentences or understand the concept of assigning different words to the same meaning.

Genie’s story is anecdotal evidence as to the importance of critical periods during language development and is somewhat complicated by the severity of her deficits in other aspects of cognitive function. More definitive evidence indicating the importance of a critical period for language development has been established through the study of the birdsong. Oscine

songbirds use the birdsong to attract their mates. In order to develop the appropriate song, juvenile birds must be exposed to their song by an adult male, memorize the song, and then recapitulate it. While birdsong is not the same as human language, it has some similarities as a form of vocal learning. If a bird is not exposed to the correct song within the first 2 months of hatching or exposed to a different song during this critical period, the bird will not develop the appropriate song and can fail to attract a mate (Doupe and Kuhl, 1999).

Oscine birds and humans share the need for environmental exposure for proper language development. Children develop proper syntax within the first year of life (Friedmann and Rusou, 2015) and it is well-established that learning a language happens spontaneously among children, but not in adults. Adults mostly must explicitly study a new language to learn it and even then, grammar, syntax and pronunciation are typically not as proficient as those who learned before adolescence. This early childhood critical period for language acquisition likely relies on the higher synaptic plasticity in language centers of the brain during this phase of development, when synapses are being established and refined.

Perinatal critical period in visual development

Perinatal sensory experience is required for the development of the visual system at several levels. One prominent example of this is development of ocular dominance in the primary visual cortex (called V1 for short). At birth, the layers of the primary visual cortex are innervated by axons from both eyes. However, by adulthood through visual stimulation, the innervations are remodeled and segregated between layers to produce ocular dominance columns (Stryker and Harris, 1986; Levelt and Hübener, 2012; Berry and Nedivi, 2016). Within an ocular dominance column, the cells respond preferentially to light being shown in one eye over the other. This process of refinement to create preference for input from one eye requires visual input, as was first demonstrated by studies in cats.

David Hubel and Torsten Wiesel performed the first key studies to establish critical periods of vision development (Wiesel and Hubel, 1963; Hubel and Wiesel, 1970; Levelt and Hübener, 2012; Berry and Nedivi, 2016). To study how exposure to light influences formation of cortical cell preference for responding to input from one eye or the other, Hubel and Wiesel used the simple model of suturing shut a single eye of feline subjects at different times. They measured ocular preference of cortical cells by recording from individual cells in the cat visual cortex while shining a light on one eye or the other. Figure 5.33 describes their findings.

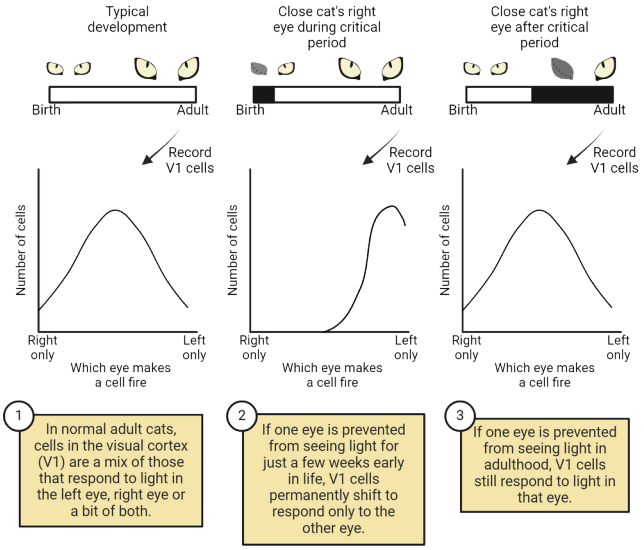

Figure 5.33 Ocular dominance critical period Image credit: Dominance curves based on data in Wang J, Ni Z, Jin A, Yu T and Yu H (2019) Ocular Dominance Plasticity of Areas 17 and 21a in the Cat. Front. Neurosci. 13:1039. doi: 10.3389/fnins.2019.01039. CC BY 4.0.

In an adult cat that never had an eye sutured shut (i.e., a normal cat), they found a mixture of visual cortical cells that responded preferentially to the right eye, left eye, or a bit of both. However, if a cat experienced just 3 to 4 days of visual deprivation when they were a kitten (perinatally), almost all their visual cortical cells responded only to light from the unsutured eye (Hubel and Wiesel, 1970). The formerly sutured eye was effectively blind because it did not stimulate any cortical cells. Importantly, if the eye was sutured shut during adulthood, there was no effect (Figure 5.33), effectively confirming a critical period for vision development. The first few weeks of life are a critical period for this part of visual development because this is when inputs to the visual cortex are forming synapses on V1 cortical cells. Cortical cells end up only connected to inputs deriving from the open eye

because of a lack of competition from the axons in the sutured eye. Opening the eye later can't fix that as the critical period for synapse formation has passed.

The significance of visual stimulation and critical periods has been further substantiated by a famous case study in Oliver Sacks' renowned publication (1985). There he described a human patient by the surname Fergal, who was born blind and received surgery to regain vision after 50 years without it. Despite the success of regaining vision, Fergal lacked the early experiences necessary for synaptic reorganization and proper vision development (Sacks, 1985). This resulted in an influx of stimuli, as his other senses were heightened. As Sacks (1985) describes, "There were no visual memories to support a perception; there was no world of experience and meaning awaiting him. He saw, but what he saw had no coherence. His retina and optic nerve were active, transmitting impulses, but his brain could make no sense of them." A second example of sensory critical periods and intervention includes the usage of cochlear implants (see Chapter 7 Hearing and Balance). The efficacy of cochlear implants is widely affected by the age of the patient. For example, the efficacy associated with cochlear implants in children at a young age, with shorter periods of auditory deprivation, is much higher than those with prolonged auditory deprivation (Pisoni et al. 1999).

Plasticity during adolescence

Adolescence refers to the stage of development in between childhood and adulthood. Thus far, we have discussed robust examples of plasticity during infancy and early development. However, the adolescent brain exhibits tremendous neural development, which makes it highly plastic and susceptible to environmental influence. Adolescence is particularly characterized by refinement in connectivity between major brain regions. For example, the connections between the frontal lobe and the amygdala are subject to extensive experience dependent refinement during adolescence. The prefrontal cortex (PFC) is responsible for higher order function and decision making called executive function and the amygdala regulates fear, aggression, and emotion. Adolescent decision making is also influenced by the immaturity of the reward centers in the brain, which include the nucleus accumbens (Spear, 2000), which contains dopaminergic input. The relative immaturity of these 3 brain regions during adolescence leads to more impulsive, reward based, and risk like behaviors relative to adults (Ernst, 2014). It also underlies their enhanced vulnerability/plasticity during adolescence. Studies have shown that chronic stress and psychological distress can have brain region specific impacts during adolescence.For example, abnormal development of the PFC can affect working memory, cognitive flexibility, and self-control.

Adolescence is also a unique critical period for the effects of substance misuse on specific regions of the brain. For instance, substance misuse that occurs during early adolescence, around ages 14-16, is associated with reduction in the volume of frontal cortex gray matter, whereas misuse in childhood selectively impacts the hippocampal gray matter volume (Larsen & Luna, 2018). Such differences can be explained by the different time points in development where growth is more prevalent for each of these two brain regions.

5.2 Growth and Development of the Early Brain

Brain segmentation is controlled at the level of gene expression and can be subject to disease through both abnormal gene expression and environmental exposures. The cells of the brain are produced from neural stem cells that occupy the neural tube and differentiate into neurons and glia. Some of these cells, such as glutamatergic cortical neurons, produce a layered structure using an inside-out pattern. These mechanisms produce a fundamental unit that will have tremendous plasticity to sense and respond to the environment during both subsequent prenatal and postnatal development.

5.3 Synapse Formation and Maturation

A differentiating neuron undergoes significant changes which produce a growth cone that migrates through a milieu of signaling to find a target tissue. Upon selection, additional cues are provided to promote the formation of a mature synapse. Specific signaling events regulate maturation of the synapse as well as neuronal survival prior to birth, but after birth the nervous system continues to undergo refinement of synapses. In the subsequent sections, we will focus more on critical periods and provide examples of disorders that arise as a consequence of changes in our environment.

5.4 Experience Dependent Plasticity

Critical periods for brain development, with long-term consequences for behavioral function, are found throughout development, from the embryonic stages of neural tube formation up to the final circuit refinement stages of adolescence. This plasticity is at its root adaptive–it allows our brains to develop in response to our specific environment, making the brain highly adaptable. However, it also creates points of vulnerability. The early embryo can be derailed by teratogens and environmental stimuli, which can cause significant structural abnormalities. Later changes in environmental stimuli, such a neglect or stress, can also have long-lasting effects on the developing brain and its function.

1.9.7: Key Terms

5.1 Gastrulation and Formation of the Neural Tube (Neurulation)

Congenital, teratogens, gastrulation, germ layers, cleavage, blastocyst, blastocoel, inner cell mass, trophoblast, primitive streak, node, blastopore lip, neurulation, neural tube, neural plate, neural induction/inducers, noggin, neural groove, neural folds, ventricles, anencephaly, encephalocele, hydrocephalus, vertebrae, transplantation assays, Spemann-Mangold organizer

5.2 Growth and Development of the Early Brain

neural stem cells, segmentation, flexure, self-renew, neurogenesis, gliogenesis, gyri, sulci, lissencephaly, multipotency, differentiation, proneural, proglial, gliogenic, ganglionic eminences, neural crest cells

5.3 Synapse Formation and Maturation

Synapse, presynaptic neuron, postsynaptic neuron, neurotransmitters, actin, polymerization, depolymerization, cell adhesion molecules, calcium dependent cell adhesion molecules, integrins, fascicles, ephrins, semaphorins, netrin, ipsilateral, commissural, fascicles, defasciculation, apoptosis, neurotrophins, Trk receptors, refinement, dorsal root ganglia, neuromuscular junction, motor neuron, muscle fiber, polyneuronal innervation, pruning, myelination

5.4 Experience Dependent Plasticity

Neural plasticity, critical periods, fetal alcohol syndrome, microcephaly, exencephaly, ocular dominance columns, executive function

1.9.9: Multiple Choice

5.1 Gastrulation and Formation of the Neural Tube (Neurulation)

1.
What is the primary goal of gastrulation in embryonic development?

a. Formation of the neural tube
b. Formation of the three germ layers
c. Differentiation of neurons
d. Formation of the limbs

2 .
Which germ layer gives rise to the neural plate, initiating the process of neurulation?

a. Endoderm
b. Ectoderm
c. Mesoderm
d. Epidermis

3.
Neurulation is the process responsible for the formation of the:

a. Brain, spinal cord, and neural tube
b. Muscles and bones
c. Circulatory system
d. Respiratory system

4 .
During neural development, what is the role of neural ectoderm?

a. Forming muscles and bones
b. Initiating gastrulation
c. Providing oxygen to developing tissues
d. Differentiating into neurons and glial cells

5.
Neural stem cells have the potential to develop into which two primary cell types in the nervous system?

a. Neurons and blood cells
b. Neurons and glial cells
c. Muscle cells and neurons
d. Skin cells and neurons

6 .
What critical event occurs during neurulation?

a. The development of the eyes and ears
b. The formation of the limb buds
c. The closure of the neural tube
d. The development of the cerebral hemispheres

7.
Which of the following is a major structural brain defect characterized by the incomplete closure of the neural tube during embryonic development?

a. Lissencephaly

b. Autism spectrum disorder
c. Spina bifida
d. Fetal alcohol syndrome

8 .
What is the primary cause of anencephaly, a severe structural brain defect where parts of the brain and skull fail to develop?

a. Exposure to excess sunlight during pregnancy
b. Alcohol consumption during pregnancy
c. Folic acid deficiency during pregnancy
d. Consumption of caffeine during pregnancy

9.
During neurulation, the neural plate transforms into which structure?

a. The spinal cord
b. The neural crest
c. The neural tube
d. The cerebral cortex

5.2 Growth and Development of the Early Brain

10 .
What is the process of brain segmentation during embryonic development primarily responsible for?

a. Formation of the cerebral cortex
b. Development of the brainstem
c. Division of the brain into distinct regions with specialized functions
d. Formation of cranial nerves

11.
During which process do daughter cells mature into their final functional form as neurons or glial cells?

a. Neurogenesis
b. Mitosis
c. Differentiation
d. Synaptogenesis

5.3 Synapse Formation and Maturation

12 .
Which of the following is NOT a structural component of a growth cone?

a. Actin filaments
b. Microtubules
c. Myelin sheath
d. Filopodia

13.
What is the growth cone primarily responsible for during neurodevelopment?

a. Forming neural synapses
b. Guiding the growing axon to its target
c. Regulating neurotransmitter release
d. Initiating apoptosis in neurons

14 .
What does the term "polyneuronal innervation" refer to in neurodevelopment?

a. The process of axons growing multiple branches
b. The simultaneous innervation of a single target neuron by multiple axons
c. The formation of myelin sheaths around axons
d. The branching of dendrites to receive synaptic inputs

15.
In the context of experience-related innervation modifications, what term describes the process by which synaptic connections are strengthened through repeated stimulation?

a. Synaptic pruning
b. Synaptic inhibition
c. Synaptic plasticity
d. Synaptic transmission

16 .
What is the function of filopodia in a growth cone?

a. Facilitating axon branching
b. Propagating electrical impulses
c. Secreting neurotransmitters
d. Sensing guidance cues in the environment

17.
What is myelin?

a. A type of neurotransmitter in the brain
b. A fatty substance that insulates and surrounds nerve fibers
c. A neuron
d. A part of the brain's gray matter

18.
Which of the following is not an example of sensory enrichment during early development that can promote synaptic connectivity?

a. Exposure to a noisy environment
b. Limited social interactions
c. Playing video games for extended periods
d. Regular exposure to a variety of sensory stimuli, such as different textures, sounds, and smells

5.4 Experience Dependent Plasticity

19.
How can environmental enrichment and learning experiences positively impact neural plasticity?

a. They reduce neural plasticity.
b. They weaken synaptic connections.
c. They only affect structural plasticity.
d. They enhance neural plasticity and promote the formation of new connections.

20 .
Experience-dependent plasticity refers to changes in neural connections that occur as a result of:

a. inherited genetic mutations.
b. random fluctuations in neural activity.
c. specific experiences or learning.
d. age-related neuronal degeneration.

21.
Which of the following is an example of experience-dependent plasticity in the visual system?

a. The process of working out a specific muscle
b. The formation of the blood-brain barrier
c. The refinement of visual acuity in response to visual experiences
d. The regulation of basic reflexes

22 .
Critical periods in development are times when:

a. learning is impossible due to neural limitations.
b. neural plasticity is heightened, making learning and development more susceptible to environmental influences.
c. the brain is fully mature and resistant to environmental influences.
d. genetic factors override environmental factors in development.

23.
Exposure to which environmental toxin during critical periods of brain development can lead to cognitive and behavioral deficits?

a. Vitamin C
b. Lead
c. Calcium
d. Oxygen

24 .
What is retinoic acid?

a. A type of steroid hormone essential for fetal development.
b. A synthetic compound used to treat birth defects.
c. A form of vitamin B.
d. A neurotransmitter that promotes healthy neural development in fetuses.

1.9.10: Fill in the Blank

5.1 Gastrulation and Formation of the Neural Tube (Neurulation)

1.
Gastrulation begins after the formation of the _____, which is a long groove that forms across the developing embryo.
2 .
Neural _____ are secreted factors that direct the surrounding tissues through neurulation.
3.
Disorders that lead to structural damage or malformations which impair lifelong function are the most common forms of _____ disorders.

5.2 Growth and Development of the Early Brain

4 .
Radial glia cells are a class of _____ located in a proliferative region called the _____.

5.3 Synapse Formation and Maturation

5.
Neuronal survival is mediated by a class of molecules called _____.

5.4 Experience Dependent Plasticity

6 .
_____ is the ability to adapt and reorganize in response to environmental stimuli.

Your immune system helps you think. Remember the last time you had a cold or the flu? You probably felt pretty lousy—chills, fever, body aches, fatigue? Maybe you even felt a little depressed. It would be easy to blame the bug for these miserable symptoms, but what if I told you that your own body is making you feel this way? It turns out, the constellation of symptoms that most of us experience when we get sick is technically known as "sickness behaviors" and are caused by our own bodies.

Rather than being harmful side effects of an infection—for instance with an influenza virus or a rhinovirus (which causes the common cold)—sickness behaviors are carefully organized and orchestrated responses from your own immune system. How does this happen? For centuries of neuroscience research, it was believed that the immune and nervous system operated completely independently. Recent knowledge shows us it is very much the opposite—our immune system has evolved sophisticated mechanisms to talk to our nervous system, and vice versa, and thereby change our behavior, which you will learn about in this chapter. We will discuss the many ways that these systems communicate and the implications for how our brains work, in both healthy conditions and during illness or injury.

But why would our immune system need a way to change our behavior? Many research studies in species ranging from honeybees to mice to humans have now demonstrated that a change in behavior during an illness or infection—often referred to as a shift in motivational priorities—is helpful to our bodies in overcoming that illness. Think about it: if you are fighting an infection like the flu, your body is working hard and spending significant metabolic energy to do so. Does it make sense to keep running around

town, going to school or work, playing sports or attending parties with friends? Or does it make better sense to rest and isolate until the infection clears? Put another way, which circumstance sounds easier for your hard-working immune system to manage? The latter, of course. If you rest your body, that frees up metabolic resources for your immune system to fight. Our immune systems therefore evolved efficient mechanisms to impact our nervous systems and alter behavior.

This crosstalk between the immune and nervous systems doesn't only happen when we are sick, however. It turns out our immune system has an impact on our behavior nearly all the time, particularly when we are stressed, when we encounter new (potentially dangerous) situations, or even when we are feeling romantic. There are multiple protein signals which make up the messengers of the immune system and these messengers impact our emotions, our mood, and our thinking abilities. These systems are like chatty teenagers, more-or-less constantly updating one another of their activities. This communication can be helpful and adaptive. However, there are times when the immune system fails to turn off its activity properly, and this can lead to neurological problems and pathology. There is growing evidence that immune cells that reside within the brain (in particular, one cell type called microglia) are important in neurological disorders that appear early in life, such as autism spectrum disorder and schizophrenia, as well as in degenerative disorders that occur at the other end of the lifespan, including Alzheimer's disease. Many researchers now seek to understand why and how this switch occurs between adaptation and pathology in neuroimmune function, thus transitioning from health to disease.

In this chapter, we begin with a brief overview of the immune system and examine many of the signaling pathways between the nervous and immune systems throughout the body. We will examine changes in behavior during illness or in response to stressors as some of the strongest (and earliest) evidence that the nervous and immune systems powerfully impact each other. We end by discussing some of the ways that immune cells can alter neuronal structure and function in the brain, during health as well as disease, and therefore mood and cognition. Neuroimmunology is one of the youngest areas of neuroscience, and also one of the most exciting and fastest growing!

1.10.2: Cells and Messengers of the Immune System

Learning Objectives

By the end of this section, you should be able to

- 17.1.1 Describe the basic components (tissues, organs, and cells) of the immune system and define important terms.
- 17.1.2 Identify key functional differences between the innate and adaptive immune systems.
- 17.1.3 Describe the historical context of immune privilege within the brain and the new information that has changed this understanding.
- 17.1.4 Describe the immune components in the brain and how they differ from what is in the periphery.

The immune system is complicated, just like neuroscience. There are many terms and labels for components of the immune system that may seem overwhelming at first, a bit like learning an entirely new language. The goal of this section is therefore not to learn all of immunology but to introduce you to the major players within the immune system and to describe some of the fundamental mechanisms by which this system functions. It will provide just enough of a foundation for you to understand another complicated topic, which is how the nervous system interacts with the immune system, and how and why these interactions can impact our behavior.

The peripheral immune system

The peripheral immune system can be roughly divided into two basic divisions, the innate or nonspecific immune system, and the adaptive or specific immune system (see Figure 17.2).

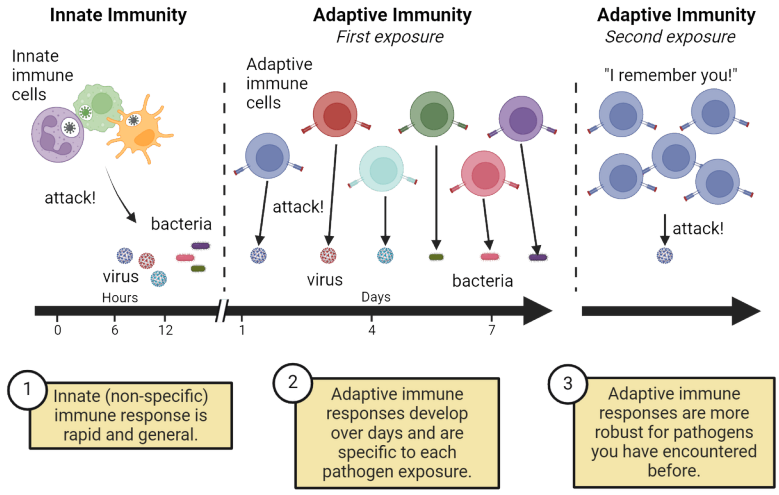

Figure 17.2 Innate and adaptive immunity

The innate immune system generates responses to stimuli like pathogens (for instance, germs like bacteria or viruses). Its responses are roughly the same each time, regardless of the specific pathogen encountered. Thus, the responses of the innate immune system are non-specific. This is the first line of defense and happens fast. In contrast, the adaptive immune system ramps up more slowly and adapts over time, such that a second encounter with the same pathogen (like a virus) will generate a more vigorous response compared to the initial response. This is exactly what happens when you receive a vaccination against the “flu” (influenza virus) or against SARS-CoV2 (the virus which causes Covid-19). Most vaccines contain small, inactive pieces of a pathogen that cannot infect you, but can help teach your adaptive immune system what a pathogen looks like. Your initial immune response to the vaccine protects you against any later exposure because you generate immunological memory for that pathogen. This latter response is specific because the cells of the adaptive immune system learn precisely which pathogens they

have previously encountered and respond only to that specific pathogen upon seeing it again, and not others. This selectivity for specific pieces of foreign material is critical for preventing autoimmune reactions which can occur when our immune cells mistake our normal cells for pathogens and attack them. There are important aspects of both innate and adaptive immunity for neuroscience and for behavior. Throughout this chapter we will consider many of these examples. We begin by learning some basics of these two components of the peripheral immune system.

Innate immune system

The innate immune system consists of physical barriers of the body including the skin (epithelium) and mucosal surfaces of the gut, lungs, and other exposed areas, as well as several critical cell types: neutrophils, macrophages, and monocytes (Figure 17.3).

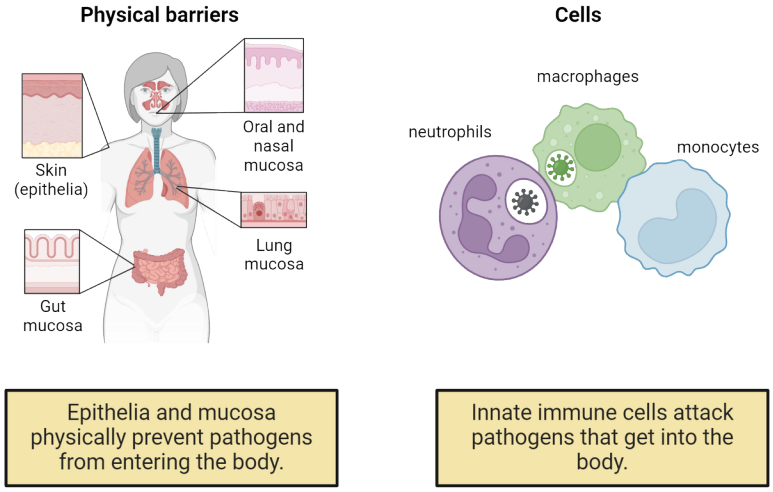

Figure 17.3 Innate immune structures and cells

All three types of innate immune cells respond broadly to multiple pathogens, which they can detect using a number of pattern recognition receptors on their cell surface (Figure 17.4). These receptors can detect evolutionarily conserved pathogen-associated-molecular-patterns (PAMPs) present on bacteria, viruses, fungi, or other foreign invaders.

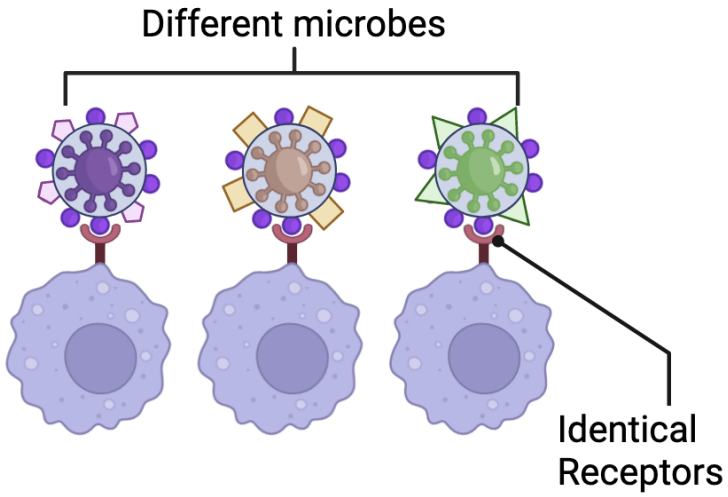

Figure 17.4 Pathogen-associated molecular patterns Pathogen associated molecular patterns (PAMPs) are structures common across classes of microbes. Innate immune cells express receptors that recognize PAMPs.

How each of these cellular components of the innate immune system functions once they detect these PAMPs is diagrammed in Figure 17.5, using the case of a penetrating skin wound that introduces some bacterial pathogens as an example. We will discuss what each cell type does in more detail below.

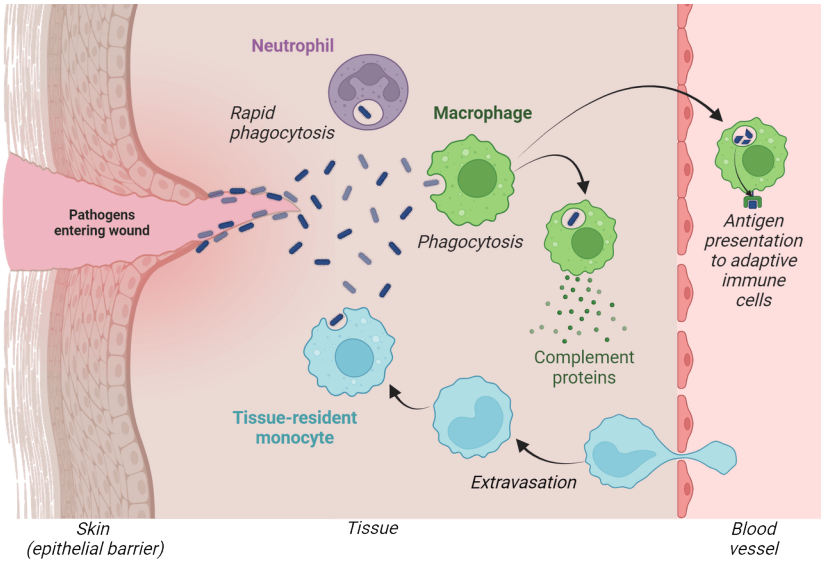

Figure 17.5 Innate immune cells in action

Neutrophils are a type of white blood cell that are affectionately known as the soldiers or footmen of the immune system. These cells react exquisitely fast and pour into infected or injured areas and unleash a battery of potent pathogen killing defenses—these cells largely create the oozing "pus" in wounds, which is basically an accumulation of dead neutrophils that have finished doing their thing. Neutrophils can also quite literally spit out their DNA in nets (called extracellular traps) to capture pathogens and pull them back in for elimination (Papayannopoulos, 2018)!

A second major player in innate immunity and in repair mechanisms is the macrophage (Greek for "big eater"), which is a type of phagocyte (phagocytic cell) meaning that they are good at eating and digesting things. These cells eat pathogens, as well as dead cells and debris, and thus are critical for overall tissue homeostasis and wound healing. They are also one of the primary antigen presenting cells (APC) along with B cells and dendritic cells. An antigen is a tiny portion of a cell or pathogen that gets processed after an APC chews it up and it gets "presented" to an adaptive immune cell like a T cell, which we cover in the next section, in order to activate that cell and mobilize a full immune response. A critical part of innate defense involves activation of the complement cascade, a series of proteins that have diverse functions including opsonization or "tagging" of pathogens for removal/phagocytosis by an APC (usually a macrophage). Complement proteins can also directly kill pathogens via punching holes in their cell membranes, as well as activate some adaptive immune cells.

A final cell type within the innate immune system important for our study of neuroimmunology is the monocyte, which is a cousin of the macrophage. Monocytes circulate freely within the blood and lymphatic system (e.g. lymph nodes) where they constantly scan for any sign of trouble. Once a pathogen or chemotactic signal (basically a "come help" signal) from another immune cell is detected, monocytes can extravasate (crawl) into tissues like the skin or adipose and thereby become macrophages (or "tissue-resident" monocytes).

Innate immune responses are rapid and stereotyped, meaning that they occur with the same time course and magnitude each time and somewhat regardless of the specific pathogen detected. One major consequence of the innate immune cell response is inflammation. Inflammation is the term we use to describe how tissues become red, swollen and hot after an injury or pathogen exposure of some kind. When inflammation happens in tissues in your body, it is also often painful (see Chapter 9 Touch and Pain).

Inflammation is quite a buzz word these days as it is implicated in many different diseases ranging from heart disease to depression to Alzheimer's disease (Figure 17.6). There is good reason for this attention, as inflammatory processes that last too long, especially within the brain, can be very harmful. It is important to remember however that inflammation is classically defined in immunology by heat, swelling, pain, and importantly, repair. Thus, inflammation is helpful when properly controlled and only becomes harmful when it fails to resolve, which is a theme that we will visit repeatedly throughout this chapter.

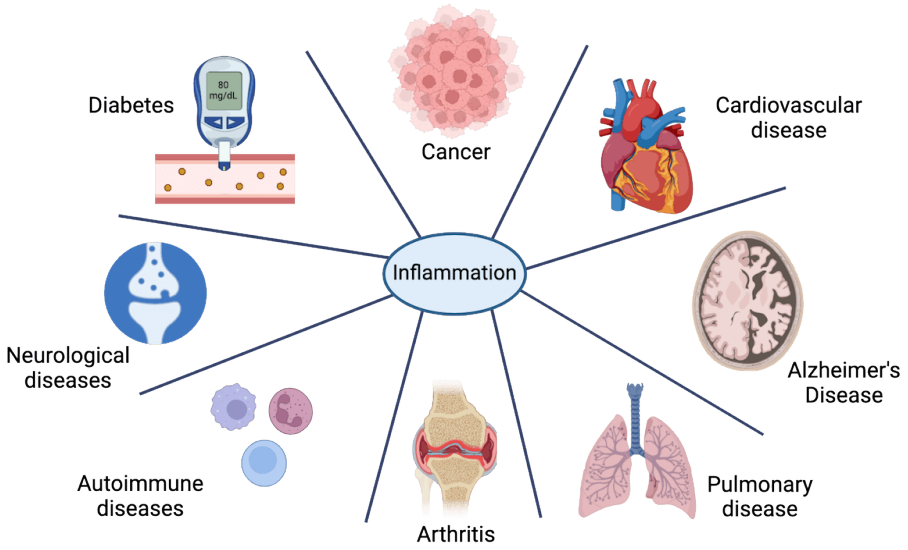

Figure 17.6 Inflammation-associated diseases

Taken together the role of innate immune cells is to quickly neutralize or contain pathogens and to mobilize the entire immune system, including the brain, in immune defense. Their parallel function is to notify the adaptive immune system which begins to generate a more specific and enduring response via the generation of memory cells.

Adaptive immune system

The adaptive immune system consists primarily of another class of white blood cells called lymphocytes, which consists of B cells and T cells. B cells are so-called because they are born in the bone marrow (like all blood cells). B cells make antibodies which are soluble (secreted) proteins produced in response to antigen stimulation and which make up the humoral immune response. This humoral immune response is generated within the extracellular spaces (the “humors” of the body, e.g. blood and lymph) and is important for neutralizing pathogens before they enter cells. Each antibody recognizes a single antigen, and each B cell generates a single type of antibody (Figure 17.7).

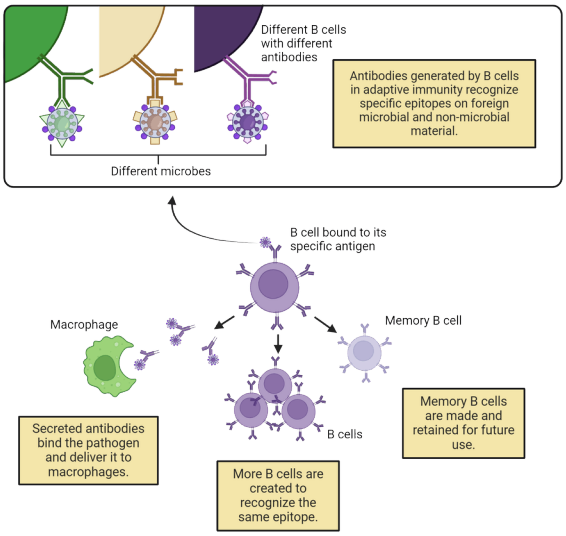

Figure 17.7 B cell function

There is a tremendous diversity of B cell receptors in your body which ensures maximal recognition of dangerous things that might make us sick. These cells are fairly sophisticated as well: B cell receptors get thoroughly “fit tested” early in their life to ensure they are not responding to your own cells (which is critical to prevent autoimmunity). If they do respond to so-called “self-

antigens", they are immediately eliminated. Indeed, most B cells will die a quiet dignified death without ever finding their non-self antigen match (this again is a good thing, as otherwise our bodies would be overrun with B cells). However, a small subset will find their match! Once a match between antibody and antigen occurs, that particular B cell will start to make many copies of itself. This process takes time; by the end of about a week, around 20,000 clones of that original B cell will be produced. This creates an army of antibody-producing soldiers—each one of which can then produce an astounding number of antibodies—about 2000 per second!

What do antibodies do? Interestingly, they don't directly kill anything. Rather, they tag (label) pathogens for recognition and removal by a macrophage. Antibodies can also bind to viruses and prevent them from entering cells, in a process called neutralization. Memory B cells are also produced during this process, which are very long-lived cells that can much more rapidly begin to replicate themselves and produce antibodies if they encounter the same antigen again. Remember vaccines? The production of memory B cells in response to vaccination is crucial to confer long-term protection.

T cells are called T cells because, while they are born in the bone marrow like all blood cells, they grow up and attend primary school in the thymus. T cells are responsible for cell-mediated immunity (which is concerned with the killing of pathogens inside of cells, see Figure 17.8) and they come in several flavors:

- Helper T cells which "help" or amplify other immune cell activities
- Cytotoxic or "Killer" T cells which, as the name suggests directly kill infected cells and thus the pathogens within them
- Regulatory T cells, which again as the name suggests, regulate the activities of other T cells
- Memory T cells which get generated in response to specific infections and mediate long-term immunity to these same pathogens in collaboration with Memory B cells, and several other types which we won't discuss.

Suffice to say, it's complicated and beyond the scope of this chapter to understand them all. The most important bit for our topic is that T cells generate receptors on their cell surface during their development in the thymus to precisely respond to a single pathogen via a very similar process to B cells. They form a primary arm of the adaptive immune response and the loss or dysfunction of these cells can be devastating. Acquired immunodeficiency syndrome (AIDS) in humans is due to a loss of helper T cells after infection with human immunodeficiency virus (HIV), which highlights their importance.

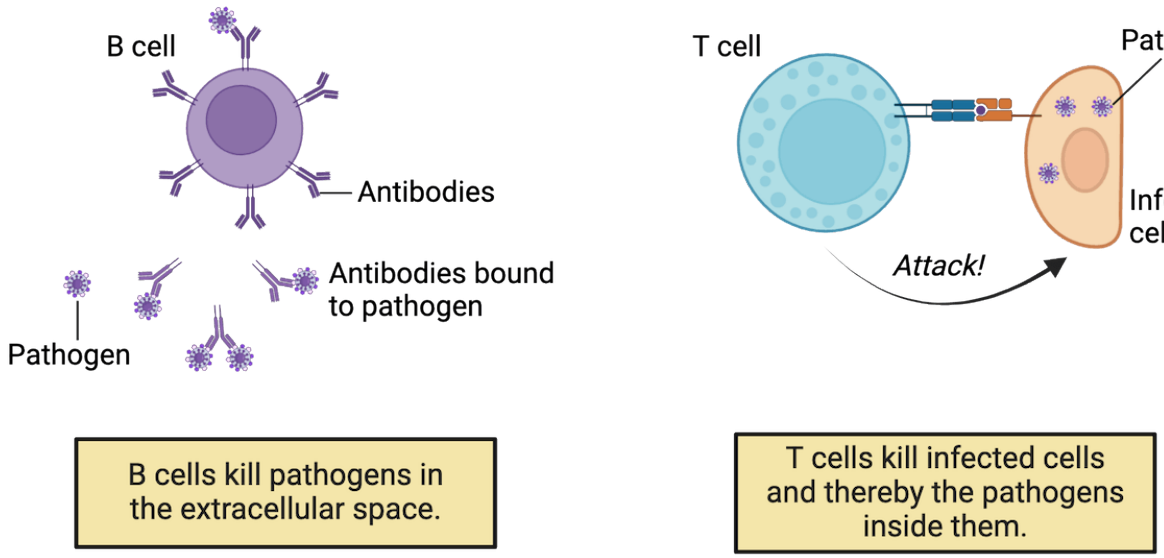

Figure 17.8 B vs T cells

T cells are called into action to attack infected cells following their activation by professional APCs like macrophages, which "present" antigen to the T cell using a molecule called the major histocompatibility complex, or MHC, also known as human leukocyte antigen (HLA) in humans. T cell attacks are very specifically targeted to only infected cells with the epitope (a small fragment of an antigen) the T cells have learned to recognize, not healthy cells and not even the APCs displaying that pathogen epitope. The MHC is critical to this selectivity. MHC comes in two forms: class I and class II. All APCs have class II, and all cells of the body have class I. Whether an epitope is displayed to a T cell using MHC class I or class II will help determine whether a T cell decides to try to kill that cell, leave it alone or learn from it.

Under healthy conditions, host cells (i.e. your own cells) use MHC I to display a tiny bit of themselves, a self-antigen, on its cell

surface (step 1 of Figure 17.9). This tells the T cell “I’m you! Don’t kill me!”. This presentation of a bit of “self” by MHC I is a crucial step because it prevents T cells from killing any healthy cells. MHC/HLA molecules are the reason that organ transplantation in humans is a bit tricky—you can’t just take any liver and give it to someone that needs it, unfortunately—it has to be a close match in terms of HLA type (sort of like blood type) or the receiving person’s immune cells (and antibodies) will rapidly detect and attack it, leading to organ failure. In contrast to all other cells in our body, APCs use MHC class II to package and display epitopes on their cell surface for the purpose of activating T cells (step 2 of Figure 17.9). The T cell learns about the pathogen epitope that the APC displays, and it also knows not to kill the APC because it is displayed with MHC II. This again prevents the T cell from going rogue and killing things without permission. They are pretty potent cells! However, if a normal cell, say a kidney cell, gets infected with a virus, it will use MHC class I to package part of that virus into a small digestible form and wave it like a flag on its cell surface. This tells any passing T cell (with a receptor that recognizes that specific antigen) that the cell has been invaded and the T cell will then kill and remove the cell and its virus (step 3 of Figure 17.9). We will learn in a subsequent section about a subset of T cells that are important for inflammatory bidirectional communication between the brain and the immune system. We will also further discuss how T cells seem to be critical for normal behavior, specifically learning and memory.

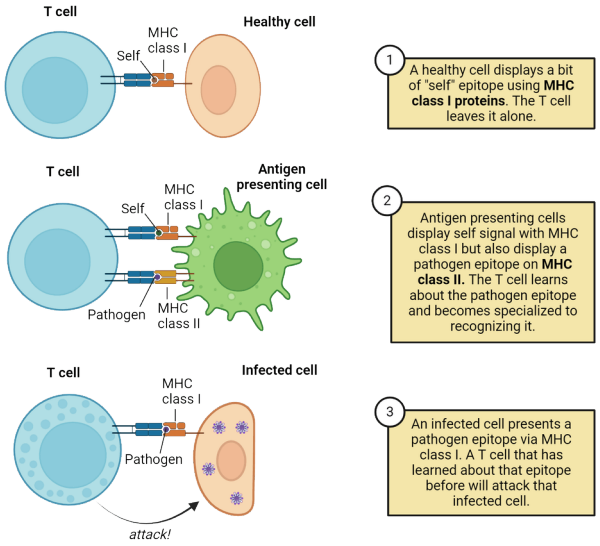

Figure 17.9 MHC complexes and self vs pathogen recognition

Interestingly, MHC is another source of diversity building for the immune system (meaning the ability to respond to a vast number of potential antigens), as the genes that encode MHC (and HLA in humans) are some of the most diverse in the entire genome. There is fascinating literature showing that animals like mice, other mammals, birds, and even fish may choose their mates based on their detection of MHC gene polymorphisms, likely via pheromonal cues contained in urine. Specifically, animals choose mates that have MHC genes least like their own, ensuring that their offspring will inherit the largest possible diversity of genes important for building a robust immune defense. Whereas this has been shown for many species (Grob et al., 1998; Roth et al., 2014; Rymešová et al., 2017), the possibility in humans remains tantalizing but controversial (Havlicek and Roberts, 2009; Havlíček et al., 2020).

Cytokines and chemokines

All cells need good communication. Immune cells, and many other cell types in the body, use cytokines and small “**chemo**tactic” cyto**kines** called chemokines to signal over long distances. Cells of both the innate and adaptive immune systems secrete cytokines and chemokines as a part of their response to pathogens. Immune cells in the brain, which we will learn about shortly, also produce these potent signaling molecules. Among cytokines are several “families”, including tumor necrosis factors (TNF), interferons (IFN), interleukins ([IL]-1 through IL-36 and counting), and others. Cytokines serve a wide variety of functions including signaling between cells and coordinating inflammation. They are produced by and affect a wide variety of cells in the brain and body. Chemokines are a type of cytokine that induce cell movement via chemical signals or gradients. An equally lengthy list of chemokines from several structural families has been described, which mediate diverse functions including cell adhesion, chemotaxis (or directed cell movement towards a signal source), and leukocyte (white blood cell) trafficking.

The naming conventions of cytokines and chemokines are based on their chemical structure rather than their functions which is a bit unfortunate when you are trying to remember what different cytokines do! However, cytokines can be roughly divided

into having pro-inflammatory (inflammation promoting) vs. anti-inflammatory (inflammation resolving) functions, although these outcomes are highly context-dependent. That is, sometimes they induce inflammation and sometimes they prevent it, and the impact often depends on the receiving cell. While acute and local inflammation/immune activation caused by the pro-inflammatory cytokines is necessary for responding to insult or injury, homeostasis and health are restored and tissue repair is elicited by regulatory anti-inflammatory processes. Cytokines released by innate immune cell response to pathogens also mediate the activation of T and B lymphocytes, which play a critical role in the adaptive immune response later in the time course of an infection.

Cytokines can induce the production of other cytokines, chemokines and inflammatory mediators, and rarely work alone, but rather in a cascade with other cytokines. You may have heard the term “cytokine storm,” which is more or less what it sounds like: when one cytokine induces the production of another, which induces another, and so on, until you have a whole storm of swirling cytokines within a given organ or tissue. Figure 17.10 shows an example of the cytokine storm process as it happens following SARS-CoV2 infections in the lungs. This is one of the major causes of death with Covid-19; the cytokine storm causes excess inflammation that damages lung cells and restricts airflow. Cytokine storms can occur in multiple kinds of severe infection and are generally bad news as it can lead to organ failure or death.

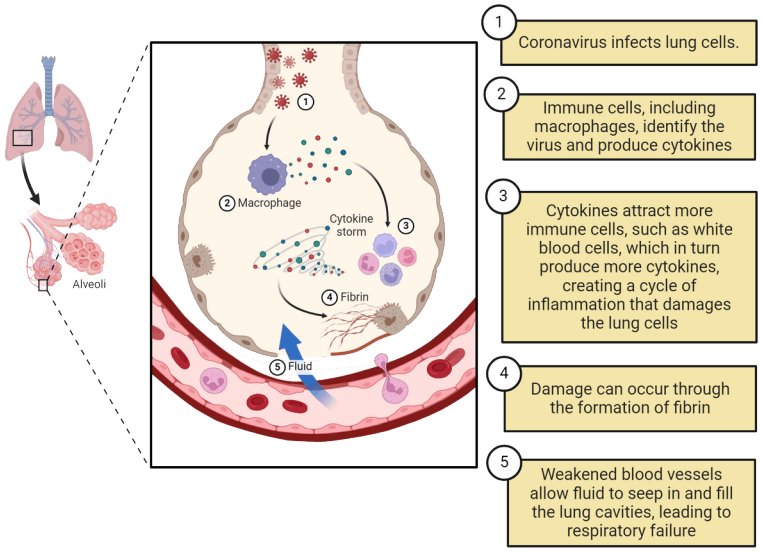

Figure 17.10 Cytokine storm

For the purposes of this chapter, the important thing about cytokines is that they have neuromodulatory (i.e. “neuron modulating”) properties within the brain during infectious and inflammatory processes by acting directly on neurons and glia. For example, one well characterized PAMP used widely in neuroimmunology research is lipopolysaccharide, or LPS, which is the cell wall component of bacteria that induces a robust immune response if injected into experimental animals (or humans!). LPS induces a suite of changes in physiology, including white blood cell (e.g. monocytes, T cells, B cells) replication (proliferation), fever, and cytokine production. Cytokines released in response to LPS signal to the brain to induce rapid changes in behavior, including fatigue, loss of interest in eating and normal behaviors, e.g. social interactions, and maybe even a form of depression (called anhedonia). These behavioral changes are not caused by the pathogens themselves, but rather by cytokine signaling in the brain. They are widely regarded as adaptive because they help you to rapidly shift motivation to prioritize rest and recovery and help to overcome illness more quickly. We will learn more about these roles of cytokines in the next section. Cytokines are also constitutively expressed in healthy brain tissue and regulate such homeostatic mechanisms and behaviors as sleep, metabolism, and even cognition. Cytokine receptors in mammals have been characterized throughout the central nervous system (CNS), with high concentrations within brain regions important for these functions, including the hypothalamus, hippocampus, striatum, amygdala, and thalamus (Hopkins and Rothwell, 1995; Rothwell and Hopkins, 1995).

History of Neuroscience: Immune privilege within the brain

Everything we have discussed so far has focused on processes initiated by immune cells in the body. For the vast majority of history of research on the immune system and the CNS, these systems were thought to be completely separate, both physically and functionally. Thus, the brain was viewed as “privileged” i.e. separate from the impacts of the immune system. Scientists would specialize in the study of one or the other, and nary a thought would be given to the one not chosen. Even today this is

somewhat the case, although it is slowly changing as new knowledge about the interconnectedness of these systems emerges. These stubborn beliefs formed for good reason. Physicians have noted for hundreds of years that tissue grafts (think organ transplants like kidneys or hearts) into the body will quickly be rejected and the tissue will die unless the immune system is powerfully suppressed—as noted above this is because any cells not possessing an MHC I complex consistent with "self" will be recognized as dangerous and quickly thrown out. But this is not the case within the brain—tissue grafts into the brain can live for a long time before they are eventually discovered and rejected (Medawar, 1948). Researchers at the time concluded that this meant the brain did not have any immune system components, and that peripheral immune components could not enter the brain. And they had several supporting observations to support that incorrect belief.

One major reason that early researchers thought the brain and immune systems did not interact is that there is a powerful barrier between the CNS and the rest of the body, called the blood-brain-barrier (BBB), which keeps most immune cells out of the brain (Figure 17.11) (see Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy).

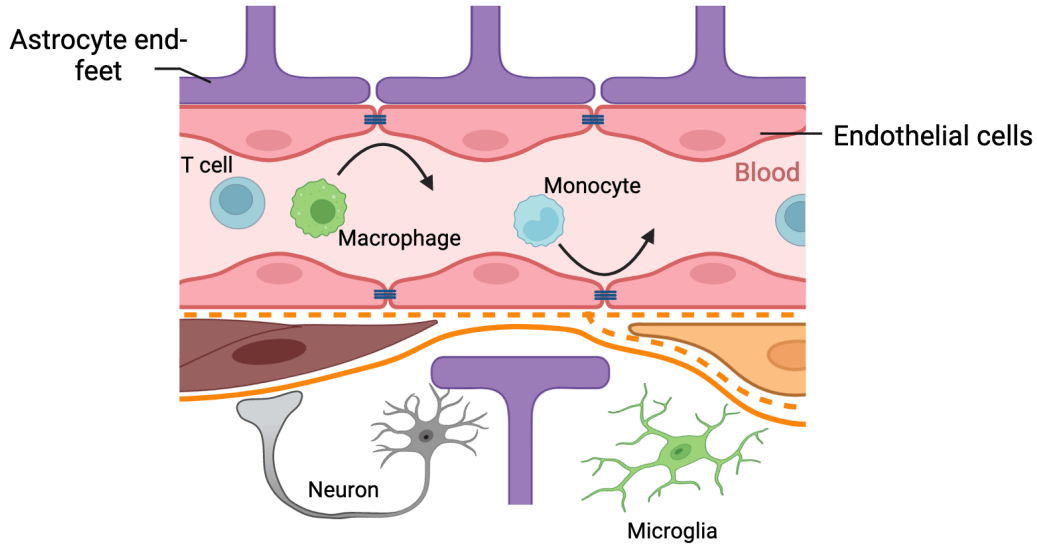

Figure 17.11 Blood-brain barrier The BBB prevents immune cells and pathogens from entering the brain under most circumstances.

The BBB consists of closely joined endothelial cells, astrocytes, and other cells, which form a tight barrier between the brain and everything else. This barrier exists for good reason: the cells within the brain, namely neurons, are delicate, and once damaged, are difficult or impossible to repair. The blood can carry numerous pathogens that could damage these delicate neurons. There is also limited space within the skull, so if immune cells reacting to a pathogen entered the brain and launched a large immune response, any swelling associated with inflammation could be fatal. Most of the time, the BBB prevents the peripheral immune cells like macrophages and lymphocytes from entering the brain, thereby reducing the chance of an inflammatory event.

Though peripheral immune cells are mostly kept out of the brain, we now know that the brain is not completely without immune cells. Most prominently, it has resident immune cells: microglia. They make up ~10-15% of the cells in the brain, depending on brain region. They are so named because they have small cell bodies (relative to much larger neurons), but they are mighty in function. They have many elaborate processes that they use to continually scan and survey the brain tissue (Figure 17.12). They play essential roles in brain development, homeostasis, pathogen defense, and are increasingly implicated in brain pathology as well. For example, complement proteins can "tag" certain synapses for removal by microglia. This process is a part of normal development but may also have relevance in some neurodevelopmental disorders when proper synaptic "pruning" by microglia becomes disrupted. For instance, there is interesting recent evidence linking complement proteins within the brain to the neurodevelopmental disorder schizophrenia, which has long been recognized as a disorder of excessive synaptic pruning, potentially by microglia (see Chapter 5 Neurodevelopment. In addition to microglia in the brain, there is some evidence that monocytes can cross into the brain in some circumstances, for instance in response to stressors or certain injuries, where they can contribute to behavioral changes, including anxiety. We discuss this in greater detail in subsequent sections as well.

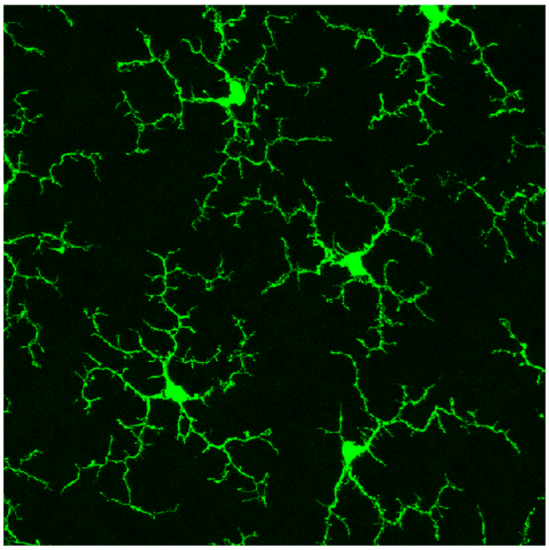

Figure 17.12 Microglial morphology Microglia have elaborate processes that they use to scan the environment. Image credit: NIH Image Gallery from Bethesda, Maryland, USA - Microglia in a Healthy Adult Mouse Retina, Public Domain, https://commons.wikimedia.org/w/inde...curid=87951906

A second major reason the brain and immune systems were believed to be separate for so long is that MHC expression is very low under homeostatic conditions within the CNS, and for a long time, was not thought to be expressed at all. We now understand that the primary immune cells (and APCs) of the brain, microglia, are capable of upregulating MHC I and II, but that they only do so in the case of immune activation, e.g. due to injury or infection.

A third reason that early neuroanatomists believed that the immune and nervous systems were separate was the belief that the brain has no means of responding to presented antigens because it lacks a lymphatic system, along with the fact that very few lymphocytes (T cells and B cells) exist within the brain. Microglia upregulating MHC is all well and good, but who are they presenting antigen "to" if there are no T cells? (Remember that T cells use MHC on the surface of cells to recognize their antigen match and generate an immune response). This question also puzzled early researchers in neuroimmunology. Once again, we have new information from only the last several years—there is in fact an elaborate lymphatic system that runs throughout the brain (Iliff et al., 2015; Louveau et al., 2015), sort of like a drainage system that runs alongside blood vessels in the brain, and there are T cells that regularly patrol this lymphatic drainage system along with the meninges of the brain, the weblike casing between the brain itself and the skull. And, these T cells seem to talk to neurons (Alves de Lima et al., 2020) and other immune cells like microglia within these border regions of the brain. Indeed, they are even critical for normal cognition. Mice that completely lack T cells show impaired learning and memory abilities, even if the rest of their immune system is intact. Normal learning and memory can be restored by transplanting normal T cells back into the bloodstream of the mice (Kipnis et al., 2012), which then make their way back into the meninges enwrapping the brain. The exact function of these T cells once they make it back into the brain is not entirely known, but it is clear that having a healthy immune system is important for many aspects of health and behavior beyond fighting infections.

1.10.3: What Does Your Immune System Have to Do with Your Behavior?

Learning Objectives

By the end of this section, you should be able to

- 17.2.1 Define sickness behavior and its adaptive function.
- 17.2.2 Discuss the role of cytokines in mediating sickness behavior.

A critical weapon in our arsenal of immune defenses is very often overlooked, and that is behavior. “Sickness behaviors” are the suite of changes we exhibit during illness, including lethargy (fatigue), changes in cognition and motivated behaviors, and loss of appetite. We already discussed one example of this–the sickness behavior animals show after injection with the bacterial component LPS–in the previous section. Injection with LPS is one of the models researchers have used to observe and better understand behavioral and motivational responses to infection. Very often these shifts in motivation may be the first changes that are apparent after infection, before other unpleasant symptoms emerge. Thus, we essentially have a “sixth sense” about immune activation (Blalock, 2005). Our awareness of our own infection state is mediated in part via low level detection of infectious molecules by pattern recognition receptors on sensory nerve afferents, which we will cover in later sections. So, even if we don’t fully “know” we are sick, parts of our brains certainly do, and mobilization of our immune defense has already begun. We now know that the robust behavioral changes that occur are adaptive, at least in the short term.

Immune system impacts on behavior

The term “sickness behavior” was first coined by a very observant veterinarian named Benjamin Hart who noticed that all sick animals in his care (typically cows or other livestock) seemed to exhibit the same stereotyped behavioral changes when sick: they would stop eating, socially isolate, and sleep a lot. Moreover, he noticed that force feeding the animals or otherwise interfering in their behavior typically made the illness worse. Thus, he proposed the rather controversial hypothesis for the time that these behaviors are happening for a good reason, and to interfere in the behavior was somehow hampering with the immune system (Hart, 1988). Many experiments since his initial observation in multiple species ranging from bumblebees to humans have supported this claim (Devlin et al., 2021).

Fever is often the first unwelcome sign of infection. We often rush to treat illnesses using fever reducing medications. However, there is quite a lot of evidence suggesting this isn’t always the wisest course of action. Despite how miserable it can make you feel, fever is helpful in our fight against infection. This is because bacteria and viruses are actually pretty wimpy, and die off once the room (i.e. your body) gets too hot. Fever is not a behavioral response in mammals, but it is in lizards (which are ectothermic and thus regulate their body temperatures via their external environments; see Chapter 16 Homeostasis). Some of the first studies to directly test the hypothesis that fever is adaptive were done by Dr. Matthew Kluger (Kluger et al., 1975)—he injected a nasty bacterium (Aeromonas hydrophila) into iguanas and then watched what they did (Figure 17.13). Every one of the animals moved to a warmer part of their terrarium, directly under the heat lamp. Next, Dr. Kluger determined what happened if some were prevented from moving to the warm end of the terrarium; sadly, those that were confined to the cold end, and could not induce a behavioral “fever”, died.

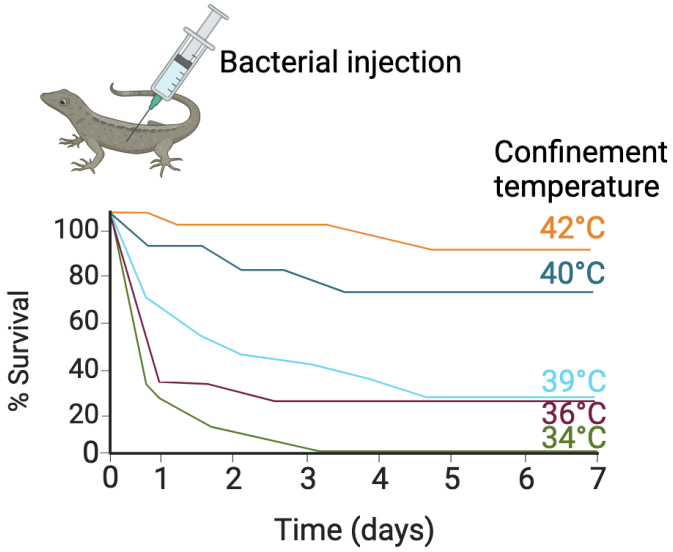

Figure 17.13 Benefits of fever Iguanas injected with bacteria move to warmer parts of their environments. Confinement to colder ambient temperatures after infection, shown here with different lines, caused greater mortality.

How the immune system makes the brain feel sick

Experiments in mammals, typically rodents, have begun to tease out the mechanisms by which sickness behaviors occur. In 17.1 Cells and Messengers of the Immune System, we discussed one example of the kinds of experiments used to understand how sickness behavior happens. Injection of a PAMP like LPS will induce sickness behavior, even though it is not a live pathogen at all—it is simply the empty shell of a bacterium, but our immune cells recognize it as if it is. These experiments tell us that infectious pathogens themselves are not the cause of sickness behavior. Instead, it is our immune response, specifically the cytokines our immune cells release.

Experiments using cytokines themselves have helped to prove that these proteins impact brain function (and therefore behavior). Though most cytokines are large proteins which do not directly cross the BBB, their signaling is frequently relayed across the barrier and recapitulated by immune cells in the brain (see Feature Box). For example, direct injection of a pro-inflammatory cytokine (like one called IL-1β which is robustly produced in response to many infections) will induce sickness behaviors in a perfectly healthy animal, and blocking cytokine receptors (which IL-1β binds to in order to induce its biological effects) within the brain will prevent sickness behaviors, even if the infection is ongoing. Blocking cytokines during illness is generally bad news for the host, however, and increases the time to recovery.

These collective experiments demonstrated two things: sickness behaviors are mediated by cytokines acting within the brain, and blocking their expression prolongs illness or even leads to death. This can stand as a cautionary tale to many of whom may be tempted to push through illnesses unheeded—it's far better to isolate and rest when we are sick as we are likely to get well sooner and come out ahead in the long run.

The effect of cytokines on the brain extends beyond just encouraging us to take a nap. When I talk to students about this concept, one of the things they find most surprising is the evidence that cytokines can impact our thinking abilities. For instance, in the context of sickness, we can feel "brain fog" or confusion for some time. However, the evidence extends beyond illness. Some cytokines are important for the cellular mechanisms underlying memory formation even when animals are healthy. For instance, experimental animals that completely lack these cytokines have been reported to have dramatic memory problems (Avital et al., 2003). It's a Goldilocks phenomenon—cytokine levels that are either too low or too high impair cognition, whereas levels that are just right, are beneficial (Nemeth and Quan, 2021).

Relaying cytokine signaling from the blood to the brain

Cytokines are produced in the body in response to virtually any perturbation of homeostasis, including trauma or infection. However, cytokines are also produced within the brain in response to peripheral cytokines, LPS, or infectious stimuli, indicating that cytokine signals are transmitted from the periphery into the brain. Cytokines are large proteins and are unlikely to cross the BBB. It is generally understood that in response to peripheral inflammation, the brain recapitulates a cytokine signal within its borders. For instance, a time course analysis of brain cytokine expression following peripheral LPS has revealed that cytokine gene expression tends to be localized in close vicinity to the BBB within 1-2 hours, and this expression fades within 8 hours. At 8-12 hours, cells producing cytokines become apparent throughout the entire brain tissues. Thus, the cytokine signal is propagated from the brain borders throughout the brain over time (Quan et al., 1998; Vitkovic et al., 2000). These cytokines can then do many things, like signal back down to peripheral organs via the autonomic nervous system (which we will discuss more in the next section) or serve as neuromodulators to impact behavior.

Environment-Brain Bidirectional Communication: Flexible sickness behavior

One requirement for a biological trait to be considered beneficial, or adaptive, is that it should be flexible or plastic according to the environmental constraints of the animal. For instance, staying in bed when you are sick is good, unless your house catches fire! Then it is much more adaptive to quickly run out of the house. In one important experiment in mice, researchers injected a mother (dam) of small babies (pups) with the bacterial mimic LPS and then watched how well the dam maintained her nest of shredded cotton provided in the cage (Figure 17.14) (Aubert et al., 1997). Normally mouse dams maintain perfect little nests, cocooning their pups inside where it is warm. Dams injected with LPS, however, did not build good nests, and pups were scattered around the cage. These moms were instead engaged in sickness behaviors, sleeping in a corner. Then the researchers added a twist. A second group of dams was injected with LPS, but the temperature in the room where their cages were located was lowered to 6 degrees Celsius (cold!). These moms promptly began to build nice cozy nests and gather their pups close—the pups would otherwise die in the cold temperatures. Thus, the sickness behaviors were flexible to the environmental constraints of the mothers, which is beneficial in the “ultimate” sense, i.e. the ability to pass on one’s genes to the next generation.

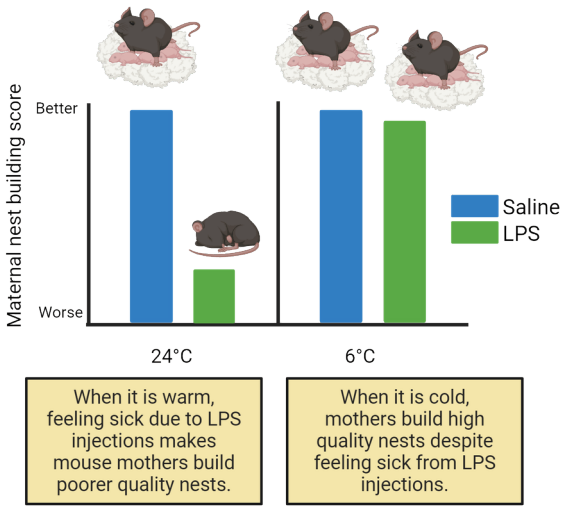

Figure 17.14 Sickness and motivation

There are many other examples of this behavioral plasticity in the course of sickness. For instance, females of many species decrease sexual receptivity following infection or injections of LPS, whereas males do not (Yirmiya et al., 1995). This makes sense, as reproduction is much more energetically costly in females. In humans, there is an interesting literature on reward processing in response to an inflammatory challenge. In one study, researchers gave healthy volunteers a typhoid vaccine (which they needed for some upcoming travel) or a placebo, and then measured their risk-taking behavior in a gambling task. Specifically, they measured the volunteers' tendency to select a high probability reward for little money vs. a low probability reward for more money.

The volunteers that received the vaccine were more likely to choose the sure thing with the lower payoff; hence they were more risk averse. Their brain activity reflected these choices—the risk averse participants receiving the vaccine showed greater activity within the ventral striatum and anterior insula, two regions that are important for "punishment prediction" (Harrison et al., 2016). The remarkable thing about this study is that participants reported no discernible effects of the vaccine—that is, they didn't "feel" sick, but their brains were clearly making different choices! It is for this reason that I always caution my students not to make any big decisions on the day they receive their flu vaccine.

In another study, researchers gave volunteers a very low dose of LPS and measured neural activity within several brain regions using fMRI. During the scan, the participants received feedback from what they thought was a peer (but was really a confederate, i.e. someone working with the experimenters) about an oral performance they had completed earlier. The feedback was either negative, positive, or neutral, but had nothing to do with their actual performance. Remarkably, those participants that received LPS (vs. a control injection of saline) showed greater activation of threat-related neural regions such as the amygdala and anterior cingulate cortex in response to negative feedback. Interestingly, a similar principle was true for positive feedback and reward system activation—greater neural activation of brain regions important for reward, like striatum, in subjects who received LPS vs the control injection. Thus, overall, the inflammatory challenge led to changes in the perception of both positive and negative feedback; the subjects who received LPS were essentially just more sensitive (Muscatell et al., 2016). Once again, we can imagine how behaving a bit more cautiously in the face of acute immune stimulation may be very adaptive for our survival and ultimate fitness.

When sickness drags on

So far, we've discussed examples by which immune system impacts on behavior are adaptive for the host. Some of you might still be a bit skeptical, and you would be right to be so. Certainly, if a fever reaches too high, it can be very dangerous for the host. Similarly, if you compare the symptoms of depression to common sickness behaviors, there are some striking similarities: loss of appetite, social withdrawal, fatigue, and anhedonia, defined as a loss of interest in normal activities. In the case of major depressive disorder, these symptoms are no longer acute, but persist long-term (see Chapter 13 Emotion and Mood). Landmark studies by Dr. Andrew Miller at Emory University have demonstrated an "inflammatory subtype" of major depressive disorder, in which chronic low-level expression of inflammatory cytokines in the blood of some patients predicts or correlates with depressive episodes or symptoms (Miller and Raison, 2016). These patients do not respond well to classic antidepressant therapies (for instance, selective serotonin reuptake inhibitors, or SSRIs) but they do improve following anti-inflammatory therapies, like cytokine inhibitors.

Depression is not the only psychiatric disorder with a well-described link to immune dysregulation. Schizophrenia, post-traumatic stress disorder (PTSD), generalized anxiety disorder, and autism spectrum disorder have all been linked to alterations in immune function (Müller and Ackenheil, 1998; Abazyan et al., 2010; Careaga et al., 2010; Garay and McAllister, 2010), although the mechanisms are still being worked out. Another set of disorders that are gaining attention for their potential link with immune system overactivation are chronic fatigue syndrome (also known as Myalgic Encephalomyelitis) and fibromyalgia, a widespread pain syndrome with poorly defined biological causes (Carruthers et al., 2011). Sometimes patients are dismissed by physicians due to a lack of diagnostic criteria and heterogeneous symptoms with no single cause. New evidence suggests it might be cytokine or immune cell activities within the brain inducing these symptoms.

Similarly, the percentage of patients presenting with the symptoms of "long covid" continues to grow. The symptoms they report include fatigue, pain, "brain fog", and other symptoms consistent with long-term immune activation (i.e. sickness behavior), persisting long after recovery from Covid-19. The numbers of patients reporting long-covid symptoms have simply become too significant to ignore. Indeed, one silver lining of the Covid-19 pandemic may be the increased attention that CNS-immune disorders are now receiving by the medical community with the hope that new studies will open new doors in the fight against these types of devastating disorders more broadly. What remains poorly understood is why immune system activation becomes exaggerated or prolonged, even in the presumed absence of an initial infection or injury (e.g. in the case of chronic fatigue). However, we do know that many factors, including exposure to various stressors, age, sex, and our own behavior, can impact how the immune system functions, which can then feed back to impact the brain. It is a constant bidirectional loop. Thus, we consider next how behavior impacts the immune system, which gives us some insight into how this communication may become dysregulated.

1.10.4: How Does the Brain Talk to the Immune System?

Learning Objectives

By the end of this section, you should be able to

- 17.3.1 Discuss how the immune system can be conditioned via learned associations.
- 17.3.2 Describe the mechanisms by which the hypothalamic-pituitary-adrenal axis and immune system communicate with each other.
- 17.3.3 Describe the mechanisms by which the autonomic nervous system communicates with immune systems.

The interactions between the immune system and brain are not a one-way street but move in both directions. Thus, our behaviors impact how our immune systems function. One particularly notable piece of evidence for brain regulation of immune function is that it turns out that learning a new association can impact how the immune system works in the body, for instance the levels of antibody in the bloodstream. Here, we'll discuss some of the ways behavior—and for this we will define it as a perceptual process that begins in the brain and manifests as an action or output—can profoundly impact how our immune system works. In the process, we will further appreciate the two-way nature of these interactions, where the brain and immune system are constantly updating and influencing one another.

Behavioral conditioning of the immune system

How do we know that the brain talks to the immune system? In classical (or "Pavlovian") conditioning in behavioral neuroscience, a previously neutral stimulus like a light or a bell (the conditioned stimulus) becomes associated with a particular outcome like fear-induced freezing (the conditioned response) because it is paired, over a few associations, with something like a foot shock (the unconditioned stimulus) (see Chapter 18 Learning and Memory). It turns out that our immune systems "learn" associations too. More accurately, our brains learn associations that are relevant for the immune response, and this results in a shift in its function in response to previously innocuous or irrelevant cues. An example—just as we can condition rats to "freeze" when they hear a bell because it signals a potential foot shock, it is possible to pair a particular tasting beverage with a change in antibody production. What?! Here's how it works.

If you give a rat (or a person) a drug called cyclophosphamide and then inject the rat with a novel antigen that they would normally make antibodies against, the rat will show decreased production of the antibodies. This is because cyclophosphamide is an immunosuppressant drug used in some cancer therapies. If you give a rat some chocolate milk to drink alongside cyclophosphamide and then inject it with an antigen, it will again produce fewer antibodies. This is perhaps expected; chocolate milk itself should not change the immunosuppressant properties of cyclophosphamide. But here's where it gets interesting—Later, if you give the rat chocolate milk alone, the rat will exhibit immunosuppression and produce fewer antibodies to the same antigen (Figure 17.15). After chocolate milk!

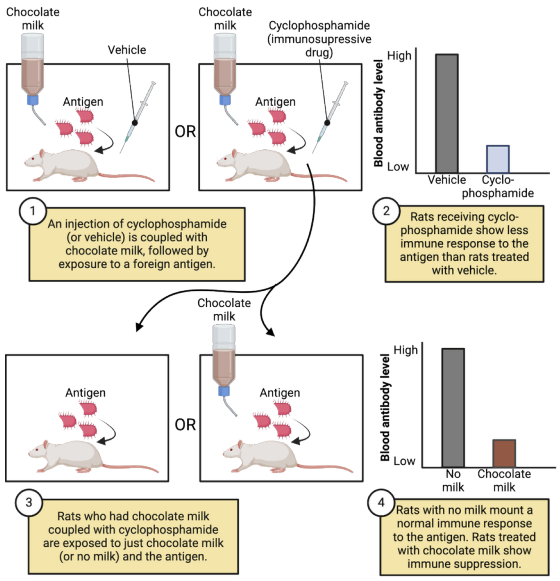

Figure 17.15 Behavioral conditioning of immune responses

Experiments where stimuli get coupled to immunosuppressants work in humans too. These types of experiments, when they were first done in the early 1990s, were groundbreaking because they showed without question that the brain and the immune system must meaningfully talk to each other (Cohen et al., 1994). At that point, the race was on to determine the mechanisms underlying this crosstalk, which we cover below. But what are the larger implications of this type of conditioning? Is this just a weird party trick? It turns out the implications could be profound. For instance, one big problem in the treatment of many cancers is that patients experience nausea in response to the chemotherapeutic treatments. Worse yet is that the patients begin, because of classical conditioning, to associate the very environment in which they receive the treatments with nausea, even if they are no longer receiving any drug. This type of nausea can be completely debilitating, and for this reason some medical centers have begun to randomize the rooms in which patients receive their treatments in order to limit these associations. More troubling is the possibility that a given environment could on its own induce immunosuppression, much like that chocolate milk. This would be devastating for already immunocompromised patients during their recovery.

The good news is that just as the immune system can be suppressed via association, it can also be enhanced. There is evidence in rodents that transient activation of the so-called reward circuit of the brain, the ventral tegmental area, can augment immune responses like antibody production, bacterial killing, and even anti-tumor activity in the periphery (Ben-Shaanan et al., 2016, 2018). These results raise the possibility that such enhancement could be amenable to classical conditioning as well. Indeed, repeated pairings of a small amount of a novel antigen with chocolate milk can boost antibody production to the later presentation of the chocolate milk alone (Ader et al., 1993). This, in a way, is the opposite of the experiment where chocolate milk was coupled with an immunosuppressant drug. In this case, we pair the presentation of the antigen with the chocolatey treat, making the chocolatey treat itself stimulate antibody production (Figure 17.16). Once again, the implications for these types of associations are profound, and they likely contribute to the “placebo effect” (Belcher et al., 2018), in which patient beliefs regarding a potential treatment are often just as powerful in causing a biological effect -in this case a change in the immune response- as the drug itself (see Chapter 9 Touch and Pain). This often doesn’t mean the drug doesn’t work, but rather that our neuroimmune link works well!

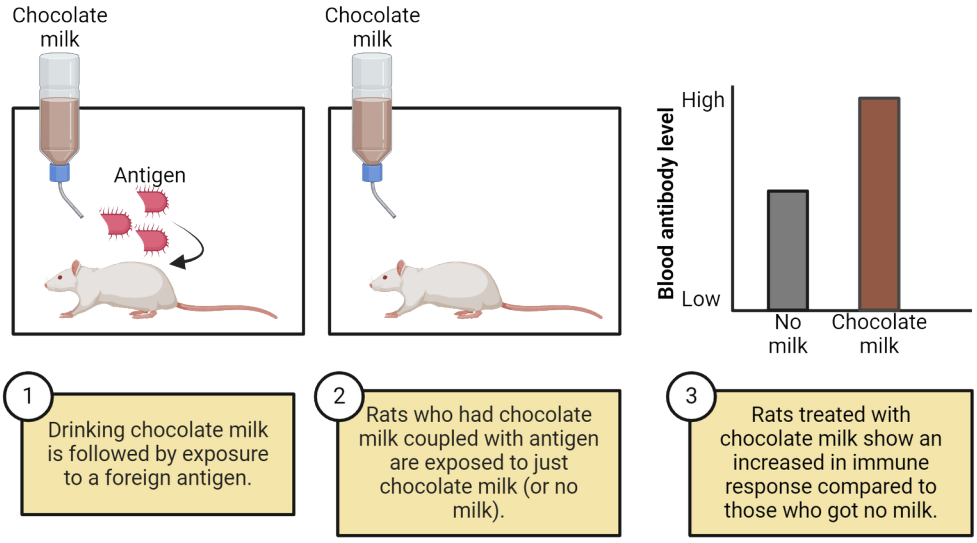

Figure 17.16 Behavioral conditioning of immune enhancement

Stress and the immune system

What if I told you that stress is good for you? Specifically, stress is good for your immune system. First, let's define some terms. A stressor is the thing that induces a biological response (like running from a raging bull or having to give a presentation in class). We call this biological response in its entirety a stress response. A major portion of the stress response is coordinated by the hypothalamic-pituitary-adrenal (HPA) axis. Figure 17.17 gives an overview of the HPA axis and its connections to the immune system and cytokines. Chapter 12 Stress covers the HPA axis in more detail. As a brief overview, during a stress response, hypothalamic cells release corticotropin releasing hormone (CRH) onto the pituitary gland. The pituitary gland, in turn, secretes and releases hormones such as adrenocorticotropin releasing hormone (ACTH) into the bloodstream. ACTH induces the release of glucocorticoids from the adrenal cortex (Turnbull and Rivier, 1999).

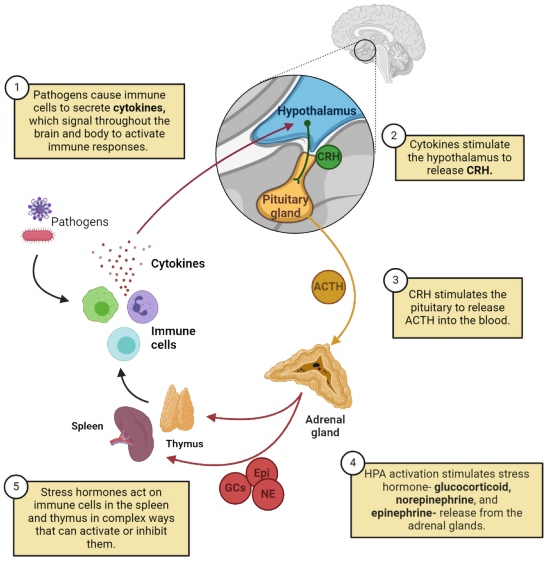

Figure 17.17 Neuroimmune communication pathways

Blood concentrations of circulating glucocorticoids increase in response to virtually any type of stimulus that poses a threat to bodily homeostasis, including immune system activation. During infection, cytokines profoundly activate the HPA axis. Cytokines produced by immune activation, such as IL-1β, IL-6, and TNFα, can act directly within the brain to induce the release of CRH via direct activation of neurons within the hypothalamus to start off the HPA cascade (Berkenbosch et al., 1987; Sapolsky et al., 1987). One of the first observations of brain-immune communication came from an experiment demonstrating that systemic

administration of LPS causes an increase in the stress hormone, known as corticosterone, in rodents (Wexler et al., 1957). Since then, it is well understood that the release of stress hormones is an important component of immune activation.

Stressors mobilize the immune system, sort of like rallying the troops. If we consider the body as a battlefield (which from a pathogen's perspective, it is!), we can think of immune organs like the spleen and lymph nodes as the barracks, where immune cell soldiers hang out playing cards and wait for a call to battle. When a stressor is perceived (which can be more "physical" like preparing to run from a bear, or "psychological" like sitting in traffic, late for class), the glucocorticoids that get released (like cortisol in humans) also bind to white blood cell soldiers in the barracks (mostly monocytes and neutrophils) which immediately jump into action, pour out of the spleen and lymph and into the bloodstream, and then crawl their way into the "battle stations" of the body—the skin, lining of the gut, and the lungs (Figure 17.18) (Dhabhar et al., 1996).

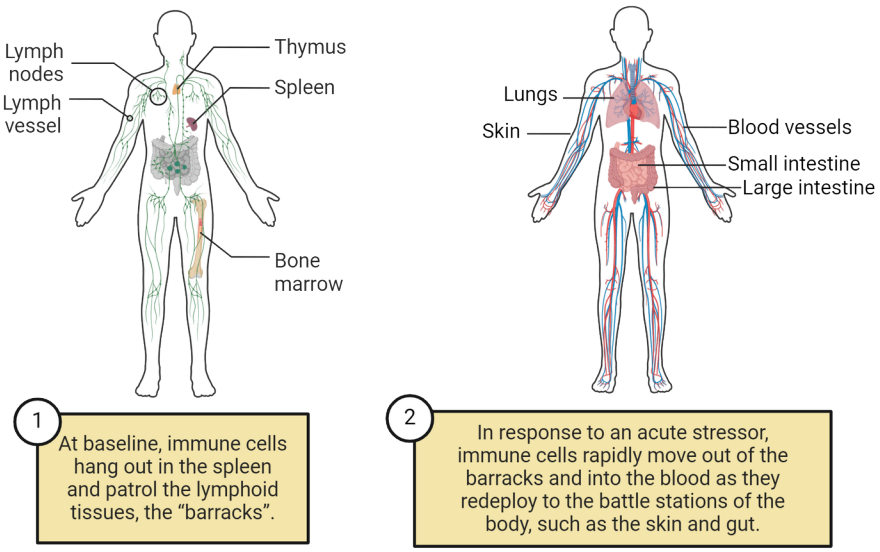

Figure 17.18 Immune deployment with stress

Why do immune cells pre-populate certain body areas just in response to stress hormones? Because these are the areas most likely to be injured, and subsequently infected, in response to a stressor (at least the types of stressors that we evolved to be scared of, like bears). The immune cell soldiers are poised in just the right location to respond. Indeed, if you stress a rodent prior to measuring an immune response in the skin, there is a larger inflammatory response (swelling) in response to a minor skin irritant compared to a rodent that was not stressed. This exaggerated response occurs whether you expose a rodent to cat urine odor alone (technically harmless) or an actual cat (potentially very harmful!). The important part is the stress perception in the brain is transmitted to the peripheral immune system in the form of inflammation, which is beneficial in the face of injury or infection.

The immune system and the "stress" system have co-evolved, and one doesn't work very well without the other. In fact, I would argue that it is impossible to have an immune response without also generating a stress response, and vice versa. But this response is again a Goldilocks phenomenon—the immune system works well when the amount of stress is just right, and not too low or too high. Chronic, uncontrollable, or unpredictable stressors can be extremely harmful for the immune system, and lead to immunosuppression, disease or pathology (Dhabhar and McEwen, 1999). Some of the earliest examples of this impact came from studies of human caregivers that experience a high burden of stress due to caregiving duties, e.g. of family members suffering from dementia. When given a small, experimentally-induced wound in the skin (using a biopsy needle), caregivers heal much slower than non-caregiver controls (Kiecolt-Glaser, et al., 1995). Similarly, dental school students healed punch biopsy wounds more slowly when exams were imminent, compared to more relaxed times of the semester (Marucha et al., 1998). In observational studies in humans, a longer recovery time after surgery is consistently observed for patients reporting higher levels of anxiety or perceived stress pre-surgery (Rosenberger et al., 2006). This pattern holds true for undergraduates as well—students who received a small wound to the hard palate of the mouth healed more slowly if they reported high levels of depression (Bosch et al., 2007).

Chronic stress can also lead to changes in anxiety via changes in immune function. In one study in mice, chronic stress led to a pathological "programming" of T cells which instructed them to enter the CNS and attack myelin, similar to what you see in some autoimmune disorders, and led to chronic anxiety (Fan et al., 2019; Bordt and Bilbo, 2020). In a series of other studies, again in mice, chronic defeat stress (which essentially entails frequent, forced interactions with a big bully mouse) led to monocytes

leaving the spleen, which travel not to the battle stations but to the brain, where they interact with neurons and microglia and stir up trouble, resulting in chronic anxiety (Weber et al., 2017; McKim et al., 2018). Blocking the entry of monocytes into the brain completely prevents the increase in anxiety. The reasons why monocytes and T cells get recruited to the brain (and not more helpful regions like the skin) in response to chronic stress in these studies is still not clear but is an active and important area of research in the field. In sum, there is a delicate balance when considering the impact of stressors on the immune system and the overall wellbeing of the host. But defining chronic stress can be surprisingly tricky, as different individuals respond quite distinctly to different stressors.

Exercise as a "good stressor"

One useful approach is to think about what stressors we evolved to confront, which are presumably bears and charging bulls, and not sitting in traffic. We increasingly understand that it is the resolution of a stress response that is key to its impact on our health, rather than its magnitude. That is, when the stressor is gone, our stress hormone levels need to drop back to normal and all those immune cell soldiers in the battle stations need to call it a day and go back home to their barracks. When we confront a physical stressor, we typically experience a physical resolution to that stressor (for example, the bear is gone and we stop running). This physical resolution helps signal for production of stress hormones to stop and calls our soldiers home. In contrast, psychological stressors may not involve any defining physical moment of resolution at all—they are profoundly "stressful" but the resolution is less clear. In this case, with resolution lacking, our soldiers never go back home, but stay on the front lines, getting bored and causing problems. Indeed, our modern stressful lifestyles and relative lack of activity are repeatedly associated with inflammation in our arteries and organs, which is very harmful for our health.

Fortunately, it turns out that bouts of physical activity (i.e. exercise) can help create that moment of resolution to more diffuse psychological stressors, just as if we had been running from a bear and then stopped when we successfully escaped. One reason that exercise, particularly "cardio" exercise, is so good for us is because it is, essentially, an acute stressor. When we exercise, we see a ramping up of our immune system very similar to any other stressor, including immune cell deployment to battle stations. Indeed, in one very exciting study in humans, light to moderate exercise (a brisk walk or jog) immediately after receiving a vaccine for either influenza or for SARS-CoV-2 increased serum antibody levels to each vaccine 4 weeks later (Hallam et al., 2022). Importantly, there were no impacts on vaccine side effects. Another study in mice demonstrates that a mild stressor prior to injection with a novel antigen (equivalent to a vaccination) resulted in greater antibodies to that antigen even 9 months later (Dhabhar and Viswanathan, 2005)! Perhaps the next time you go to get your flu shot you should run around the block a few times first! Importantly, at the resolution of the exercise/stressor, the soldiers go home. In fact, exercise may be critical in conditioning our immune system to resolve and return to homeostasis following activation. Over time, this has tremendous benefits for our health.

Autonomic nervous system control of immune function

Above, we discussed how the hormonal response to stress coordinates immune-brain crosstalk via the blood. The hormones and cytokines involved comprise a "humoral" route of communication. There is also a major "neural" route, in which the nervous system directly connects to the visceral organs of the body via the autonomic nervous system.

The autonomic nervous system (ANS) organizes interactions between the CNS and endocrine and immune organs (Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy) (Figure 17.19).

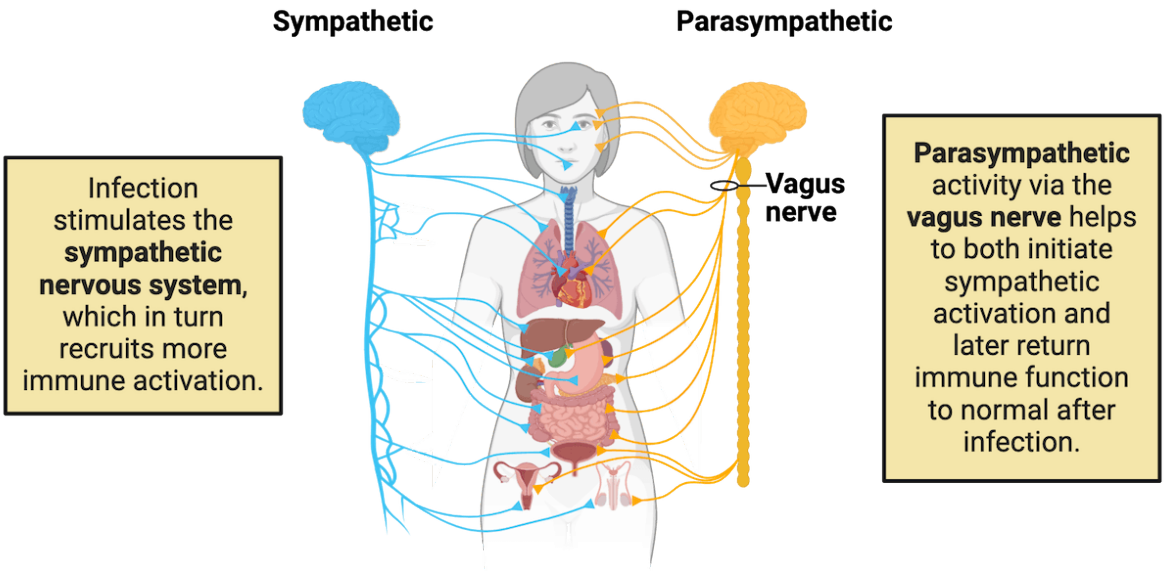

Figure 17.19 Autonomic regulation of immune function

As a review, recall that the ANS controls visceral body functions and innervates peripheral glands, and can be further divided into the sympathetic nervous system, which controls the fight or flight responses, and the parasympathetic nervous system, which controls functions under basic arousal such as digestion. The sympathetic nervous system is important in "ramping up" peripheral responses such as heart rate, and it does something similar to the immune system (Figure 17.20). For instance, during an infection, cytokines can bind to sympathetic fibers and this signals to the brain to mobilize the immune system in the periphery to fight the infection. The cells of the immune system (lymphocytes, monocytes, etc) possess receptors for many neurotransmitters and neuroendocrine mediators—many of these neurohormones are produced by the nervous system and thus allow the immune system to react to neural regulation. For instance, sympathetic activation of leukocytes via norepinephrine (NE) along with cortisol is the mechanism underlying leukocyte trafficking from the barracks to the battle stations that we discussed earlier.

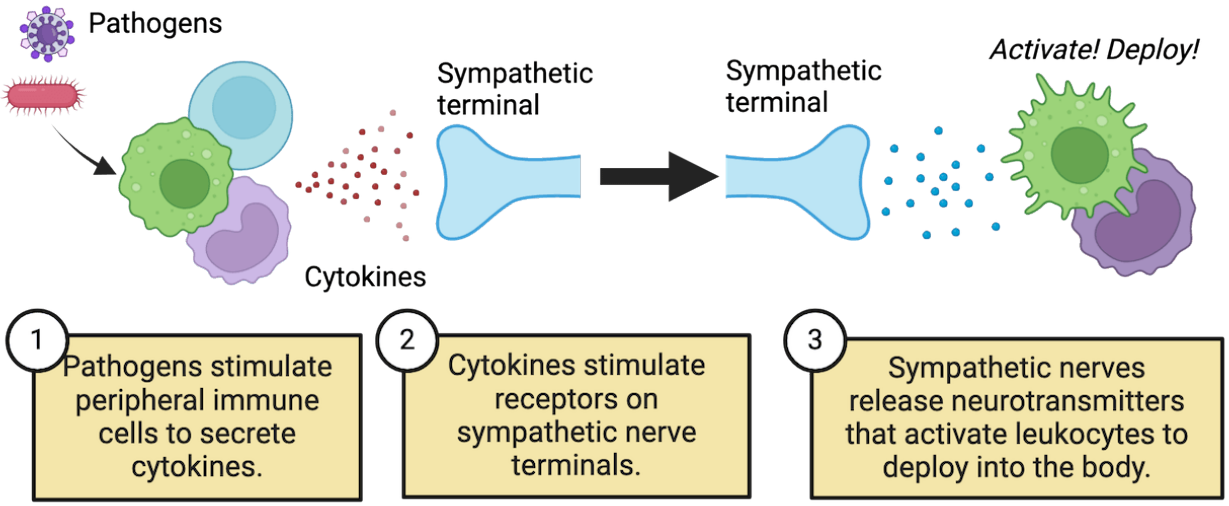

Figure 17.20 A closer look at sympathetic nervous system-immune system interaction

Whereas the sympathetic system is especially important for ramping up, the parasympathetic system is important for restoring homeostasis after an inflammatory challenge or stressor is initiated, primarily via the actions of the vagus nerve. Vagal efferents from the brainstem innervate the heart, gastrointestinal tract, liver, biliary system, and pancreas, among numerous other tissues (see Figure 17.19) (Berthoud and Neuhuber, 2000). The vagus nerve is also the primary nerve to innervate the major immune organs in the periphery, including the thymus, spleen, lymph nodes and bone marrow (see Figure 17.21). Thus, it can directly and discretely affect immune function at the level of an individual organ or localized tissue.

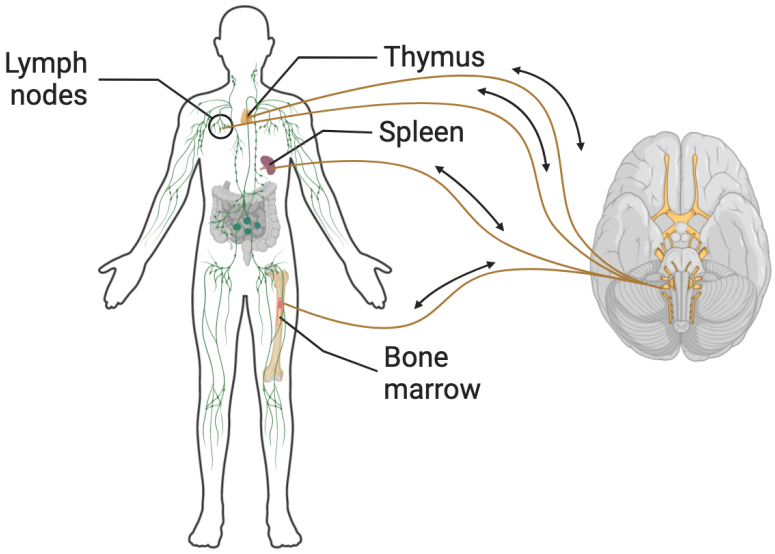

Figure 17.21 A closer look at parasymphatetic nervous system-immune system interaction In addition to other organs, the vagus nerve directly stimulates and receives inputs from many immune tissues.

The vagus nerve also transmits information regarding the state of the periphery to the brain. In fact, more than 80% of vagal fibers are afferent, conveying sensory information from the body to the brain. Some of that input is used to help initiate response to an infection–parasympathetic fibers throughout the body respond to signs of infection and further stimulate sympathetic activity, working in concert with the direct stimulation of sympathetic fibers by cytokines. For this reason, it's been suggested that the vagus nerve is the basis of our "sixth sense" and the reason that we have a "gut feeling" we may be sick, before we actually have any symptoms (Blaylock 1995). The importance of these innervations from the periphery to the brain has been demonstrated in many experiments which use surgical division of the vagus nerve, known as a vagotomy. Vagotomy blocks the induction of fever caused by peripherally administering the cytokine IL-1 or low doses of LPS. Vagotomy can also attenuate the sickness behaviors, e.g. decreases in behavioral exploration, caused by peripheral IL-1 administration (Luheshi et al., 2000; Hansen et al., 2001). Thus, the brain has the capacity to directly influence the peripheral immune system through specific neural pathways during peripheral immune activation and in response to all types of physiologically stressful situations.

The vagus nerve and the inflammatory reflex

Given its widespread distribution and localized innervation of specific tissues, the vagal afferent system is in an excellent position to convey immune-related stimuli to central areas via a so-called inflammatory reflex pathway (Berthoud and Neuhuber, 2000; Tracey, 2002). Just as a motor reflex within the body involves a sensory perception of pain or trauma and a rapid motor response, e.g. limb withdrawal to avoid that stimulus, the inflammatory reflex essentially describes the phenomenon that an inflammatory response mediated by parasympathetic afferent signaling and subsequent sympathetic activation is quickly followed by an anti-inflammatory response that returns the system to homeostasis. For instance, let's say that vagal afferents in the gut are activated by cytokines due to an infection, as shown in step 1 of Figure 17.22. This activation quickly sends a signal up to the brain which subsequently sends a sympathetic signal back to organs like the spleen, which activates cells like T cells and macrophages for deployment as described earlier (step 2 in Figure 17.22). This response is rapid, like a reflex. This immune activation/inflammation is short lived however, because within minutes to hours, the vagus nerve once again jumps into action, which culminates in the release of acetylcholine (ACh) that suppresses inflammatory cytokine production by macrophages (step 3 in Figure 17.22).

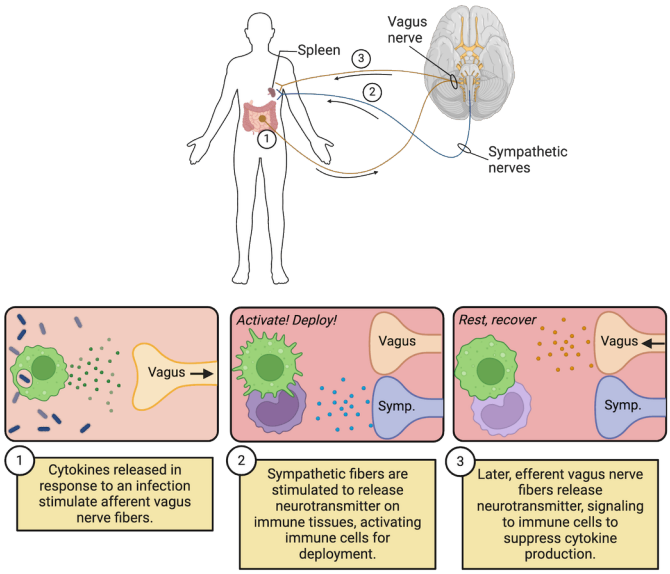

Figure 17.22 Inflammatory reflex

This “cholinergic anti-inflammatory response” is critical to prevent excessive immune activation, which could lead to organ failure and even death if not carefully held in check. For many years, however, the mechanisms by which this anti-inflammatory signal is received by the immune system was a mystery. The reason comes down to anatomy. It turns out that the splenic nerve which directly innervates the spleen produces norepinephrine (NE), not ACh. How, then, do macrophages in the spleen receive the ACh signal to stop producing cytokines? The answer is...wait for it...T cells! Truly groundbreaking experiments by Dr. Kevin Tracey completed in the early 2010s demonstrated this ingenious system (Rosas-Ballina et al., 2011)– during an immune response, sympathetic activation produces NE to rapidly activate macrophages. Shortly thereafter, the vagus nerve signals the splenic nerve to also produce NE which binds to a specialized subset of T cells that slowly ramp up production of ACh. This ACh binds to acetylcholine receptors on nearby macrophages to quickly shut off inflammatory cytokine production before it becomes dangerous (Figure 17.23). This system is a beautiful example of neuroimmune crosstalk that has stimulated a flurry of promising research designed to harness the vagus nerve “anti-inflammatory reflex” for the treatment of multiple disorders, including pathological pain and autoimmune conditions.

1.10.5: What Do Immune System Signals Do Once They Reach the Brain?

Learning Objectives

By the end of this section, you should be able to

- 17.4.1 Describe the historical foundations of the field of microglial biology and its neglect for the majority of neuroscience research history.
- 17.4.2 Describe how CNS-resident immune cells impact behavior via their interactions with neurons.
- 17.4.3 Describe how immune activation or inflammation during critical developmental windows may disrupt normal neurodevelopment and lead to neurological disease.

We've covered up until now the mechanisms by which the brain and immune system send signals back and forth to one another, and some of the implications for immune system function. We've also discussed earlier in this chapter some of the striking changes in behavior that occur during immune system activation, and why these changes might have evolved to occur. But what happens within the brain to mediate these behavioral changes, and are there any implications for normal behavior, i.e. when we are not sick? In this section you will learn about the primary "immunocompetent" cells of the brain and why they are important for brain and behavioral function, in sickness and in health.

Immune responses within the central nervous system

Immune responses within the brain are not identical to the periphery; inflammation is severely limited, but robust communication does occur among distinct cell types using cytokines and chemokines and other neuromodulators (i.e. neurotransmitters and neuropeptides). The majority of cell types within the brain, including neurons, glial cells (astrocytes, oligodendrocytes), and cells that line the vasculature, can produce and respond to cytokines in the course of an immune response. This communication goes beyond immune activation as well. For instance, some chemokines are important for neuronal migration during development, and may act essentially as neuromodulators, relatively independent of any classic "immune" functions. Importantly, as we first introduced in 17.1 Cells and Messengers of the Immune System, the brain has its own population of "resident" immune cells, microglia, which are essentially macrophages that enter the brain early in development and mediate several critical neurodevelopmental processes in addition to their functions in host defense. Microglia interact closely with neurons and can profoundly impact their function, in both health and disease. For these reasons, we will spend the majority of this section learning about these fascinating and important cells, and how their actions relate to behavior.

Microglia: a unique cell with a unique origin

During early brain development, neural progenitor cells (or stem cells) rapidly divide and differentiate into the distinct cell types that make up the CNS. These progenitors arise from a distinct layer of the developing embryo called the neuroectoderm, and give rise to essentially the entire nervous system, including neurons, astrocytes, and oligodendrocytes (see Chapter 5 Neurodevelopment). Microglia are a notable exception to this shared origin, beginning instead as immature macrophage precursors in the extra-embryonic fetal yolk sac. Starting early in fetal development, around embryonic day 8.5 (E8.5) in mice and around 5 weeks of gestation in humans, these baby microglia begin to exit the yolk sac and enter the developing fetal nervous system (around E9.5 in mice) via the ventricles and developing vasculature. This occurs during a process called primitive hematopoiesis in which most of the tissues (spleen, liver, gut, etc) of the body are first colonized by these early macrophage precursors, many of which are long-lived and slowly give rise to subsequent tissue-resident macrophages in any given tissue throughout life (Figure 17.24).

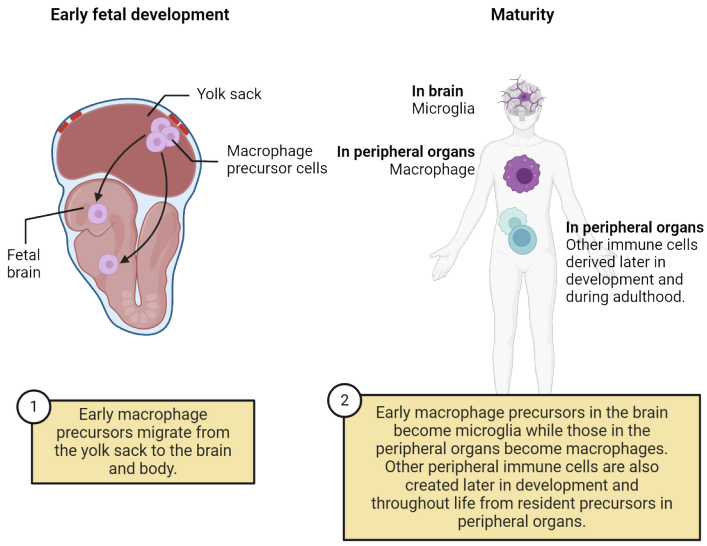

Figure 17.24 Origins of microglia

Subsequent waves of macrophages colonize and maintain most other tissues of the body from the fetal liver and eventually the bone marrow throughout life, but the brain is unique. Once the BBB closes around 2/3rds through pregnancy in mice and the end of the first trimester in humans, the microglia that originally seeded the brain from the yolk sac will divide and expand in number, self-renewing throughout the lifespan. This means that the earliest microglia to arrive into the CNS divide to create new microglia as needed throughout life. This attribute suggests that even small changes to these early microglia could profoundly impact future brain function, a concept we discuss a bit later (Askew and Gomez-Nicola, 2018; Thion and Garel, 2020).

Beyond the primary wave of microglia described above, there is also evidence that another, smaller subpopulation of microglia, homeobox (Hoxb8)-lineage microglia, colonize the brain a few days later, traveling from the yolk sac and through the fetal liver and aorta-gonad-mesonephros (AGM), a region of the embryonic mesoderm, to appear in the brain around E12.5 (Chen et al., 2010; De et al., 2018). Interestingly, a specific loss of Hoxb8+ microglia results in an overall reduction of microglia in the brain and a compulsive over-grooming phenotype in mice, a behavior that has been compared to obsessive compulsive behavior in humans (Chen et al., 2010).

This migratory mechanism for how microglia are introduced into the brain explains why microglia are known as “resident” immune cells of the CNS; much as immigrants to a new country are not native born but can become permanent residents and profoundly impact their environments. Remarkably, some of the earliest neuroanatomists to identify and describe microglia within the nervous system correctly surmised that these cells were “a third element” (Tremblay et al., 2015), as we discuss in the following section.

History of Neuroscience: The discovery of microglia

In 1852, a boy named Santiago Ramón y Cajal was born in Spain and forever changed the face of modern science. He was an aspiring artist that grew up to become a neuroanatomist and pathologist and shared the Nobel Prize in Medicine with Camillo Golgi in 1906 for their development of novel techniques to visualize and describe the nervous system. Cajal is widely viewed as the “father of neuroscience,” based in large part on the exquisite drawings he made of the fine features of the nervous system, using no more than a simple light microscope. Cajal is also famous for his legacy of trainees and students (Figure 17.25), counting among them icolás Achúcarro and Pío del Río Hortega (called by many the “father of microglia”) who first thoroughly described microglia and speculated on their functions based on methods to observe the fine processes of these cells and thus identify them as having a unique origin and lineage.

Figure 17.25 Students of Santiago Ramón y Cajal Nicolás Achúcarro: By J.R.Alonso, CC BY-SA 4.0, https://commons.wikimedia.org/w/inde...curid=37308995 Pío del Río Hortega: By Wilder Penfield. - Fotografía extraída del libro "Historia Argentina";. Hortega's discovery was apparently first met with skepticism and derision by Cajal as it contradicted his own classification of the cells as a type of oligodendrocyte. Eventually Hortega's careful body of work won out and we now recognize the cells as unique, with a cellular origin from the yolk sac and several specialized functions (Tremblay et al., 2015). Nonetheless, for the vast majority of the time since their discovery, around 100 years ago, these fascinating and important cells were ignored. Considering the long timescales of disciplines like medicine and physiology, our modern knowledge of their lineage and function is very new, having emerged within the last 20 years or less. So what changed? In large part, technology. Specifically, the ability to see microglia in action. Using a new method known as 2-photon microscopy, which allows researchers to visualize brain cells tagged with a fluorescent dye to observe their activities in "real time" in intact, living brains (usually through a clear window placed into the skull or via a very thin, transparent part of the skull), two neuroscientists near simultaneously in 2005 made an astounding discovery about microglia based simply on watching them (Davalos et al., 2005; Nimmerjahn et al., 2005).

Back in 2005, the prevailing dogma of the time was that microglia are largely static, "quiescent" (meaning resting) cells that sit in the brain and wait for an immune disruption like infection or injury to occur. But this theory didn't "sit" well for many (forgive the pun); given that microglia make up ~10-15% of the total cells in the brain, why would the brain invest so much energy in these cells only to have them function during relatively rare occurrences of CNS infection or injury? It turns out, they don't. The researchers were able to image these cells because of a genetic trick which inserts a green fluorescent protein into them so they glow bright green. Using this new type of imaging researchers discovered that microglia in a healthy, normal brain are extremely active all of the time, extending and retracting their processes into their nearby extracellular environments, even when a mouse is resting quietly (Nimmerjahn et al., 2005). Human microglia do this too and you can watch it in action here. If you compare them to cells like neurons, they are astoundingly active, wiggling their processes around like little spiders in your brain on the order of minutes. Given this rapid timescale, it is estimated that microglia scan the entire surface area of the brain in just a few hours. Moreover, if the researchers applied a brief laser injury to a part of cortex during one of these experiments, the microglia rapidly (within seconds!) moved their processes over to the point of injury (Davalos et al., 2005), like bees protecting their honeycomb, walling off and containing the injury to protect the surrounding tissue. You can see this effect in Figure 17.26, where a cloud of green microglia rush around the laser pulse location within minutes. They are indeed the soldiers of the brain in this case and are anything but quiescent the rest of the time.

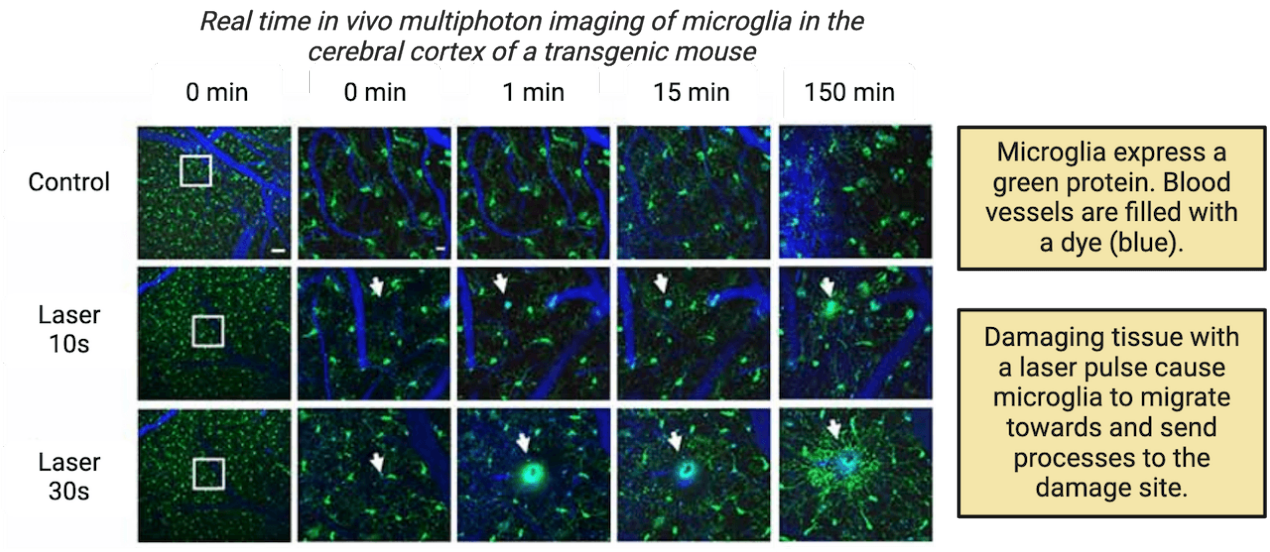

Figure 17.26 Photon imaging of microglia Data adapted from Hierro-Bujalance et al., 2018. "In vivo imaging of microglia with multiphoton microscopy." Front. Aging Neurosci., 19 July 2018 | https://doi.org/10.3389/fnagi.2018.00218. CC BY 4.0.

What are they doing?

What are microglia doing when they wave their processes in and out of the surrounding tissue? At this point, we don't entirely know, but we have some good clues. Their activities include detecting and responding to neural activity, removing debris and dead and dying cells, and chomping down on unneeded or unwanted synapses (Figure 17.27). Some of these activities have been directly linked to changes in behavior, including cognitive and social behaviors.

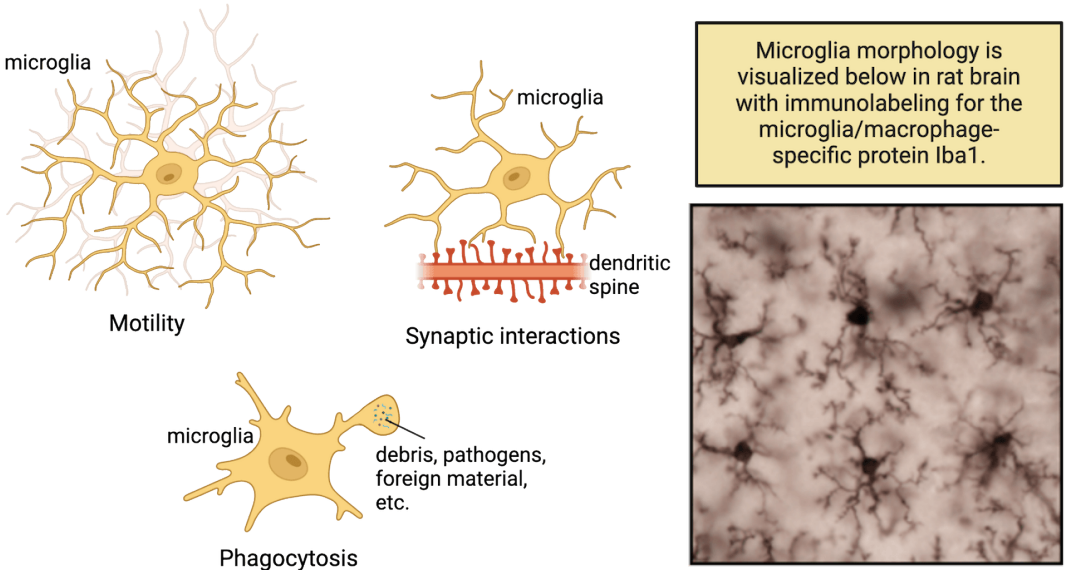

Figure 17.27 Microglia, multifaceted functions Microscopy image courtesy of SD Bilbo.

"Listening" to neural activity

Using the same imaging technique described above, researchers suspected that microglia might be moving their processes in and out of synapses, the small gaps in between neurons, in order to sample or "listen" to their chemical language, i.e., the neurotransmitters passed from cell to cell. Microglia have receptors for many of the major neurotransmitters, including serotonin, dopamine, and ATP. In one early experiment, Wake and colleagues discovered that microglial processes make contacts with synapses about 1x per hour. Moreover, they make more contacts with synapses from active neurons, as drugs like the sodium

channel blocker tetrodotoxin (TTX) which reduces neuronal activity also reduces the amount of contact between microglia and the silenced neuron (Wake et al., 2009). Similar results were obtained when animals were reared in complete darkness during a critical period of visual cortex development (Tremblay et al., 2010). In contrast, increasing neuronal activity in zebrafish by repetitive visual stimulation resulted in increased contact by microglial processes (Li et al., 2012). Therefore, microglia appear to monitor synaptic function and alter their behavior in response to changes in neuronal activity.

Often the result of all this listening and contact is to engage in phagocytic (eating) behavior. For instance, after stroke, microglia contact neurons within the affected region for much longer, and this is followed by the disappearance of presynaptic boutons from the affected cells, presumably removed by microglia as a protective mechanism designed to dampen cell damage (Wake et al., 2009). In general, microglia are very proficient at eating cells and parts of cells. During normal development, many cells die via a process called apoptosis (programmed cell death), and microglial cell division closely tracks the peaks in cell death within the early postnatal brain (see Chapter 5 Neurodevelopment). Microglia also regulate the number of developing neural stem cells within the prenatal cortex via phagocytosis even independent of cell death (Cunningham et al., 2013). This is in keeping with the fact that microglia enter the developing brain so early, much before other glial cells like astrocytes and oligodendrocytes are born. Notably, gene mutations that cause microglia to die early in development result in profound neuroanatomical abnormalities including loss of corpus collosum, ventricular enlargement, and even death in rodents and in humans (Hume et al., 2019; Oosterhof et al., 2019), pointing to the critical role of these cells in fetal brain development. Moreover, one of the most exciting discoveries of the past decade has revealed that microglia are also essential for eating neuronal elements postnatally, in a process called synaptic pruning.

Synaptic pruning

During postnatal brain development there are intense periods of exuberant formation of synaptic connections between neurons followed by a “pruning back” of inappropriate or excessive synapses (see Chapter 5 Neurodevelopment).

Given their proclivity for eating things, it was long suspected that microglia might play a role in synaptic pruning. However, it was previously unclear what molecular signals may promote synapse elimination by microglia and, more importantly, if this process was restricted to states of injury, or if it may have broader implications for shaping neuronal connectivity. These questions were methodically addressed by Beth Stevens and Dorothy Schafer in the context of visual system development (see Chapter 6 Vision). Axons from retinal ganglion cells in the eyes form many synaptic connections in the lateral geniculate nucleus (LGN) of the thalamus early in development. These imprecise and overlapping projections are then selectively eliminated in an activity-dependent fashion, resulting in remarkably precise eye-specific segregation of synaptic input (Luo and O’Leary, 2005). During the early postnatal period when synaptic refinement is still ongoing, microglial phagocytosis of retinal ganglion cell inputs is high, compared to time periods after eye-segregation is established (Schafer et al., 2012). This synaptic pruning is dependent upon neuronal activity. When neuronal activity in one eye is inhibited, microglia preferentially engulf and prune retinal ganglion cell input from that eye; conversely, when neuronal activity in one eye is augmented, microglia preferentially engulf and prune retinal ganglion cell input from the opposite eye. Thus, microglia participate in synaptic refinement during development by engulfing the synapse with relatively “weak” synaptic strength and then pruning it away. This general principle is diagrammed in Figure 17.28.

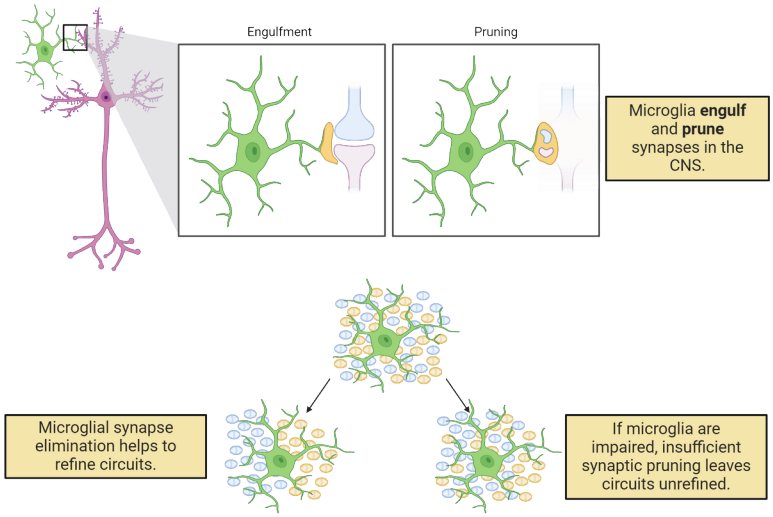

Figure 17.28 Microglial synaptic pruning

A more recent study has extended this landmark paper by demonstrating some of the behavioral consequences of microglial synaptic pruning. Yan Gu and colleagues found that microglia prune synapses in the hippocampus, an important region for learning and memory. Interestingly, if microglial pruning was inhibited in this region, the mice maintained a fear memory for much longer than if microglia remained unperturbed. Follow-up studies showed that microglia seem to target active memory supporting cells within the hippocampus as a component of normal forgetting (Wang et al., 2020). These exciting data may someday have implications for the treatment of stress disorders like PTSD via targeting the neuroimmune system.

Finally, recent experiments have also determined that microglia may even eliminate precise neurotransmitter receptors within certain synapses, and that this elimination is important for normal behavior. For instance, dopamine receptors, specifically Type 1 receptors known as D1r, are critical for the developmental regulation of social behavior in rodents. D1r numbers peak within the nucleus accumbens (a critical reward region) during a discrete period of adolescence in rats and then decline to adult levels. Moreover, this developmental decline in D1rs is directly linked to the normal developmental change you see in social play behavior in rats, as well as other “reward” driven behaviors that adolescents exhibit, like increased risk-taking behaviors and illicit drug use. Until recently, the mechanism by which this normal developmental decline in D1rs during adolescence occurs was unknown. Enter microglia! A recent paper shows that microglia very precisely prune these dopamine D1rs in adolescence in male rats. Moreover, blocking the removal of D1rs by microglia leads to a disruption of normal social behavior (Kopec et al., 2018) (Figure 17.29).

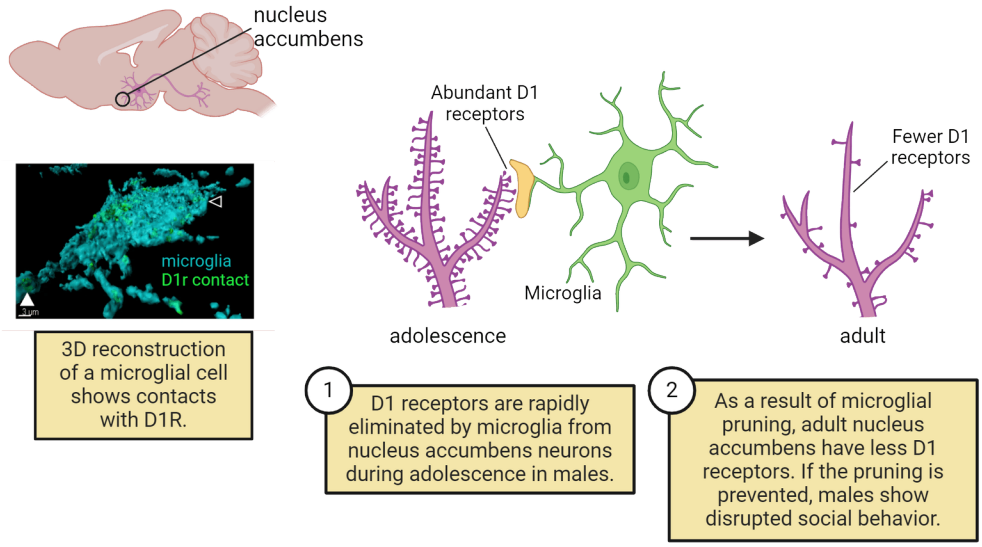

Figure 17.29 Microglia regulate social behavior 3D microglia from Kopec, A.M., Smith, C.J., Ayre, N.R. et al. Microglial dopamine receptor elimination defines sex-specific nucleus accumbens development and social behavior in adolescent rats. Nat Commun 9, 3769 (2018). https://doi.org/10.1038/s41467-018-06118-z. CC BY 4.0.

This role for microglia in the developmental elimination of dopamine receptors during adolescence raises the possibility that microglial pruning is also involved in the organization of other neural systems that regulate specific behaviors. Moreover, the data bring up very intriguing questions about how immune activation during critical windows of neural development, such as the prenatal, early neonatal, and adolescent periods might impact microglial function, including their pruning functions, and therefore long-term brain and behavioral outcomes. Interestingly, this receptor pruning by microglia was only observed in males. Female rats used a very different mechanism. This is only one of many examples of sex differences in microglial function that have emerged in recent years (Lynch 2022). This is currently a very active and exciting area of research in neuroscience because of the potential implications for neurological disorders, as we discuss in the next sections.

Developmental perspective: A starring role in neurological disorders

Up to this point, we've largely discussed the non-immune functions of microglia. Of course, let's not forget that microglia remain the primary immunocompetent cells of the CNS. They are the major source of cytokines. They share many functional and molecular characteristics with macrophages outside the brain, and play an important role in phagocytosing dead and dying cells and debris (Marín-Teva et al., 2004; Bessis et al., 2007). The fact that microglia can both respond rapidly to immune system signals with their own production of inflammatory signaling molecules (e.g., cytokines), as well as perform functions such as prune synapses and eat cells, has led to the hypothesis that immune activation, especially during discrete developmental windows, may disrupt the latter functions (proper eating and pruning), and thereby disrupt normal brain development and function (Hanamsagar and Bilbo, 2017; Bilbo et al., 2018; Dziabis and Bilbo, 2021).

Indeed, there is a growing literature examining the impact of immune activation, such as following infection or certain stressors, particularly during pregnancy and during the early perinatal period, on the developing brain, and thus the risk of a number of neurological disorders. This association has long been recognized in the epidemiological literature: maternal infection with a variety of pathogens during pregnancy, including influenza, streptococcus, and toxoplasma, is a risk factor for neurodevelopmental disorders in the developing offspring, including autism spectrum disorder (ASD) and schizophrenia (Atladóttir et al., 2010; Knuesel et al., 2014). Interestingly, the complement component (C4) gene is associated with synaptic refinement and has been linked to schizophrenia in humans, with greater expression associated with increased risk (Sekar et al., 2016). It is not yet clear what the role of microglia is in the association, if any, but given their important role in pruning and their robust response to immune activation, an association would not be surprising.

The type of infection during the prenatal period doesn't seem to be key for links between maternal infection during gestation and neurodevelopmental disorders, as associations have been noted with bacterial, viral, and parasitic pathogens. In rodent models, injection of LPS or a viral mimic or even exposure to environmental pollutants such as air pollution during gestation induces a so-called maternal immune activation (MIA) response along with behavioral abnormalities in the offspring consistent with some features of human autism and schizophrenia, such as social deficits (Smith et al., 2007; Bilbo et al., 2018; Kwon et al., 2022; Block

et al., 2022).

The consequences of early-life immune activation are also not confined to the prenatal period. Neonatal (right after birth) bacterial infection in rats induces a persistent change in microglial function within the brain such that they are more vulnerable (or "primed") to overreact to a subsequent LPS challenge in adulthood, an inflammatory reaction that results in cognitive problems (memory deficits) (Williamson et al., 2011). Similarly, mice that receive LPS as juveniles (postnatal day 14) are more susceptible to a stressor during adolescence due to persistent changes in their microglia, which results in excess synaptic pruning within the prefrontal cortex and depressive-like behaviors (Cao et al., 2021).

Notably, across species, perturbations during the adolescent period often have profound impacts on long-term behavior, as we alluded to above. For instance, the brain is highly neurobiologically vulnerable to addiction and social stress in humans at this time (Chambers et al., 2003; Kopec et al., 2019) (see Chapter 5 Neurodevelopment). Rodents that are exposed to chronic stressors as adolescents have increased anxiety-like behaviors weeks after exposure, much longer than rodents that went through the same stressors as adults (Yohn and Blendy, 2017; Cotella et al., 2019). Interestingly, administration of minocycline, a microglial inflammatory inhibitor, can prevent the development of schizophrenia-like behaviors following an adolescent stressor in mice, providing more support for the critical role of microglia in both the initial wiring and the refinement of circuits up through the adolescent period (Giovanoli et al., 2016).

Finally, moving beyond early developmental windows, there have also been several recent examples of how the normal phagocytic or synaptic pruning behavior of microglia may become reactivated or dysregulated later in life, contributing to disease and neurodegeneration. For example, in both Multiple Sclerosis and Alzheimer's disease, microglia wrongly engulf active synapses that are still very much in use (Hong et al., 2016; Werneburg et al., 2020). What are the mechanisms by which microglia go rogue? There is evidence that changes in microglia themselves may be key. Intriguing work by Anne Schaefer and colleagues has demonstrated that microglia possess different clearing functions in distinct brain regions commensurate with the cell clearing requirements of those regions. Specifically, microglia in the cerebellum clear many more cells compared to the striatum due to the much higher levels of normal cell death and turnover in the cerebellum (Ayata et al., 2018).

It is not clear what leads to the aberrant activation or "reprogramming" of microglia outside of experimental conditions, but a number of environmental factors which we have spoken about, such as infection, toxicants, and stressors, are hypothesized to lead to or increase inflammation and thereby result in aberrant pruning or phagocytosis during aging. Taken together, the results of both human and animal studies reviewed above show that this is an important and rapidly developing area of neuroscience right now, especially given the startling percentages of neurodegenerative diseases that are predicted for the coming decades as the population ages. The good news is that as we learn and appreciate more about the understudied role of the immune system in these nervous system pathologies, we can identify new and novel therapies to target and treat them.

The immune system is broadly divided into innate and adaptive responses. Innate responses are rapid, non-specific, and stereotyped, meaning that they occur in more or less the same pattern and intensity each time a pathogen or antigen is encountered. Adaptive responses are specific to the antigen encountered, ramp up slowly, and build long-term memory for specific pathogens. The immune system uses a diverse army of signaling molecules called cytokines and chemokines to communicate among its distinct cell types, as well as with the nervous and endocrine systems. The brain was once thought to be completely separate from the immune system, but we now know that it has its own resident immune cells- microglia- and likely is more exposed to peripheral immune cells than originally thought.

17.2 What Does Your Immune System Have to Do with Your Behavior?

In the face of acute illness, we have striking changes in our motivation and in our behavior, and these adaptive changes help us prioritize rest and isolation to overcome illness more quickly. These behavior changes are strongly influenced by cytokine signaling to the brain from immune cells responding to infection. In the long-term, however, these changes in sickness or stress-induced behaviors can become maladaptive, and the risk factors underlying this shift from a healthy immune response to a prolonged or pathological one are under intense investigation within the biomedical community.

17.3 How Does the Brain Talk to the Immune System?

Despite hundreds of years of prevailing dogma that the brain is “immune privileged”, we now know that the immune, endocrine, and nervous systems communicate via a number of well-defined routes. There is growing evidence that the nervous and immune systems co-evolved to keep us well. Our immune system can “learn”, changing its activity based on associations between environmental stimuli and perturbations in immune function. Cytokines or immune activation in the periphery potently activate the HPA axis leading to catecholamine and stress hormone release, which regulate immune responses. Stressor perception alone is also sufficient to profoundly impact the immune system via this response. The autonomic nervous system directly innervates the tissues of the immune system in the periphery. Immune activation of afferent fibers rapidly signals the brain to activate and mobilize the immune cells in the body via an efferent inflammatory reflex. Soon after, parasympathetic activation and release of anti-inflammatory acetylcholine leads to a tamping down of inflammation and return to homeostasis.

17.4 What Do Immune System Signals Do Once They Reach the Brain?

Microglia are specialized macrophages that colonize the developing brain and spinal cord from the fetal yolk sac early in development. They are the primary immune cells of the CNS and thus primary producers of cytokines, chemokines, and other neuromodulatory substances. Microglia were virtually ignored for the vast majority of neuroscience research, but we now know that they play critical roles in synaptic plasticity via actions such as pruning and phagocytosis of neural stem cells in the healthy CNS, in addition to their roles as immune cells. Given that they wear two hats—both building a normal brain and responding to immune activation and other threats to homeostasis—there is intense interest in the possibility that aberrant immune activation by diverse environmental factors or exposures during discrete windows of development and even aging could lead to pathology.

These data can hopefully lead to novel treatments or interventions.

1.10.7: Key Terms

17.1 Cells and Messengers of the Immune System

Innate immune system, adaptive immune system, pathogen, neutrophils, macrophage, phagocyte, antigen presenting cells (APC), B cells, antigen, T cell, complement cascade, monocyte, lymphocytes, antibodies, thymus, major histocompatibility complex (MHC), human leukocyte antigen (HLA), cytokines, chemokines, lipopolysaccharide (LPS), fever, blood-brain-barrier (BBB), lymphatic system, meninges

17.2 What Does Your Immune System Have to Do with Your Behavior?

Sickness behavior

17.3 How Does the Brain Talk to the Immune System?

Stressor, hypothalamic-pituitary-adrenal (HPA) axis, immunosuppression, autonomic nervous system, sympathetic nervous system, parasympathetic nervous system, vagus nerve, inflammatory reflex

17.4 What Do Immune System Signals Do Once They Reach the Brain?

Neuroectoderm, fetal yolk sac, primitive hematopoiesis, synaptic pruning, maternal immune activation (MIA)

1.10.9: Multiple Choice

17.1 Cells and Messengers of the Immune System

1.
The innate immune response:

a. is specialized to each specific pathogen.
b. ramps up slowly and adapts over time.
c. has a similar response to all pathogens.
d. uses T cells.

2 .
The adaptive immune response:

a. consists of cells and physical barriers.
b. is rapid and similar to each pathogen.
c. is carried out primarily by neutrophils and macrophages.
d. is specialized to each specific pathogen.

3.
Which of the following are ways macrophages attack pathogens?

a. Eating pathogens
b. Releasing complement proteins
c. Showing a piece of the pathogen to adaptive immune cells so that they can attack it too
d. All of these

4 .
What is the role of macrophages?

a. To make antibodies
b. To directly kill infected cells
c. To phagocytose pathogens
d. Spit their DNA out in nets to draw pathogens in

5.
T cells:

a. make antibodies.
b. directly kill infected cells.
c. phagocytose pathogens.
d. spit their DNA out in nets to draw pathogens in.

6 .
The cells that “remember” a pathogen you have encountered before so that your next adaptive immune response is stronger are:

a. B cells.
b. Monocytes.
c. Macrophages.
d. Neutrophils.

7.
Recognizing self-antigens is critical to preventing your immune system from attacking your own cells. How do your cells tell T cells not to attack them?

a. By presenting some self-antigen via MHC I

b. By presenting some self-antigen via MHC II
c. By presenting some pathogen antigen via MHC I
d. By presenting some pathogen antigen via MHC II

8 .
Lipopolysaccharide (LPS) is frequently used by neuroimmunologists to study sickness and inflammation responses. What is LPS?

a. A live bacterium that causes infection and fever
b. A piece of a bacterial cell component that causes an immune response but no actual infection
c. A vaccine that stimulates B cells
d. An antibody

9.
Which cells will you find in the brain of a typical healthy human?

a. Microglia
b. Neutrophils
c. T cells
d. B cells

17.2 What Does Your Immune System Have to Do with Your Behavior?

10 .
Sickness behaviors are caused by:

a. the loss of infected cells.
b. the pathogens infecting our neurons.
c. our immune system response to pathogens.
d. pathogens overwhelming our innate and adaptive immune responses.

11.
Blocking the cytokine response to illness will most likely:

a. increase sickness behaviors.
b. decrease sickness behaviors.
c. not affect sickness behaviors.

12 .
Sickness behaviors:

a. are stereotyped and do not change.
b. only change in response to temperature changes.
c. have only been studies in animal models, not humans.
d. are adaptable and can change with different environmental factors.

13.
Which of the following diseases may be associated with immune dysfunction?

a. Schizophrenia
b. Depression
c. PTSD
d. All of these

17.3 How Does the Brain Talk to the Immune System?

14 .
Which of the following is NOT a major reason that early researchers thought the brain had no immune system?

a. The BBB kept most innate and adaptive immune cells out of the brain

b. There were no diseases that affected the brain
c. Transplants in the brain were not generally immune rejected
d. MHC expression levels were very low under healthy conditions

15.
Which of the following statements is false?

a. The brain is immune privileged and has no immune response capabilities
b. The brain has a lymphatic system that allows interaction of T cells with neurons
c. The brain has resident immune cells that are critical to normal functioning and development
d. The BBB prevents entry of most peripheral immune cells into the brain under normal conditions

16 .
The HPA axis _____ the immune system response.

a. induces
b. is induced by
c. both induces and is induced by
d. is unrelated to

17.
Stress-induced activation of the immune system happens in response to which?

a. Physical stressors like an injury
b. Psychological stressors like sitting in traffic
c. Both physical and psychological stressors
d. Only the most severe stressors

18 .
Long-term, uncontrolled stress can lead to:

a. immunosuppression.
b. immunoactivation.
c. immunoprivilege.
d. immunocorrection.

19.
What appears to be critical to the beneficial effects of exercise as a stressor that activates the immune system?

a. Exercise has a clear resolution point at which the stressor ends and the immune activation resolves
b. Exercise leads to a smaller immune response than other stressors
c. Exercise lead to a larger immune response than other stressors
d. Exercise does not activate the HPA

17.4 What Do Immune System Signals Do Once They Reach the Brain?

20 .
Which of the following are roles that microglia play in the brain?

a. Eliminating synapses
b. Helping with development
c. Attacking pathogens
d. All of these

21.
Microglia can:

a. prune whole synapses.
b. cleave specific proteins off synapses.

c. eat cells and parts of cells.
d. Do all of these things.

22 .
What technique helped researchers discover that microglia are constantly moving?

a. Activating them with optogenetics
b. Activating them with chemogenetics
c. Watching them with a microscope
d. Genetic knockdown models

23.
During development, neurons and microglia come from:

a. neuroectoderm.
b. the fetal yolk sack.
c. different parts of the embryo.
d. the endoderm.

24 .
Maternal immune activation is associated with:

a. neurodevelopmental disorders in offspring.
b. offspring with a better immune system.
c. no real effect on offspring.
d. impaired maternal immune response to later pathogen exposure.

1.10.10: Fill in the Blank

17.1 Cells and Messengers of the Immune System

1.
The two basic divisions of the immune system are the _____ and the _____.
2 .
The three main types of innate immune cells are _____, _____, and _____.

17.2 What Does Your Immune System Have to Do with Your Behavior?

3.
Isolating, loss of appetite, and feeling fatigue when we are sick are examples of _____.
4 .
Interleukin-1 beta is a pro-inflammatory_____, and can induce sickness behaviors.

17.4 What Do Immune System Signals Do Once They Reach the Brain?

5.
Microglia come from this early embryonic structure: _____.
6 .
Microglia help remove synapses that are not being used early in development in a process called _____.

1.11: RESEARCH METHODS- HISTOLOGY IMAGING AND STIMULATING- HISTOLOGY REVIEW

- 4 main tissue types (by adult appearance)
  1. epithelia
  2. connective tissue
  3. muscle
  4. nervous
- 3 main tissue types (by embryonic lineage)
  1. ectoderm
  2. mesoderm
  3. endoderm

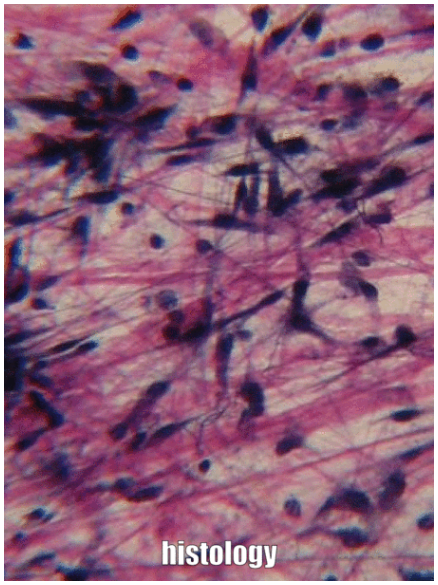

Figure 2.1: Histology of areolar CT, highlighting the cells, collagen fibers, elastic fibers and ground substance.

A short history of histology

The aim of this chapter is to review histology covered in your Anatomy & Physiology classes– but only the tissues that appear in the head and neck, and only the parts that are relevant to this course. This is by no means a comprehensive review. If you need an extra review on basic histology, try these links:

- An interactive histology flowchart
  - by Laird C. Sheldahl, Ph.D.
- The Internet Pathology Laboratory for Medical Education
  - at The University of Utah, Eccles Health Sciences Library.
- Histologyguide.com
  - by T. Clark Brelje, Ph.D. and Robert L. Sorenson, University of Minnesota.

Histology is the study of what tissues look like under a microscope. A **tissue** is a group of cells, all of the same major type, working together to perform a function. Because most cells are transparent, microscopists use of a number of different stains to highlight different parts of cells. Fig 2.1 is an image of a very common staining technique using the dyes **Hematoxylin and Eosin** (H&E)**.** These two stains turn molecules with negative charges blue, and positive charges pink. DNA and RNA take up both colors, which makes nucleuses purple, while most proteins turn pink. Unfortunately, most cells are full of proteins and their cytoplasm turns pink, but the extra-cellular matrix is also full of protein, which turns pink as well. We are therefore often trying to make sense of a sea of pinks with purple spots. On the plus side, if you purchase a histology coloring book, you only need two crayons.

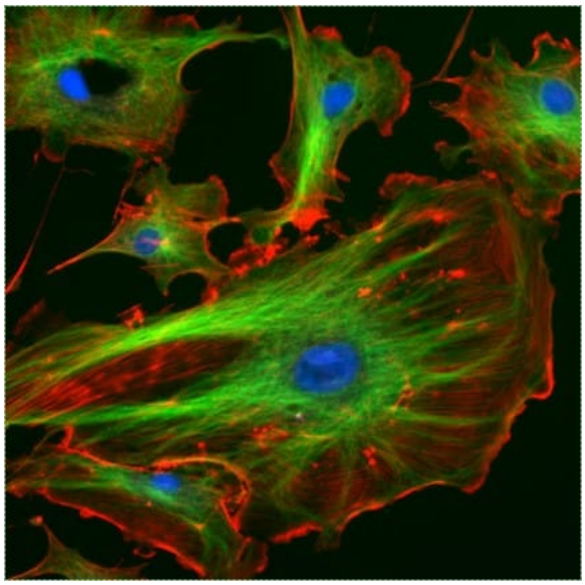

Figure 2.2: Example of a confocal microscope image. Image credit: : Fluorescent cells by NIH image is in the Public Domain CC0

Imaging

Most of the images you see in histology textbooks use stains such as H&E stains– this type of technology dates back to the 1800s. Microscope technology has improved since then, such as the image in Fig. 2.2, which comes from a confocal microscope. The confocal microscope uses expensive lasers to generate very beautiful images, but relies on stains which are theoretically similar to H&E. Sadly, most textbooks still use the old-fashioned (uglier) images. Since you should be using neither the newer nor the older microscopes in your line of work, we have illustrated most of the histology images in this book. This allows us to focus on the concepts, and spend less time developing the skills necessary to interpret pictures of pink blobs with purple spots. We presume that in the Anatomy and Physiology classes you took to get into this program, you learned to spot the differences between different types of tissues. We review those differences in this chapter. We ask you to keep an eye out for similarities between different tissues (aside from they all look like pinkish blobs with purple spots). If you jump ahead and read the embryology chapters, you'll have a better idea of what to look for, but for now just keep that thought in the back of your head as we cover the major tissues of the human body.

Enough embryology to start learning about histology

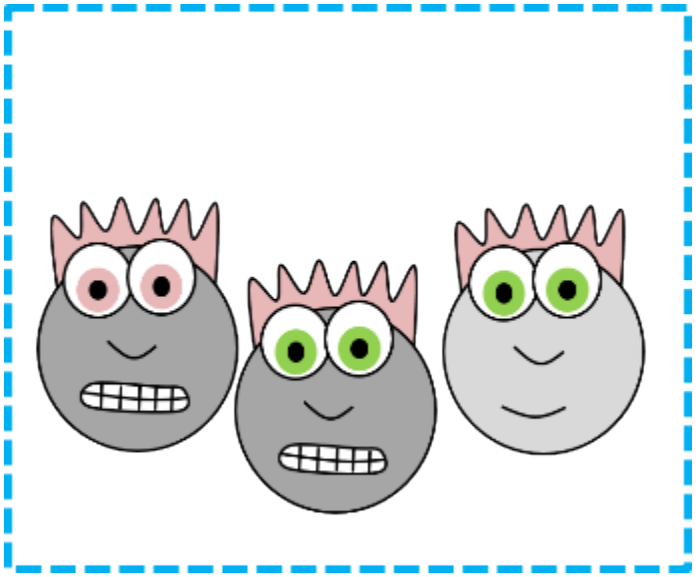

Figure 2.3: One possible way to group cartoon faces, based on a few physical characteristics.

Classification: the old way, and a better way.

Histology categorizes tissues based on what the cells look like in adulthood. If we determined people's families based off what they look like as adults, we might do an OK job of it, or we might make mistakes. For instance, we might lump the cartoon faces in Fig. 2.3 into two families based primarily on hair and eye color. That is how the 4 major tissues types we are going to review are categorized. The major problem with this sort of classification system is it is hard to tell what physical traits are due to nature (genetics, such as eye color) versus nurture (environmental factors, such as hair dye).

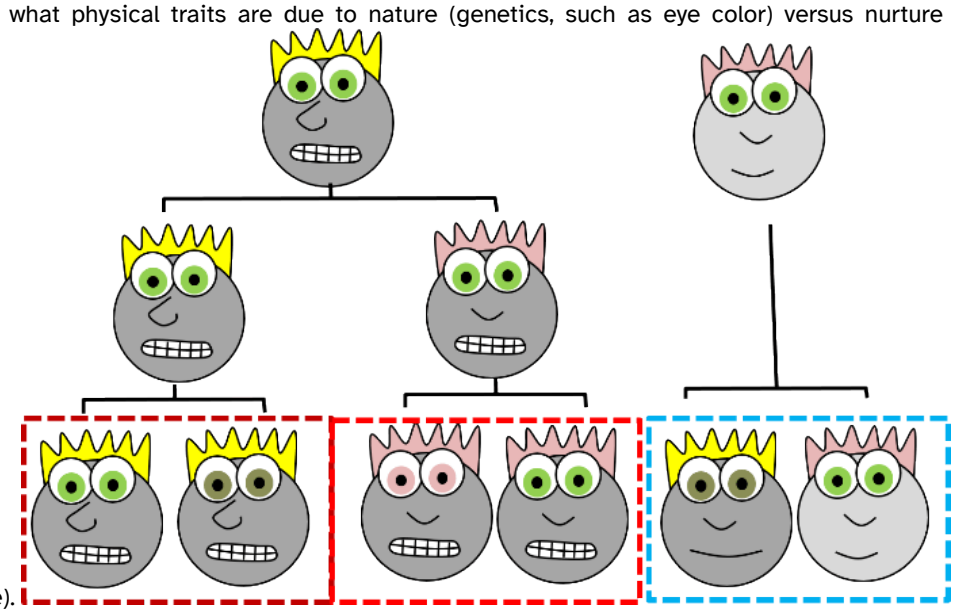

Figure 2.4: Another way to categorize cartoon faces, based off of lineage data.

When we learn about embryology, however, we see we can do better. We can categorize tissues using cell **lineage** instead, tracing who the adult cells are related to by following which cell they came from during embryogenesis. Early embryologists stained individual cells and followed them through cell division after cell division to see what they became. Others, such as Hans Spemann, moved cells from one place to another and asked whether they still turned into what was expected, based on their new location. When transplanting just a few cells lead to embryos with two complete heads, Spemann concluded that was unexpected. To get a better idea how that happens, science had to wait for the discovery of DNA-storing genetic information for an organism. Then, developmental biologists like Christiane Nüsslein-Volhard were able to determine the mechanisms by which a single embryonic cell became different types of cells in an adult organism–her organism of choice was flies, and for that work she won the Nobel Prize. Unlike earlier histologists and embryologists who named everything after themselves, we get fun names like Bicoid, Dickkopf, Frizzled and Sonic Hedgehog. These scientists followed the lineages of cells, watched what they become, and determined how the cells make decisions as to when and what to become. Rather than use the *appearance* of our cartoon people, if we knew their **lineage** (you might also see the fancier term **ontogeny**), we can classify them into more accurate families, with one sub-family (Fig. 2.4). When you see the word lineage, think family line, where differentiated cells are the youngest generation, and stem cells are their parents and grandparents. Sadly, this is not how histology is taught, so we're going to look at what adult cells look like and classify them based on physical characteristics. When we do, look to see whether two tissues have distinct borders (likely different lineages) or blended borders (often the same lineage).

The 4 main tissue types
Epithelial
Connective Tissue
Muscle
Nervous

Table 2.1: the 4 main tissue types

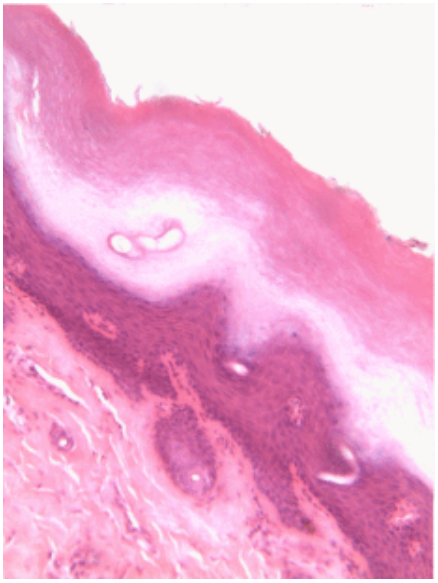

Figure 2.5: Example of an epithelium (with connective tissue below).

Epithelia

Location of epithelia

An **epithelium** is composed of epithelial cells, usually connected to one another in a sheet. There is very little ECM in an epithelium, mostly cells. The cells are anchored together by desmosomes, which holds them in a sheet. Tight junctions ensure that the things that travel from one side of the epithelium to the other pass through the epithelial cells, and therefore must either be lipid-soluble, or be recognized by transport proteins on the apical and basolateral plasma membranes. An epithelium therefore has **apical-to-basolateral polarity**. The apical surface faces the outside of the body, and the basolateral inward, and polarity means the two sides are different. The *outside* can mean the outer surface of the skin, or an inner surfaces, such as lining the oral cavity, stomach, and bladder. Every surface of the human body is an epithelium. Therefore, under the microscope, if you see an empty space, an epithelium borders that space. The inner lining of a sweat duct is an epithelium. The inner lining of a blood vessel is an epithelium. All other tissues are between that epithelium and the epithelium on the outer surface of our body. Even enamel is made by an epithelium, so if anyone tells you enamel is a connective tissue because it is *look*s similar to bone tissue, they haven't studied embryology, and need to be educated. Use words like *ontogeny*.

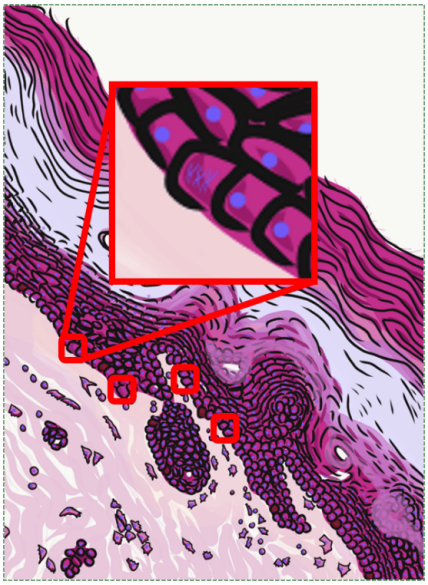

Figure 2.6: Stem cells in the basal layer of a stratified epithelium.

Epithelia are thin

Epithelial tissue is good at healing because it contains numerous stem cells capable of undergoing mitosis (you can tell by the presence of visible chromosomes, rather than chromatin). For thicker epithelia, stem cells reside in the deepest layer. Epithelia cannot be terribly thick, however, because they are **avascular** (without their own blood vessels). Nutrients for an epithelium must diffuse from underlying connective tissue, which is why in Fig 2.6, the epithelial cells on the apical side lack nuclei. They are dead, but still connected to the rest of the epithelium. The down-side to being good at mitosis is it means those cells are a few steps closer to becoming cancerous. Many people regularly expose themselves to high doses of carcinogens found in alcoholic beverages and tobacco (chewing tobacco in particular), which leads to oral cancers. In addition to membranes, glands are made of epithelial cells. Exocrine glands, such as the salivary glands, contain a single layer of epithelial cells, rolled up into tubes called ducts. These ducts bring exocrine secretions to a surface of the body. Endocrine glands, however, are different. They are not arranged in a sheet, but are amorphous clusters of epithelial cells. Endocrine glands aren't avascular, either. Blood vessels grow right into the epithelia of an endocrine gland. This is important because endocrine glands secrete hormones directly into the blood.

Number of layers	Shape of cells
Simple	Squamous
Stratified	Cuboidal
	Columnar

Table 2.2: The basic categorization of most epithelia.

Epithelia are mostly classified based on two criteria. With a few exceptions, epithelia have a name from the first column and a name from the second column of Table 2.2. **Simple epithelia** have just one layer of cells, while **stratified epithelia** have more than one. **Squamous** means the cells are flat, like fried eggs. **Cuboidal** means square-ish in appearance (cells are 3D, but look 2D under the microscope). **Columnar** means the cells are tall (like columns).

Figure 2.7: Simple squamous epithelia (endothelia) forming the walls of capillaries.

Simple squamous epithelia

If you look at the lining of a capillary, you *might* be able to see the **simple squamous epithelium** that lines the inner surface. These cells, called endothelial cells, are functionally really cool cells, even if they are hard to see. Normally, endothelial cells keep blood inside of a capillary, but they can become damaged, such as during probing, flossing or coughing.

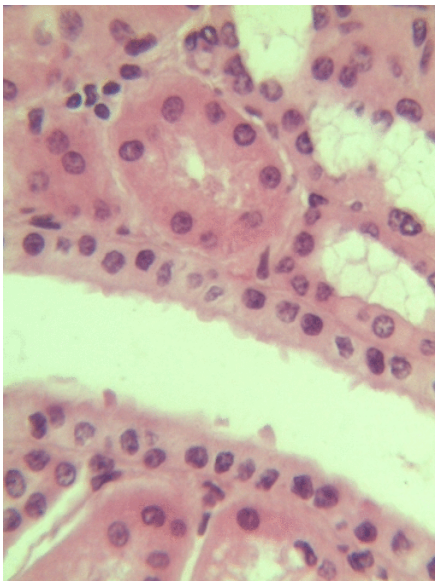

Figure 2.8: Simple cuboidal epithelia, histology and illustration. Legend: cuboidal epithelial cells (pink). underlying connective tissue (light blue) and lumen of tubes (white).

Simple cuboidal epithelia

Simple cuboidal epithelia line most exocrine gland ducts, such as sweat and salivary glands. In Fig 2.8, you should see two ducts coming out towards the camera, and one duct running side-to-side. The lumen of each duct is lined by a simple cuboidal epithelium. The cuboidal cells in the epithelium are connected to their neighbors on the sides by anchoring junctions. Where two ducts get close together, it is two simple cuboidal epithelia, not one stratified one, there are two separate layers of epithelia, with a little ground substance between them. Stratified cuboidal epithelia exist, such as in parts of the parotid salivary gland, but they are rare enough that we can skip them. The capillaries in Fig. 2.7 are lined by flat cells to allow for diffusion of nutrients out of the capillary and waste products in, while salivary ducts in Fig. 2.8 have thicker cells to keep saliva from leaking out and dissolving connective tissues of the face.

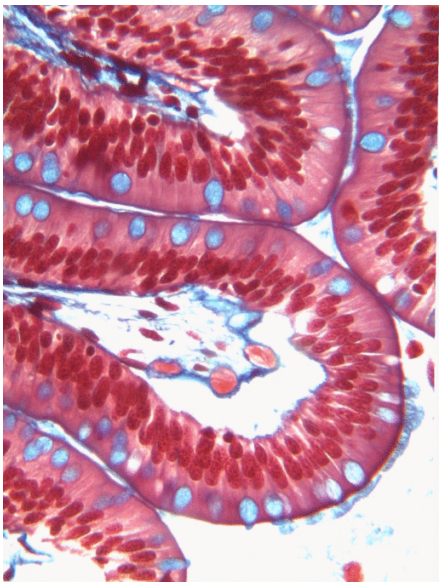

Figure 2.9: Histology of a simple columnar epithelium (highly folded), with illustrations highlighting the columnar cells (pink), goblet cells (blue) and the underlying connective tissue (lighter blue).

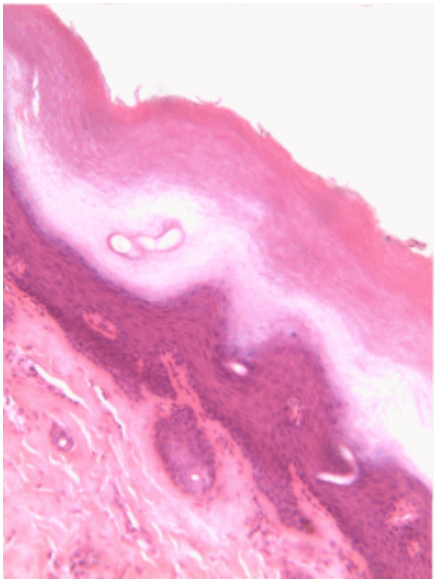

Simple columnar epithelia

Simple columnar epithelia are not found in the adult oral cavity, but in an embryo the columnar Inner Enamel Epithelium differentiates into enamel-producing ameloblasts during embryogenesis. The cells' shape isn't important other than it helps histologists to identify these cells in a developing tooth.

Figure 2.10: Lateral view of bed, showing a cat between the basolateral surface of the comforter and the apical surface of the thin bed sheet. Image credit: "photo" by unknown is in the Public Domain, CC0

If you are looking at the illustration in Fig 2.9, you may wonder why there are fewer cartoon nucleuses than visible in the histology picture. Did the illustrator mistakenly give you a picture of a stratified columnar epithelium and try to pass it off as simple? No. When we say an epithelium is simple, it means one cell thick from apical-to-basolateral. But when we cut a tissue sample to view under the microscope, the slice may be several cells thick from side-to-side. And when we lay the tissue sample on its side, the cells that were running side-to-side are now sitting on top of one another. We have illustrated what a simple epithelium *should* look like if we had the ideal one-cell-thick slice of tissue. This might be a good time to bring up perspective. Epithelia form flat sheets, and in Fig. 2.9 we are looking at a (folded) sheet in cross section. Imagine slicing through your bed and looking at it from the side view. You could make out the individual, single layers of your bed sheet and comforter. Furthermore, you might note that while each is a single layer, the bed sheet is thin and the comforter is thicker. You could identify the basolateral surface of your bed sheet (the side that touches you when you sleep) and the apical surface (the side close to the comforter). In Fig. 2.10, if there was a second cat on top of the first cat, we could say the layers of cats is stratified. But if the bed sheet was covered in a single layer of cats, side-to-side and front-to-back, the layer of cats would be simple. Under the microscope, we're doing the same thing, but unfortunately cells are semi-transparent, so it gets messy. When we call this a simple epithelium in Fig. 2.9, that means there is only one pink cell between the white space (here, the lumen of the intestines) and the very light-blue space (the connective tissue, where nutrients can be absorbed into blood vessels). Those cells are thicker than cells we looked at in Fig. 2.8, but there

are no columns on top of other columns.

Figure 2.11: Histology and cartoon of a stratified squamous epithelium (and a little connective tissue below).

Stratified squamous epithelia

Stratified squamous epithelia can be found in the outer lining of the skin, and the inner lining of the oral mucosa. While we have different names for the skin and the oral mucosa, if we were to name them based off of embryology, rather than superficial appearance, they would both contain a stratified squamous epithelium. Chapter 3 covers in more detail the epidermis of the skin, which is a keratinized stratified squamous epithelium. Keratin is a tough, water-resistant protein made by the main type of epithelial cell in this tissue, the keratinocyte. The stratified squamous epithelium changes at the vermilion border to less-keratinized, and the stratified squamous epithelium of the oral mucosa is either less or not keratinized. Based on that information, should we classify the vermilion zone as an extension of the labial mucosa, or as part of the skin and lips? Or is there a line in the vermilion zone that divides into a skin half and an oral mucosa half? It's times like this we could use the advice of an embryologist to inform us we shouldn't always look for lines in adult tissues, nor define borders between the skin, the vermilion and the oral mucosa based on color. If you change careers and go into proctology, use this same information down there.

Stratified cuboidal, stratified columnar and transitional epithelium

These tissues are not appearing in this textbook.

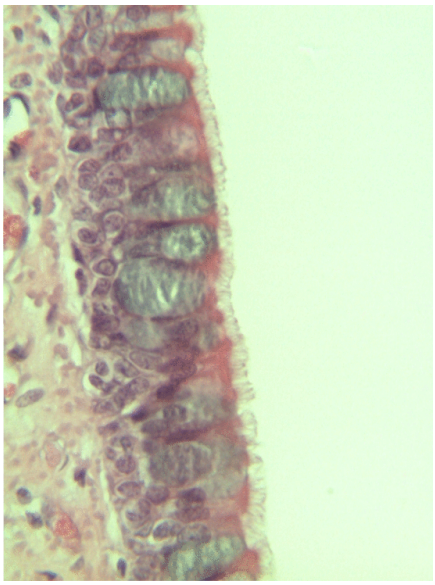

Figure 2.12: Pseudostratified epithelium, histology and cartoon. Order of appearance: epithelial cells, goblet cells, underlying connective tissue.

Pseudo-stratified epithelia

Ciliated pseudo-stratified columnar epithelium, or as many people say, **pseudostratified epithelium**, can be found in upper portions of the respiratory tract, such as lining the nasal cavity and the para-nasal sinuses. This tissue definitely deserves a different name from the stratified squamous epithelia of the skin, labia and oral mucosa. However, it probably didn't need to break the naming rules outlined in Table 2.2. A pseudostratified epithelium has more than one layer, but it is hard to count how many. As a result, someone named this tissue *pseudo*-stratified. The big fat blue cells in Fig. 2.12, which don't have cilia, are **goblet cells**. These cells produce **mucus**. Goblet cells synthesize mucous proteins within their rER and secrete them, and when they attract water, they become mucus. This is very similar to ground substance, however mucus is secreted out of the body, ground substance is a part of the body. The blue coloring of the goblet cells tells us that mucous proteins do not carry the same ionic charges as most proteins found within the epithelial cells of the pseudo-stratified epithelium. Due to this difference in color, they are classified as a distinct cell– a unicellular gland found within the pseudo-stratified epithelium. But what does our friend the embryologist say? Well, the columnar cells can't become goblet cells, and the goblet cells can't become columnar cells, but they do share a common ancestor (or stem cell), so we probably should consider the goblet cells a part of the pseudo-stratified epithelium. Does it matter? No, but questions like this matter later in the book, it's good to start practicing now.

Connective tissue (CT)

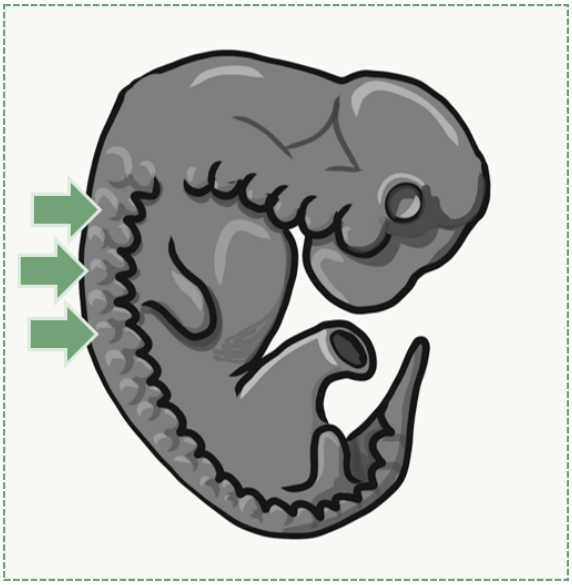

Figure 2.13: Somites of an early stage embryo, from which connective (and muscle) tissue develop

General characteristics of connective tissue

Many textbooks tell you **connective tissue** connects 2 other tissues. That's like saying your smart-phone connects you to other people. It is technically true, but glosses over the fact these could be people you know, people you don't know, or people you don't want to know. It ignores the fact you could be communicating synchronously with people on the other side of the world, communicating asynchronously over email, accessing information from the near sum-of-all human knowledge (the internet), or reading the sophomoric rant of some disgruntled knuckle-dragger who, years ago, posted a rude comment on a YouTube video recording of a histology class lecture (also the internet). So far, we've tried to keep you, the reader, safe from extraneous information about histology that is not be relevant to your career. Here we go into *more* detail than your average undergraduate histology class. Connective tissues come from segments of tissue in an embryo, found between two layers of epithelium, called somites (Fig. 2.13). Because of their shared lineage, connective tissues share a number of common features. The average connective tissue has few cells, and is mostly composed of Extra-Cellular Matrix. That matrix includes glycoproteins and polysaccharides made by the cells, which attract water to form the gel matrix of ground substance. It also includes more visible fibers. Some important ground substance molecules covered earlier are Fibronectin and Hyaluronic Acid. The three main types of visible fibers are collagen, reticular and elastic fibers. Connective tissues are typically highly **vascular**, meaning they contain blood vessels. There are a number of different cell types found within a connective tissue. The stem cells are **mesenchymal stem cells** (MSCs). Mesenchymal stem cells are extremely important cells (here is further reading), and since you can find them in adult tissues they are called a type of **adult stem cell**. These cells are capable of undergoing mitosis to produce more adult stem cells, which can differentiate into fibroblasts, lipoblasts, chondroblasts, osteoblasts, hemocytoblasts, myoblasts and neuroblasts. Thus, they form most connective tissues, including bone, cartilage, blood (both red and white blood cells), plus muscle tissue. That's pretty much everything except epithelia, which mesenchymal stem cells can form as well after going through a transition.

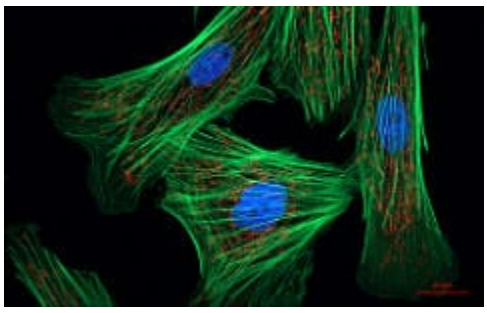

Figure 2.14: Fibroblasts, as seen under a confocal microscope. Image credit: Indian Muntjac fibroblast cells By Michael W. Davidson is licensed CC BY 2.0

In a basic connective tissue, mesenchymal stem cells divide and differentiate into **fibroblasts**, the cells that blast out the fibers and ground substance found in ECM. There may be other cells found in a connective tissue, including adipocytes, red and white blood cells, or other cells that have emigrated from their tissue of origin. In a mature connective tissue, the fibroblasts are sometimes called fibrocytes, which fits with our regular nomenclature for a cell going through stages of differentiation. More frequently, however, they are called fibroblasts and we don't worry about whether they are actively blasting out fibers at the time or taking a rest.

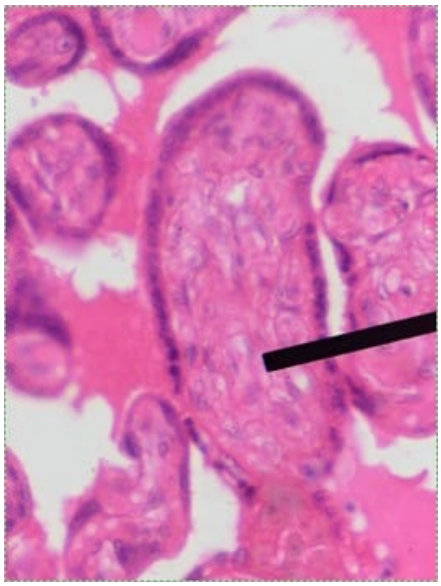

Figure 2.15: Mesenchyme, the generic embryonic connective tissue, doesn't have any specialization. Image credit: Human Mesenchyme By Jpogi at Wikipedia is in the Public Domain CC0

Mesenchyme

Mesenchyme is the first type of connective tissue an embryo makes. It differentiates into other connective tissues. It is an embryonic tissue that has yet to decide what it will become when it grows up. It is composed mainly of mesenchymal stem cells and **mucous** ground substance (*mucous* is an adjective to describe loose ECM, while *mucus* is a substance excreted from the body). There is a special type of mesenchyme important to face and tooth development, called **neuro-mesenchyme**. The lineage of neuro-mesenchyme is not from mesoderm like most connective tissues, but from a special type of neuronal cell called a Neural Crest cell. Neuro-mesenchyme forms special connective tissues we have yet to mention: dentin, cementum and the periodontal ligament.

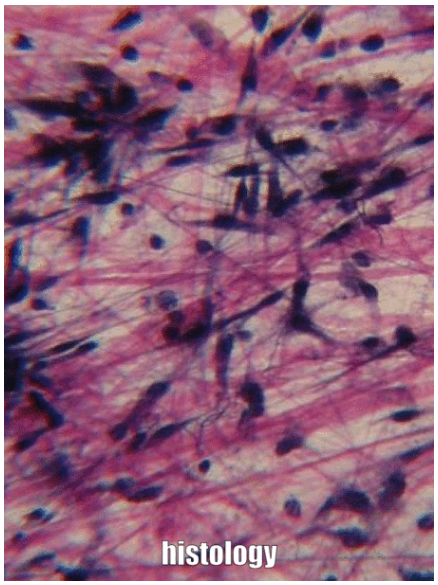

Figure 2.16: Areolar connective tissue, histology and cartoon.

Areolar connective tissue

Areolar connective tissue is the quintessential connective tissue, or the most boring depending on how you look at it. It contains a little of everything other connective tissues might have: cells, ground substance, and all 3 fibers. Because it has a good amount of ground substance, it is an ideal tissue to occupy places where blood vessels might need space to grow in the future. Hence areolar CT is found in regions that are highly vascular. This is why you can find a small layer of areolar connective tissue directly underneath nearly every epithelium, including the stratified squamous epithelium of the various types of oral mucosa. Ground substance also absorbs water and swells in size, which is why the areolar connective tissue of the nasal cavity is also referred to as erectile tissue.

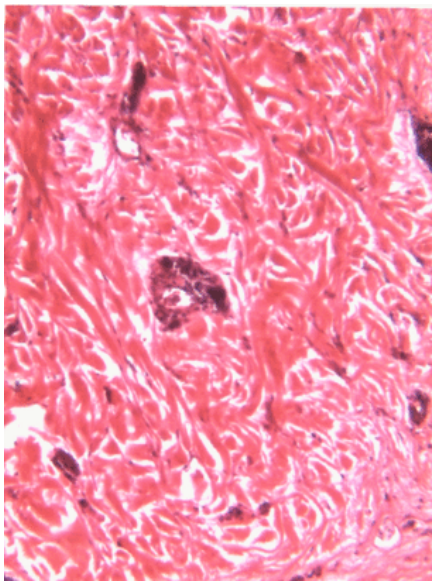

Figure 2.17: Dense irregular connective tissue, histology and cartoon

Dense irregular connective tissue

Underneath the areolar CT of the oral mucosa is **dense irregular connective tissue**. Fibroblasts make the bulk of the tissue: collagen fibers, the strongest of the 3 fiber types. In a dense irregular CT, the collagen fibers point in all directions. This makes this tissue particularly strong in all directions. In Fig. 2.17, most of the pink is extracellular collagen fibers, and the white space

ground substance. You can find dense irregular CT (along with its buddy, areolar CT) in the dermis of the skin. Why in both places, you ask? Lineage.

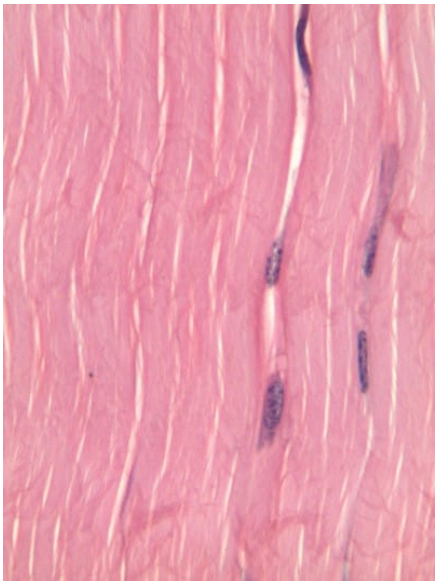

Figure 2.18: Histology of dense regular connective tissue.

Dense regular connective tissue

Like dense irregular CT, **dense regular connective tissue** is mostly collagen fibers, only the fibers run parallel to one another. That makes this tissue strong in one direction. You mostly find dense regular CT between muscle and bone, or between bone and bone. The only place in this book where we find dense regular CT is the periodontal ligament, between bone and cementum. You might be thinking the collagen fibers look wavy, not parallel. When someone sliced this section of a tendon, they sliced through the tissue using a thin blade. As a blade cuts the tissue, the tissue moves, and so the blade pushes fibers in one direction, then pulls them back, and pushes again as the person slices as thin of a slice as they can. For better results, use an expensive device that freezes or embeds soft tissues in wax, such as a microtome, cryotome, or vibratome. We bring this up because many textbooks suggest histology is a nearly-perfect representation of what is found in the human body, when in reality there are **artifacts**, or errors, that histologists have learned to ignore when we see them. We have chosen to illustrate many of the images in this book to avoid discussion of artifacts where possible, and focus on concepts relevant to dental hygiene.

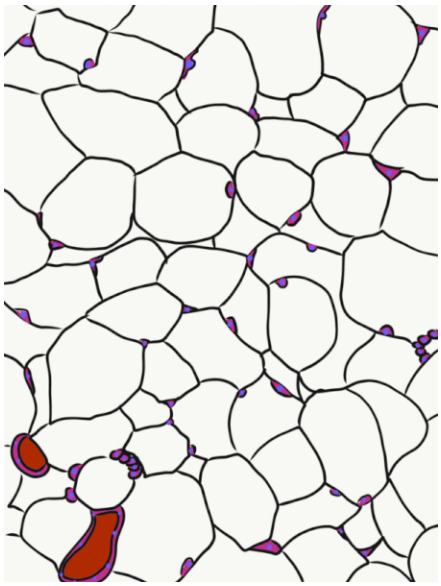

Figure 2.19: Adipose connective tissue, histology and cartoon

Adipose connective tissue

Adiposetissue is a type of connective tissue. It is special in that is has very little ECM. It contains mostly **adipocytes**, the mature cells that store triglycerides. It also contains mesenchymal stem cells, which if a person needs more adipose tissue, divide and differentiate into more adipocytes. Technically, Mesenchymal Stem Cells differentiate into a lipoblast first, but this is only important for the sake of staying consistent with the naming system. Maybe if they had named the cells adipoblast and adipocyte, we'd use the -blast name more frequently, but someone messed that up. Many textbooks place adipose tissue next to areolar connective tissue and categorize them both "loose", on account of their low number of visible fibers. That's fine if you like categories based on appearances, but you don't need to call either of them "loose". It is descriptive and does not correspond to anything embryological. We find adipose tissue in many places throughout the body, either between two other tissues, or embedded within another tissue (such as the adipose you find in bacon). On the other hand, areolar connective tissue is found next to dense irregular connective tissue, which is why we've deviated from the grouping found in most textbooks.

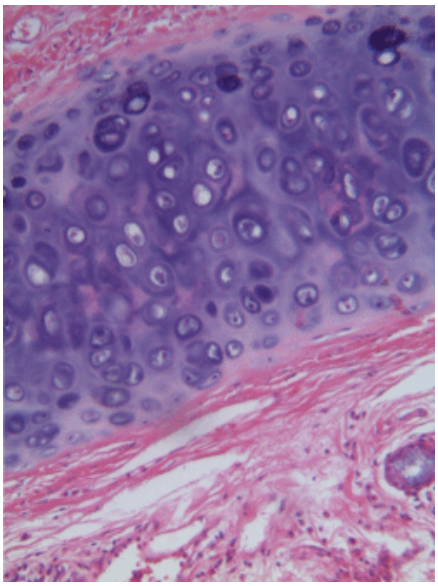

Figure 2.20: Hyaline cartilage, histology and illustration. Order of appearance: lacunae, chondrocytes, ground substance, perichondrium, surrounding dense connective tissue.

Cartilage connective tissue

Cartilage connective tissue comes in three basic flavors: hyaline cartilage, fibrocartilage and elastic cartilage. The hallmark feature of cartilage connective tissue is its ample amount of ground substance. **Chondroblasts** secrete glycosaminoglycans and glycoproteins, such as Hyaluronic Acid, which attract water, forming a very dense but slippery gel. The ECM of cartilage contains collagen– there is more collagen in the fibrocartilage of the temporo-mandibular joint, whereas the elastic cartilage of the epiglottis has more elastic fibers. After secreting ECM, the chondroblasts differentiate into **chondrocytes**, and reside within the tissue in spaces called **lacunae** (lakes). The outer edges of cartilage are a thin layer of parallel collagen fibers known as the perichondrium. If you look at Fig 2.20, the perichondrium appears like a layer of dense regular connective tissue (it is, it just has a second name), and the edge of the perichondrium blends into dense irregular connective tissue. The reason the cartilage blends into dense irregular connective tissue is they share the same lineage: chondroblasts and fibroblasts both differentiate from mesenchymal stem cells.

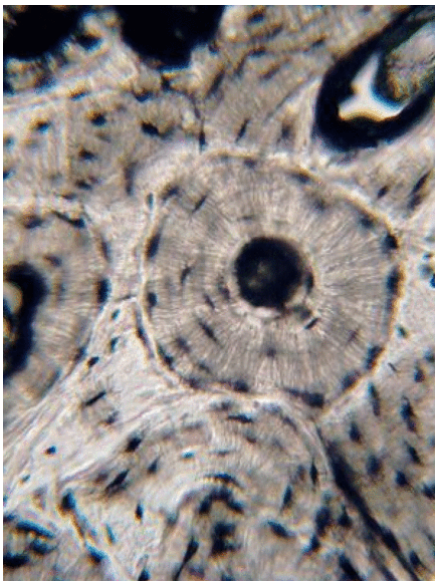

Figure 2.21: Bone connective tissue, histology and cartoon highlighting osteocytes and lamellae of ECM.

Bone connective tissue

Bone tissue (or osseus tissue) is the last type of connective tissue we cover in detail. Because of its similarity to dentin, cementum and enamel, we cover bone tissue in a fair amount of detail. Like any connective tissue, bone tissue starts as mesenchymal stem cells, which differentiate into an intermediate stem cell called an osteo-chondro-progenitor cell, which can in turn decide to adopt an osteoblast or a chondroblast fate, depending on what signals it receives. A stem cell that has adopted the osteoblast fate (and denied the chondroblast fate) would be an **osteo-progenitor cell**. These osteo-progenitor cells are stem cells within the connective tissues surrounding bones, the **periosteum** (superficial) and **endosteum** (deep). When stimulated, they undergo mitosis, and one daughter differentiates into an osteoblast. An **osteoblast** is the cell that secretes the ECM that makes up the bulk of bone tissue. Osteoblasts secrete collagen fibers and ground substance, which later mineralizes, trapping the osteoblasts inside of a **lacuna** (a small space within dense ECM). At this point, they differentiate into **osteocytes** and maintain the bone tissue. Next, a new set of osteoblasts lay down another layer of bone tissue around the previous one. This creates either the concentric layers of bone tissue found in the osteons of **compact bone**, or the thinner spiral layers of bone tissue found in the trabeculae of **spongy bone**.

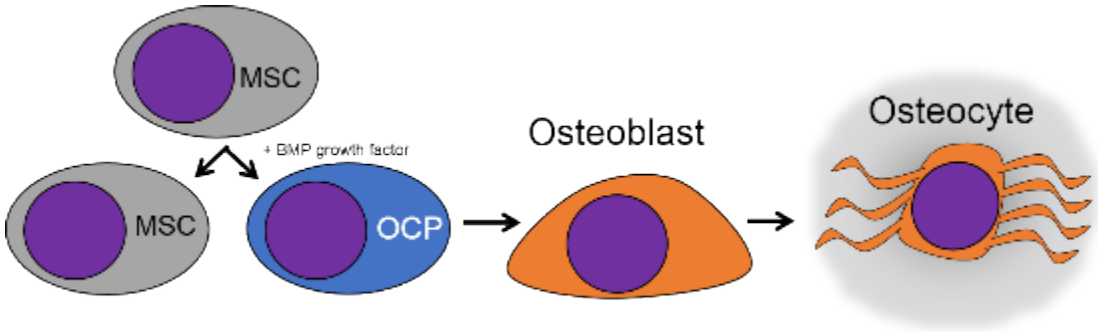

Figure 2.22: Three (of four) major cell types found in bone tissue and their lineage. MSC = mesenchymal stem cell, OCP = osteo-chondro progenitor cell.

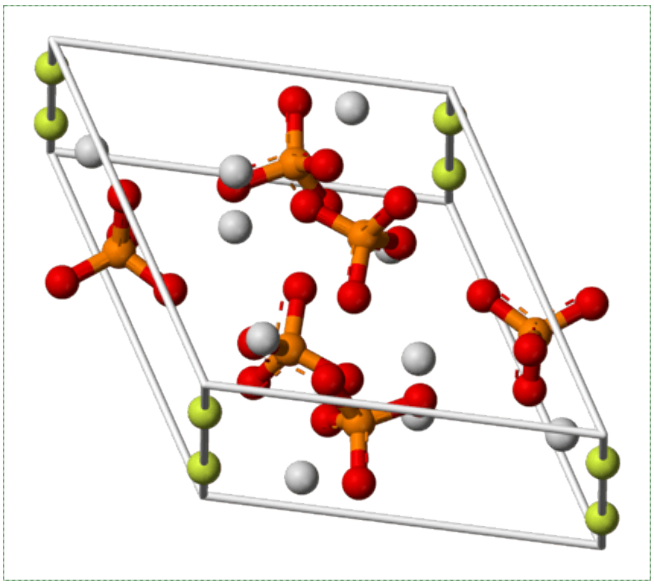

Figure 2.23: Calcium hydroxyapatite crystal structure of bone ECM. Legend: Red/orange = phosphate, white = calcium ions, yellow = hydroxide ions. Image credit: Fluorapatite by Von Benjah-bmm27 in the Public Domain CC0

The extra-cellular matrix of bone tissue is roughly 1/3 collagen fibers (organic protein) and 2/3 mineral (inorganic). The mineral component is a mixture of positive-charged Ca^{2+} ions, which react with negative-charged phosphate (PO_4^{3-}) to form a hard, crystalline matrix. Because most cells are full of phosphate, Ca^{2+} levels in the cytoplasm must always be kept very low, so if a cell like an osteoblast wishes to store Ca^{2+}, it does so within its smooth Endoplasmic Reticulum. The $Ca^{2+}PO_4^{3-}$ further react with water (or more specifically, hydroxide ions OH^-) and small amounts of fluoride(F^-) to form a crystal named **calcium hydroxyapatite**. Dentin, enamel and cementum have ECM very similar to bone tissue, only with varying amounts of collagen versus mineral components. Collagen fibers run parallel within one layer of bone tissue, and 90° in the next layer. While the mineral component of bone and tooth tissues provides strength, the collagen provides the ability to bend or flex, reducing the chances the tissue will shear off under stress. Collagen fibers, therefore, have a function similar to the rebar in reinforced concrete. The lower percentages of collagen found in enamel makes it harder and more resistant to caries than dentin or cementum, but still susceptible to fracture if enough force is applied.

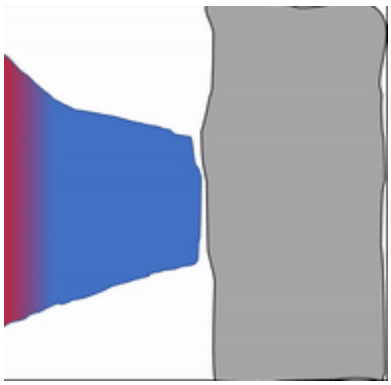

Figure 2.24: Collagen fibers of a tendon are continuous with the periosteum and Sharpey's fibers of bone tissue.

Bones are surrounded by a layer of dense regular connective tissue called the periosteum. This tissue is a continuation (not a separate structure) of the same tissue of tendons and ligaments. The periosteum also contains osteo-progenitor cells, the semi-differentiated cells that came from Mesenchymal Stem Cells, as well as osteoblasts and osteoclasts (coming up). Collagen fiber bundles from this layer named **Sharpey's fibers** penetrate the superficial layers of compact bone. This makes a very strong connection between bone tissue and tendons or ligaments.

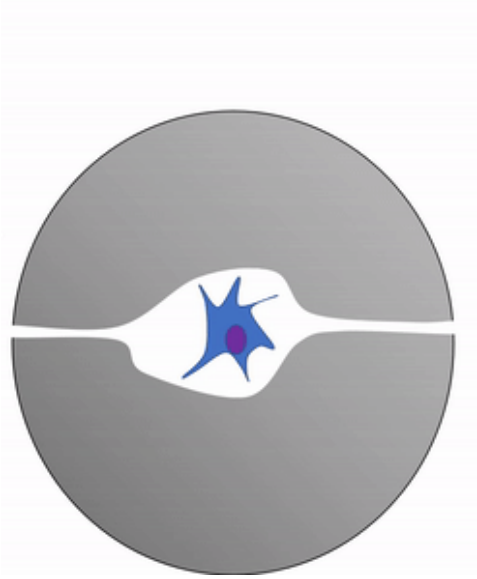

Figure 2.25: Osteoclasts demineralize bone tissue.

Another important cell found in the periosteum and endosteum is the **osteoclast**. This cell is not derived from the osteo-chondro-progenitor cell that gives rise to osteoblasts and osteocytes. The lineage of an osteoclast traces to the bone marrow, from a stem cell that also gives rise to red and white blood cells. An osteoclast is a close relative of a white blood cell called a macrophage, more than it is to bone cells. Osteoclasts demineralize bone tissue, releasing Ca^{2+} into the bloodstream. This is important because muscle and nervous tissue cannot function without Ca^{2+}, which our diet cannot provide continuously. Hence, bone tissue can be thought of as a calcium storage organ.

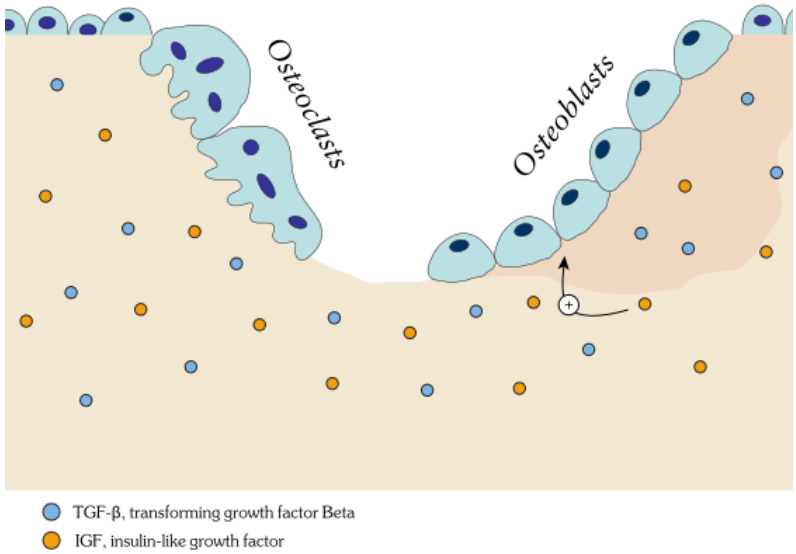

Figure 2.26: The bone remodeling unit: osteoblasts plus osteoclasts. Image credit: Own work By Shandristhe Azylean is licensed under CC BY-SA 3.0

Osteoclast activity is important during the exfoliation of teeth, as bone tissue is removed to loosen the connection between bone and tooth. Osteoclasts activity is also key to the mechanism by which orthodontia works. Lastly, osteoclasts play an important role in maintaining bone health– this may seem counter-intuitive, because osteoclasts destroy bone tissue. Bone tissue is constantly being repaired by a group of osteoblasts and osteoclasts working together, known as a **remodeling unit**. Because compact bone tissue is dense, there is little room for cells to work. Osteocytes can repair small amounts of damage, but larger amounts of damage would build up over time. To prevent this, remodeling units constantly work to remove bone tissue and replace it with fresh bone tissue. The remodeling units cannot find damaged bone tissue, they simply keep removing and replacing bone tissue. Physical stress on bone tissue causes osteoblasts to work a bit harder, which leads to increased bone density. Loss of osteoblast-

stimulating hormones (such as estrogen) can cause osteoblasts to work more slowly than osteoclasts, which can lower bone density and potentially lead to osteoporosis.

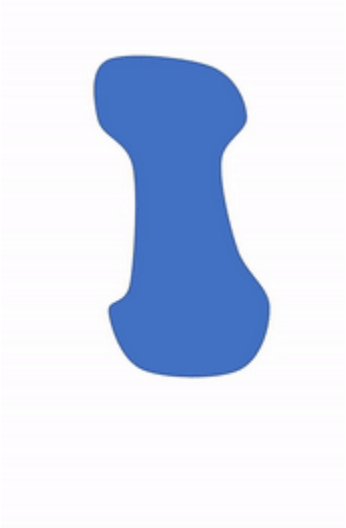

Figure 2.27: The basic steps of endochondral ossification.

Bones form either by **endochondral ossification**, or by **intra-membranous ossification**. The two processes are similar, the major difference is that endochondral ossification begins with a hyaline cartilage model, whereas intra-membranous ossification begins with a dense connective tissue model. Most of the skull develops by intra-membranous ossification, except the mandible and maxilla, which use both. Because of their similarity, we cover only endochondral ossification.

Figure 2.28: Blood vessels and nerves develop first, and are later surrounded by bone tissue. Image credit: "Dissected skull, Maison Tramond model, Paris, nineteenth century" by Centre for Research Collections University of Edinburgh is licensed under CC BY-SA 2.0 Most of the skeleton starts off not as bones, but as cartilage. Cartilage is typically avascular, but when chondrocytes receive the correct signals, blood vessels grow into the ground substance. The growth of new blood vessels into a tissue is called **angiogenesis**. Angiogenesis provides the pathway that mesenchymal stem cells use to migrate into the central area, where they differentiate into osteoblasts. After that, osteoblasts replace cartilage tissue with spongy bone tissue. This first site of ossification is named the *primary ossification center*. As remodeling occurs at the primary ossification center, blood vessels grow into the epiphyses and begin the same process at what are named the *secondary ossification centers*. Ultimately, most of the cartilage is replaced, except in two important places. First, cartilage may remain between the primary and secondary ossification centers, leaving growth plates (such as in bones of the arms and legs). Cartilage also remains at the ends, providing articular cartilage found in synovial joints, such as the temporo-mandibular joint. Intra-membranous ossification, because it begins with a dense connective tissue, leaves fontanels (soft-spots) between bones until ossification is complete, rather than cartilaginous connections.

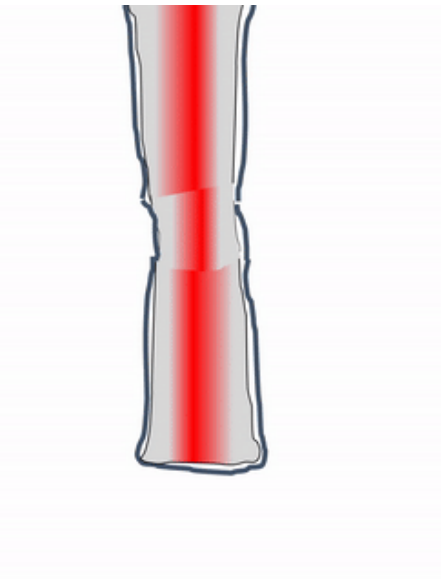

Figure 2.29: The basic steps of bone repair. Note the similarity to endochondral ossification.

When bone tissue is injured, it goes through a healing process similar to endochondral ossification. Perhaps you remember mention of wound healing recapitulating development? Here is an example of an adult tissue re-using the same mechanism to heal that it used during embryogenesis to grow in the first place. Similar to an injury to the skin, bone tissue first goes through an inflammatory process, and damaged blood vessels form clots. External blood clots are known as scabs, but inside the body they are named a **hematoma**. A blood clot contains an ECM fiber named **fibrin** that acts as a scaffold. This scaffold allows blood vessels to grow into the area, by angiogenesis. This in turn allows mesenchymal stem cells to migrate into the injured area, leave the blood and migrate along the scaffold, and differentiate into chondrocytes. The chondrocytes replace the fibrous hematoma with fibrocartilage– this cartilage step is really the only step that is does not have a **homologous** step (a shared step) in wound repair in the skin. Unlike repair of the skin, bone tissue growth needs a cartilage model first. With this new cartilage scaffold, more mesenchymal stem cells migrate and differentiate into osteoblasts, and replace the cartilage with bone tissue. Later, spongy bone tissue is remodeled so that it roughly matches the original compact and spongy layers. One difference can be seen afterwards, the former site of injury is a little bit thicker after it is repaired—similar to the way skin tissue can be made stronger after an injury because the collagen fibers in scar tissue have more covalent cross-links than in dense irregular CT.

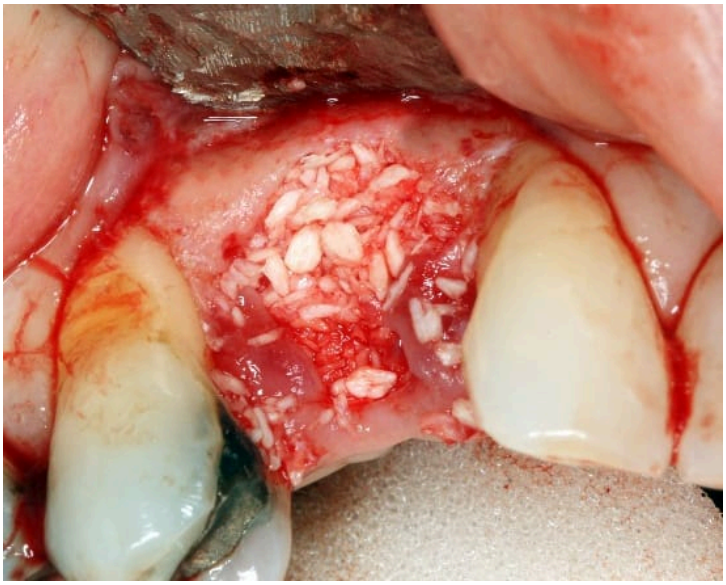

Figure 2.30: Artificial scaffolds help mesenchymal stem cells migrate into an injured area, differentiate into osteoblasts, and produce bone tissue. Image credit: Alloplastic particulate graft by Coronation Dental Specialty Group is licensed CC BY SA 3.0

Knowing the steps of endochondral ossification and bone fracture repair are important in instances where stimulating or mimicking the natural healing process can reduce the need for surgeries and implants. For instance, patients may lose a

significant amount of bone tissue with prolonged periodontitis. If enough bone tissue is lost, a surgeon may use a bone tissue graft to replace it. Bone tissue from a cadaver can be ground up, destroying the cells but leaving the collagen and minerals. Other sources may include a patient's own bone tissue (a full set of ribs or fibulas is less important than an intact set of jaw bones and teeth). The harvested ECM is spread into the injured site., where it acts as a scaffold, not as a replacement. The patient's mesenchymal stem cells migrate through the scaffold and begin the healing process, which can proceed quickly because all the raw materials are in close proximity. The grafted scaffolding does not have to come from actual bone tissue. It can be ground-up dentin, fibrin, or synthetic polymers printed using a 3-D printer. The scaffolds, synthetic or biological, are ultimately replaced, which is why you may see this referred to as Guided or Resorbable Tissue Regeneration. Later we learn a scaffold is just one part of the healing process, there are important signals that can be used to guide mesenchymal stem cell migration, division and differentiation. If you wish to know more, We have a short YouTube video that covers this new technology in more detail, aimed at 200-level Anatomy and Physiology students.

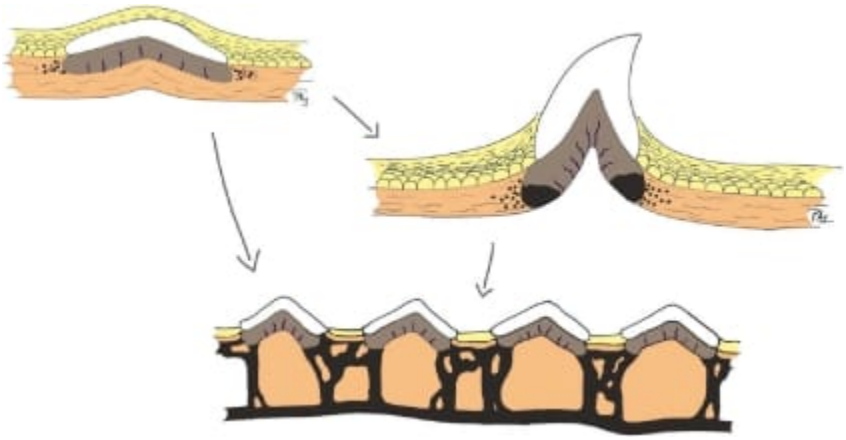

Figure 2.31: Mineralized tissues first evolved in the ectoderm (similar to enamel and were later produced by mesoderm (such as bone). Image credit: "The origin of bone. " by Darja Obradovic Wagner and Per Aspenberg is licensed under CC BY-NC-SA 4.0

Lastly, it is interesting to consider, from an evolutionary viewpoint, the lineage of the four mineralized tissues (bone, enamel, dentin and cementum) in humans and other vertebrates. Did one evolve first, and the others modified from the parent tissue? Fig. 2.31 provides a hint. We consider this question of lineage from a developmental viewpoint, in chapters 8-11.

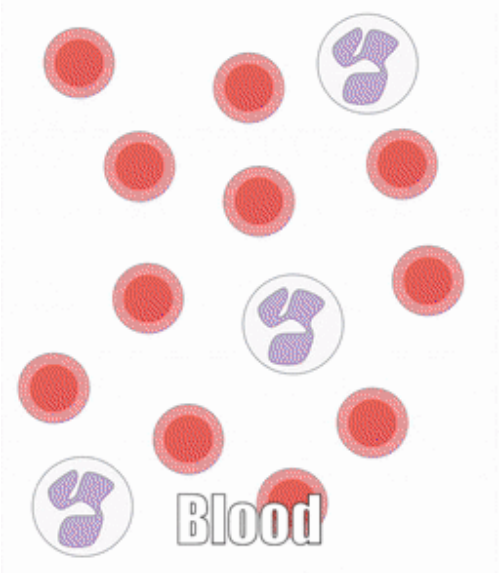

Figure 2.32: Hypothetical comparison between blood connective tissue and reticular connective tissue.

Blood, Reticular, and Lymph Connective Tissue

There are other connective tissues covered in histology classes, here we cover them briefly. **Blood** is a type of connective tissue, composed of cells (red blood cells, mostly), liquid ground substance (blood plasma) and fibers (fibrin). **Lymph** is primarily white

blood cells, plus liquid ground substance. **Reticular connective tissue** contains blood cells, liquid ground substance and reticular fibers. It can be found in lymphatic organs where blood cells tend to rest rather than flow, such as lymph nodes.

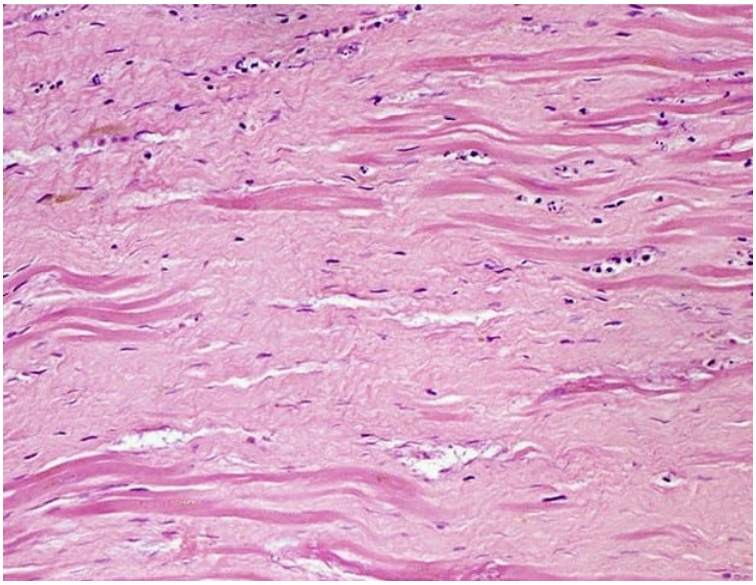

Figure 2.33: Scar tissue in the heart after a myocardial infarct. Image credit: "Histopathology of dense fibrous scar replacing myocyte loss in myocardial infarction" by Katarzyna Michaud et al is licensed under CC BY-SA 4.0

There are other forms of connective tissue that aren't typically covered in 200-level histology classes, we cover one of them: **scar tissue**. Scar tissue is made by fibroblasts following an injury. This occurs after an injury to any tissue that is large enough that it cannot be replaced quickly by stem cells. One example is sclerotic dentin. Scar tissue is very similar to dense regular connective tissue, except the collagen fibers in scar tissue are highly cross-linked. This makes scar tissue very strong, but also reduces its mobility and capacity to be remodeled. Scar tissue can be formed wherever there are large injuries to an organ– fibroblasts can often fill up the space more quickly than waiting for regeneration to occur. Once formed, scar tissue is difficult to remodel, so it is more-or-less permanent.

Muscle tissue

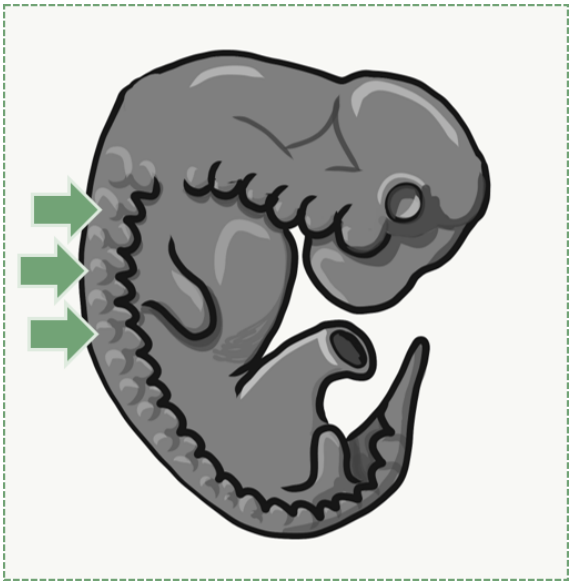

Figure 2.34: Somites, from which connective tissue and muscle tissue develop.

General characteristics of muscle tissue

Muscle tissue, like connective tissue, is derived from somites. The stem cell that differentiates into one of the several types of muscle cells is called a **myo-satellite cell.** Given the correct set of extra-cellular signals, myo-satellite cells differentiate into skeletal, smooth or cardiac muscle cells. Skeletal muscle cells are long multi-nucleate cells that were once hundreds of **myoblasts** that fuse together. Like a fibroblast, a myoblast is stem cell that has undergone some differentiation, enough to limit its fate, and is responsible for building the adult tissue. In muscle tissue, myoblasts create protein fibers that are mostly intra-cellular (such as actin thin-filaments and myosin thick filaments). After fusing with other myoblasts, the adult muscle cells are often confusingly referred to as muscle fibers, but they are definitely cells, not molecules like the protein and glycoprotein fibers found within the ECM of connective tissue. Thus, they can also be called **myocytes**. In fact, they aren't the only multi-nucleate cell you read about in this chapter, is perplexing as to why this cell often receives a special suffix, while osteoclast cells do not. In adult muscle tissue, myo-satellite cells remain, ready to undergo mitosis and fuse to form larger muscle cells in response to exercise or injury. We see skeletal muscle in the tongue and underneath regions of oral mucosa, but we do not cover smooth or cardiac muscle tissue.

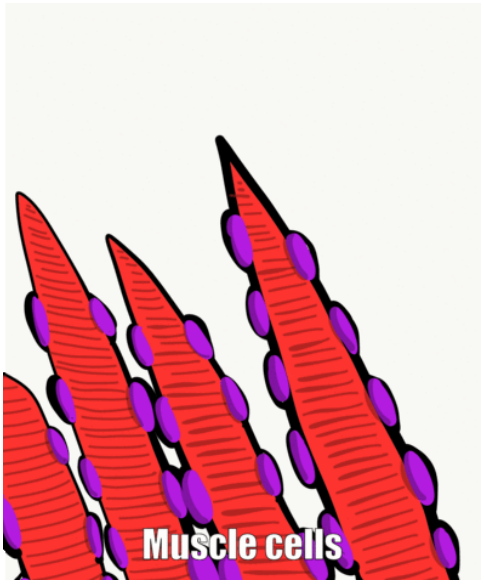

Figure 2.35: Muscles (organs) contain muscle tissue and dense regular connective tissue.

Muscle tissue is composed primarily of muscle cells, connected by collagen fibers. Unlike connective tissue cells, which may bind to collagen or other ECM proteins for migration using trans-membrane linkers such as integrins, muscle cells anchor in place to the ECM. Muscle cells express different linker proteins to do this, such as the protein Dystrophin. The layers of collagen are thin between cells, and thicker on the outer surface of a muscle. These layers of collagen fibers ultimately become the dense regular connective tissue of a tendon. It is often difficult to determine where muscle tissue ends and connective tissue begins, because of the collagen fibers in both tissues. By extension, it is also difficult to tell where the tendon ends and the periosteum begins. Some histologists draw lines between these tissues, but the junction is better described as a blending. This is because both muscle tissue and connective tissue have the same lineage, from the mesenchyme of somites. For people studying musculo-skeletal diseases like Muscular Dystrophy, there is interest in identifying the instructions that guide mesenchymal stem cells to differentiate into myo-satellite cells– especially considering the larger number of mesenchymal stem cells in the bone marrow compared to myo-satellite cells in the muscle of a child or adult. If novel treatments result from this research, it could make dental hygiene procedures for patients with Muscular Dystrophy much simpler.

Nervous tissue

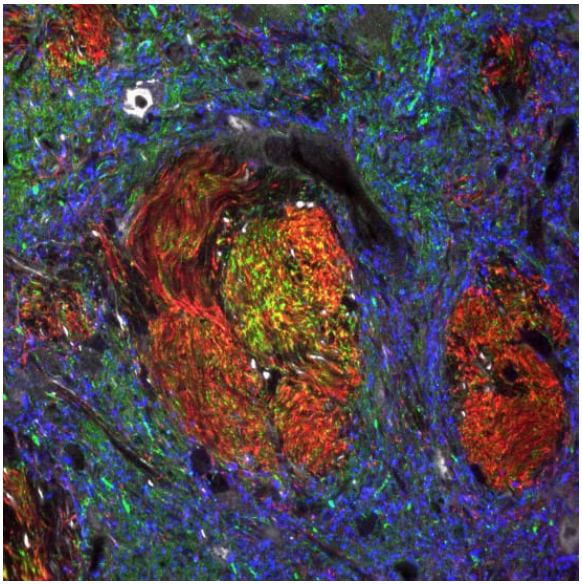

Figure 2.36: Confocal image of neural tissue, including neurons and glial cells. Image credit: Desert rose by Tarzerind is licensed under CC By SA 4.0

General characteristics of neural tissue

Shown to the left is a confocal image of **neural tissue**. What I like about this image, and is often absent from images of neural tissue, is that this one shows all of the cells. The typical image of neural tissue uses stains to highlight **neurons**—the cells specialized at conducting electricity– leaving out the **glia—**the majority of cells in the nervous system that do everything else, including guide neurons connections and change the strength of those connections when we learn. What you should see at this time is neural tissue is composed primarily of cells, and has very little ECM. While the brain especially has a huge number of blood vessels inside of it, technically they do not run within the neural tissue. Instead, there is a thin blood-brain-barrier separating the brain from the blood vessels. Normally, we wouldn't call neural tissue avascular, we do so now only to make a point: neural tissue shares a lot in common with epithelial tissue. By now, we hope you have guessed why: neural and epithelial tissues share the same lineage.

3 major embryonic tissues

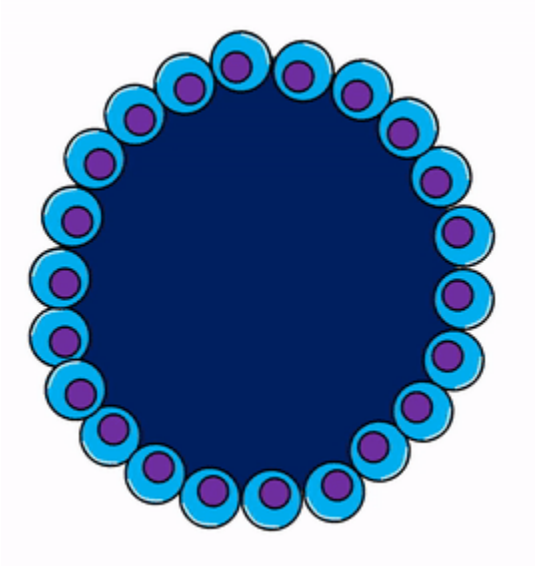

Figure 2.37: Animated illustration of gastrulation.

Gastrulation

When an embryo implants in the uterus, it is a hollow ball of identical, omnipotent stem cells that resemble a simple cuboidal epithelium. But soon, some of these epithelial cells migrate inwards, in a very important process called gastrulation. At this stage, we have two distinct layers of cells. The layer on the outside becomes the epidermis, oral mucosa and the central nervous system. The layer one on the inside becomes the lining the gut and other hollow organs. Next, some cells from the outer layer change. They lose contacts with neighboring cells, and migrate into the middle. As this happens, they stop looking like epithelial cells and begin to look like mesenchymal cells. This produces a third layer of cells in an embryo. The three layers are listed below, along with what they form in the adult:

3 embryonic layers	Cell fate
Ectoderm	Epithelium of skin and oral mucosa, neural tissue
Mesoderm	Connective and muscle tissue
Endoderm	Epithelial lining of hollow organs

Table 2.3: the three embryonic tissues We have now sneakily introduced you to two important terms used in development. The first is cell lineage, which means where a cell came from in the past, and now **cell fate**, which means what that cell *can* become in the future. If we didn't think your license exam would include questions on the four major tissue types, we would stick with the three embryonic tissues, with neural being a sub-family of epithelia (you'll see why later). We'd have put connective and muscle tissue within the same lineage, rather than separate them. But we can see why academia hasn't changed the way it teaches histology, the confusion that comes with change would not be worth the benefits we'd gain by grouping cells by linage rather than appearance. But this, we think, is more than enough basic histology for a dental hygienist, it is time to move on to the histology of the oral cavity.

1.11.1: Introduction to Research in Biological Psychology

Learning Objectives

1. Differentiate between the purpose of structural and functional imaging.
2. Describe the differences between spatial resolution and temporal resolution.

Overview

This chapter will describe the various ways that biological psychologists study the brain. There are many ways to categorize the techniques that are used when studying the brain. We will start by covering the non-invasive techniques, where we are able to study the brain without getting direct physical access to the brain (think of fixing a broken pipe in a wall without having to open the wall up). Then we will move into the invasive techniques, where we study the brain by having direct access (an example would be fixing a broken pipe in a wall by tearing a hole in the wall). Then we will discuss various neuropsychological techniques, where we learn about the brain using people with some sort of brain "issue." For example, people with epilepsy have been extensively studied and we can learn a lot about how the brain works from them. Finally, the last section will address ethical considerations of biological psychology research.

In this section, we will start with a discussion of many modern day neuroscience terms that are important for understanding the different techniques in future sections.

The Terminology of Modern Research Techniques

We have come a long way since Phineas Gage with how we study the brain. Many techniques now allow us to understand how the brain works without waiting for a horrific accident to occur or conducting some sort of surgery (although, as you will see, we still use surgical techniques to study the brain). Techniques have been developed that allow us to see what the brain looks like, as a still image (structurally) or in action (functionally).

Structural Imaging

Structural imaging techniques are useful in many situations such as locating tumors, sites of physical brain damage, or finding size differences between the structures of the brain between various groups. Magnetic resonance imaging (MRI), for example, is one such technique that is commonly used to study the brain and to diagnosis knee and shoulder injuries. Structural imaging techniques allow us to look inside the brain (or body) without having to go inside.

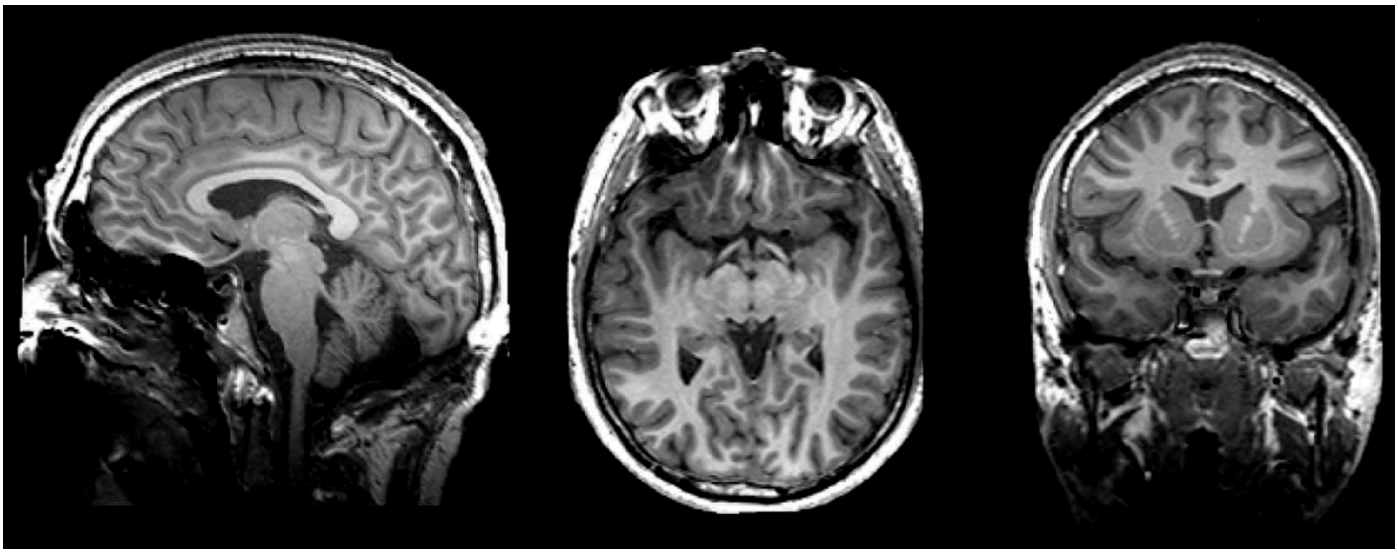

Figure 1.11.1.1: An MRI (A structural image) of the brain. Note the ability to see specific gyri (bumps) and sulci (grooves).

A series of MRI images can be used to create a picture of the brain.

Functional Imaging

Many researchers are also interested in how the brain works. Some studies begin with the scientific question of “what does this part do?” Or more commonly, “Where in the brain does this happen?” **Functional imaging** techniques allow researchers to learn about the brain activity during various tasks by creating images based on the electrical activity or the absorption of various substances that occurs while a subject is engaging in a task. Such techniques can be used, for example, to visualize the parts of the brain that respond when we're exposed to stimuli that upset us or make us happy.

Temporal Versus Spatial Resolution

Within functional imaging techniques, researchers are frequently focused on one of two questions. They may ask “When does this activity occur?” Or “Where does this activity occur?” Some techniques are better for answering one of these questions, whereas other techniques are better for answering the other question. We describe how well a technique can determine *when* the activity has occurred as **temporal resolution.** For example, was the brain region activity occurring sometime in the last hour, the last minute, the last second, or within milliseconds? While some techniques are excellent at determining precisely when the activity occurred and other techniques are quite terrible at it. Additionally, we can describe how well a technique can determine *where* the activity has occurred as **spatial resolution.** For example, did the activity occur in the temporal lobe somewhere or can we narrow that down to a specific gyrus (ridge) or sulcus (groove) of the cerebral cortex? If it occurred on a particular gyrus can we narrow it down to a particular portion of that gyrus? As with temporal resolution, some techniques are excellent at determining precisely where the activity occurred whereas other techniques are less accurate.

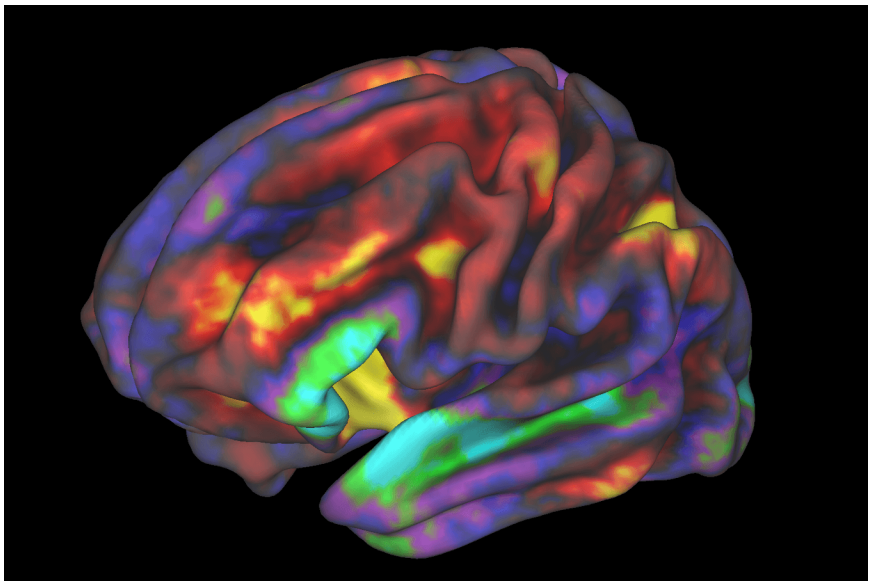

Figure 1.11.1.2: Functional MRI of a teenage brain conducting a working memory test. The regions in red and yellow, primarily in the frontal lobe and occipital lobe, are the most active.

Summary

How we study the brain has come a long way since the days of Phineas Gage. Although, as we will discuss, we still learn about the brain from accidents and other traumatic brain events, we have a variety of other techniques that we can use now to study the brain in healthy individuals. These techniques allow us to answer questions about what the brain looks like, what specific parts do, and when they do it.

1.11.2: Non-Invasive Techniques- Structural Imaging

Learning Objectives

1. Explain how X-rays, CT scans, and MRI scans differ.
2. Describe the pros and cons of the three main structural imaging techniques.

Overview

Structural imaging techniques typically come in three different options: X-rays, computed tomography (CT) or computed axial tomography (CAT) scans, and magnetic resonance imaging (MRI) scans. Each uses different types of technology to provide a representation of a structure without having to remove the skin or bone that protects that structure. Each of these non-invasive techniques has advantages and disadvantages.

X-Rays

German physicist Wilhelm Röntgen (1845–1923) was experimenting with electrical current when he discovered that a mysterious and invisible "ray" would pass through his flesh but leave an outline of his bones on a screen coated with a metal compound. In 1895, Röntgen made the first durable record of the internal parts of a living human: an "X-ray" image (as it came to be called) of his wife's hand. Scientists around the world quickly began their own experiments with X-rays, and by 1900, X-rays were widely used to detect a variety of injuries and diseases. In 1901, Röntgen was awarded the first Nobel Prize for physics for his work in this field.

The **X-ray** is a form of high energy electromagnetic radiation with a short wavelength capable of penetrating solids and ionizing gases. As they are used in medicine, X-rays are emitted from an X-ray machine and directed toward a specially treated metallic plate placed behind the patient's body. The beam of radiation results in darkening of the X-ray plate. X-rays are slightly impeded by soft tissues, which show up as gray on the X-ray plate, whereas hard tissues, such as bone, largely block the rays, producing a light-toned "shadow." **Thus, X-rays are best used to visualize hard body structures such as teeth and bones.** Figure 1.11.2.1 depicts an X-ray of a knee. Like many forms of high energy radiation, however, X-rays are capable of damaging cells and initiating changes that can lead to cancer. This danger of excessive exposure to X-rays was not fully appreciated for many years after their widespread use.

Figure 1.11.2.1: X-Ray of a Knee: High energy electromagnetic radiation allows the internal structures of the body, such as bones, to be seen in X-rays like these.

Due to the development of other techniques that are considerably better at looking at soft tissue, X-rays are largely not used for studying the brain anymore.

Modern Medical Imaging

X-rays can depict a two-dimensional image of a body region, and only from a single angle. In contrast, more modern medical imaging technologies produce data that are integrated and analyzed by computers to produce three-dimensional (3D) images or images that reveal aspects of the body functioning.

Computed Tomography

Tomography refers to imaging by sections. **Computed (or computerized) tomography (CT)** is a noninvasive imaging technique that uses computers to analyze several cross-sectional X-rays in order to reveal small details about structures in the body. The technique was invented in the 1970s and is based on the principle that, as X-rays pass through the body, they are absorbed or reflected at different levels. In the technique, a patient lies on a motorized platform while a computerized axial tomography (CAT) scanner rotates 360 degrees around the patient, taking X-ray images. Figure 1.11.2.2 shows a CT scanner with a platform for the subject to lie on. A computer combines these images into a two-dimensional view of the scanned area, or "slice." Figure 1.11.2.3 shows a series of slices of the brain for one subject.

Figure 1.11.2.2: A CT scanner at the University of Pittsburg Medical Center East.

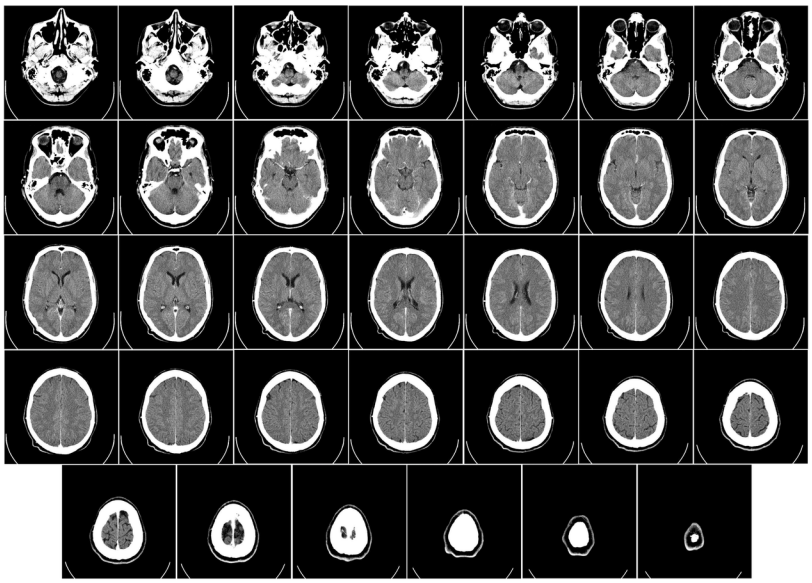

Figure 1.11.2.3: A series of axial CT scans of the brain of one subject. Each image is a slice of the brain starting with a bottom slice and incrementally moving to higher and higher slices.

Since 1970, the development of more powerful computers and more sophisticated software has made CT scanning routine for many types of diagnostic evaluations. It is especially useful for soft tissue scanning, such as of the brain and the thoracic and abdominal viscera. Its level of detail is so precise that it can allow physicians to measure the size of a mass down to a millimeter. The main disadvantage of CT scanning is that it exposes patients to a dose of radiation many times higher than that of X-rays. Whether this is particularly dangerous is still being debated (McCollough et al., 2015).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a noninvasive medical imaging technique based on a phenomenon of nuclear physics discovered in the 1930s, in which matter exposed to magnetic fields and radio waves was found to emit radio signals. In 1970, a physician and researcher named Raymond Damadian noticed that malignant (cancerous) tissue gave off different signals than normal body tissue. He applied for a patent for the first MRI scanning device, which was in use clinically by the early 1980s. The early MRI scanners were crude, but advances in digital computing and electronics led to their advancement over any other technique for precise imaging, especially to discover tumors. MRI also has the major advantage of not exposing patients to radiation.

Drawbacks of MRI scans include their much higher cost, and patient discomfort with the procedure. The MRI scanner subjects the patient to such powerful electromagnets that the scan room must be shielded. The patient must be enclosed in a metal tube-like device for the duration of the scan, sometimes as long as thirty minutes, which can be uncomfortable and impractical for ill patients. The device is also so noisy that, even with earplugs, patients can become anxious or even fearful. These problems have been overcome somewhat with the development of “open” MRI scanning, which does not require the patient to be entirely enclosed in the metal tube. Figure 1.11.2.4 shows an MRI machine with a platform for the patient to lie on. Patients with iron-containing metallic implants (internal sutures, some prosthetic devices, and so on) cannot undergo MRI scanning because it can dislodge these implants.

Figure 1.11.2.4: An MRI machine.

Using Structural Imaging Techniques to Study a Disorder: Autism Spectrum Disorder

One example that we will use throughout this chapter is that of how we use these research techniques to study Autism Spectrum Disorder (ASD). ASD is a developmental disorder frequently characterized by issues including various combinations of interaction issues, communication difficulties, and even repetitive behaviors. Throughout each section, we will discuss some of the ways the main tools of brain research have been used to examine this disorder.

Structural imaging techniques with ASD have focused on which brain structures have physical differences. MRIs have found a thicker frontal cortex (Carper & Courchesne, 2005) and a thinner temporal cortex (Hardan et al., 2006) in patients with ASD. These areas are notable because the frontal cortex is linked to communication and language abilities and the temporal cortex is linked to auditory processing (ie. language input), both of which are issues that many with ASD struggle with.

Summary

Structural imaging techniques, including X-rays, CT scans, and MRIs, allow researchers to get a look at what the brain looks like without having to do anything invasive to the patient, like surgery. These techniques, particularly CT scans and MRIs are extremely useful in constructing an image of what the brain looks like and allow doctors to detect any structural abnormalities in their patients. They also allow researchers to learn about the sizes of different structures in the brain and possibly correlate those differences to various functions.

1.11.3: Non-Invasive Techniques- Direct Functional Imaging Techniques

Learning Objectives

1. Apply the terms spatial and temporal resolution to EEG and MEG.
2. In basic terms, describe EEG and MEG.
3. Describe the key characteristic of direct functional imaging techniques.

Overview

In this section, we will discuss the two main direct functional imaging techniques, electroencephalography (EEG) and magnetoencephalography (MEG). We will also generally discuss what makes a technique a direct brain imaging technique.

EEG

Electroencephalography (EEG) is one technique for studying brain activity. This technique uses at least two and up to 256 electrodes to measure the difference in electrical charge (the **voltage**) between pairs of points on the head. These electrodes are typically fastened to a flexible cap (similar to a swimming cap) that is placed on the participant's head. Figure 1.11.3.1 shows a patient wearing such a cap. From the scalp, the electrodes measure the electrical activity that is naturally occurring within the brain. They do not introduce any new electrical activity.

Figure 1.11.3.1: A subject with a group of EEG electrodes on their head.

Given that this electrical activity must travel through the skull and scalp before reaching the electrodes, localization of activity is less precise when measuring from the scalp, but it can still be within several millimeters when localizing activity that is near the scalp. While EEG is lacking with respect to spatial resolution, one major advantage of EEG is its temporal resolution. Data can be recorded thousands of times per second, allowing researchers to document events that happen in less than a millisecond. EEG analyses typically investigate the change in amplitude (wave height) or frequency (number of waves per unit of time) components of the recorded EEG on an ongoing basis or averaged over dozens of trials (see Figure 1.11.3.2). The EEG has been used extensively in the study of sleep. When you hear references to "brain waves", those are references to information obtained using EEG.

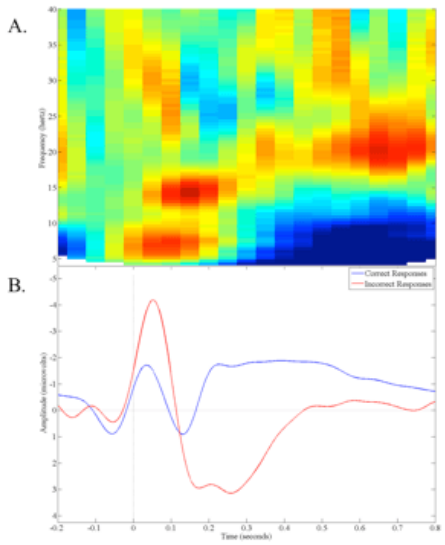

Figure 1.11.3.2: Example of EEG analysis output. Panel A represents changes in the relative strength of different frequencies in the EEG data over time. Panel B represents changes in the amplitude in the instantaneous EEG voltage over time.

MEG

Magnetoencephalography (MEG) is another technique for noninvasively measuring neural activity. The flow of electrical charge (the current) associated with neural activity produces very weak magnetic fields that can be detected by sensors placed near the participant's scalp. Figure 1.11.3.3 depicts a subject in an MEG machine. The number of sensors used varies from a few to several hundred. Due to the fact that the magnetic fields of interest are so small, special rooms that are shielded from magnetic fields in the environment are needed in order to avoid contamination of the signal being measured. MEG has the same excellent temporal resolution as EEG. Additionally, MEG is not as susceptible to distortions from the skull and scalp. Magnetic fields are able to pass through the hard and soft tissue relatively unchanged, thus providing better spatial resolution than EEG. MEG analytic strategies are nearly identical to those used in EEG. However, the MEG recording apparatus is much more expensive than EEG, so MEG is much less widely available.

Figure 1.11.3.3: A subject/patient getting an MEG.

General Information About Direct Imaging Techniques

EEG and MEG both have excellent temporal resolution and are useful when someone is particularly interested in studying the timing of brain activity. For example, if someone is reading a sentence that ends with an unexpected word, how long after reading the unexpected word does the brain react to it? In addition to these types of questions, EEG and MEG methods allow researchers to investigate the degree to which different parts of the brain "talk" to each other. This allows for a better understanding of brain networks, such as their role in different tasks and how they may function abnormally in psychopathology.

Direct imaging techniques are those that allow for a direct measure of brain activity. EEG and MEG are both considered direct brain imaging techniques since EEG measures the electrical activity from groups of neurons and MEG measures the magnetic fields that the electrical activity gives off. Neither of these techniques relies on measuring something else with an assumption that they are linked. This is not true in the next set of techniques we will discuss.

Using Direct Functional Imaging Techniques to Study a Disorder: Autism Spectrum Disorder

EEG and MEG have been used to examine ASD. One of the findings included a delay in the brain wave associated with auditory stimuli. In short, there are differences in the time for processing auditory sounds in children with ASD compared to those without ASD. Furthermore, this delay appears more pronounced in children with ASD who have language developmental delays as opposed to children with ASD without linguistic delays (Roberts et al., 2019). This delay has even been proposed to help clinicians diagnose autism in young children.

Summary

Direct imaging techniques are extremely useful ways to measure electrical brain activity in a non-invasive way. Both EEG and MEG are most useful at identifying differences in timing patterns of electrical activity.

1.11.4: Non-Invasive Techniques- Indirect Functional Imaging Techniques

Learning Objectives

1. Describe the key characteristics of indirect functional brain imaging techniques.
2. In basic terms, describe functional MRI (fMRI) and positron emission tomography (PET).
3. Discuss the pros and cons of FMRI and PET.

Overview

EEG and MEG are direct functional imaging techniques as they measure the actual activity in the brain. In this section, we will discuss what makes a technique an *indirect* brain imaging technique and the two main indirect imaging techniques, functional MRI (fMRI) and positron emission tomography (PET), will be introduced.

FMRI and PET

Indirect brain imaging techniques rely on an assumption that activity in the brain correlates to something else that we are able to measure. In these cases, these techniques measure blood flow in the brain. The assumption is that blood flow in the brain is related to the activity level in that area of the brain. Of course, with any assumption, there is always the risk that it could be wrong. Thankfully there is extensive research examining this assumption and the scientific consensus currently is that blood flow is an appropriate indication of brain activity. The two main indirect brain imaging techniques that we will cover are functional MRI (fMRI) and positron emission tomography (PET).

Functional magnetic resonance imaging (fMRI) is a method that is used to assess changes in the activity of tissue, such as measuring changes in neural activity in different areas of the brain during thoughts or experiences. This technique builds on the principles of structural MRI techniques and also uses the property that, when neurons fire, they use energy, which must be replenished. Glucose and oxygen, two key components for energy production, are supplied to the brain from the blood stream as needed. Oxygen is transported through the blood using hemoglobin, which contains binding sites for oxygen. When these sites are saturated with oxygen, it is referred to as oxygenated hemoglobin. When the oxygen molecules have all been released from a hemoglobin molecule, it is known as deoxygenated hemoglobin. As a set of neurons begin firing, oxygen in the blood surrounding those neurons is consumed, leading to a reduction in oxygenated hemoglobin. The body then compensates and provides an abundance of oxygenated hemoglobin in the blood surrounding that activated neural tissue. When activity in that neural tissue declines, the level of oxygenated hemoglobin slowly returns to its original level, which typically takes several seconds. Figure 1.11.4.1 shows a subject about to go into a functional MRI machine.

Figure 1.11.4.1: A Functional MRI machine. While it is pictured here with the patient outside of the magnet, to scan the patient, they would be moved into the circular magnet.

fMRI measures the change in the concentration of oxygenated hemoglobin, which is known as the blood-oxygen-level-dependent (BOLD) signal. This leads to two important facts about fMRI. First, fMRI measures blood volume and blood flow, and from this we infer neural activity; as stated previously, fMRI does not measure neural activity directly. Second, fMRI data typically have poor temporal resolution; however, when combined with structural MRI, fMRI provides excellent spatial resolution. Temporal resolution for fMRI is typically on the order of seconds, whereas its spatial resolution is on the order of millimeters. Generally speaking, under most conditions there is an inverse relationship between temporal and spatial resolution—one can increase temporal resolution at the expense of spatial resolution and vice versa. In other words, as one increases the other decreases.

This method is valuable for identifying specific areas of the brain that are associated with different physical or psychological tasks. Clinically, fMRI may be used prior to neurosurgery in order to identify the brain areas that are associated with language so that the surgeon can avoid those areas during the operation. fMRI allows researchers to identify differential or convergent patterns of activation associated with tasks. For example, if participants are shown words on a screen and are expected to indicate the color of the letters, are the same brain areas recruited for this task if the words have emotional content or not? Does this relationship change in psychological disorders such as anxiety or depression? Is there a different pattern of activation even in the absence of obvious performance differences? fMRI is an excellent tool for comparing brain activation in different tasks and/or populations. Figure 1.11.4.2 provides an example of results from fMRI analyses overlaid on a structural MRI image. The blue and orange shapes represent areas with significant changes in the BOLD signal, thus changes in neural activation.

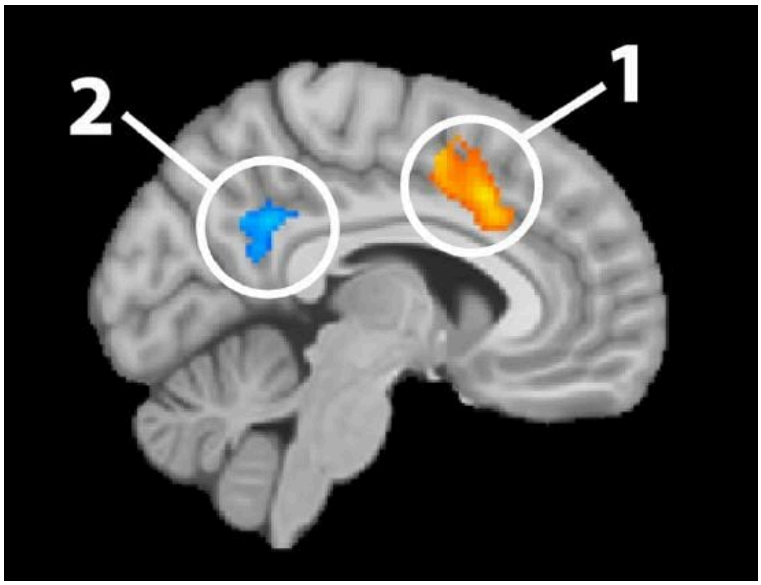

Figure 1.11.4.2: Example of fMRI analyses overlaid on an sMRI image. Area 1 (orange) indicates an increase in the BOLD signal, and Area 2 (blue) indicates a decrease in the BOLD signal. We infer that neural activity increased in the Area 1 and decreased in Area 2.

Positron emission tomography (PET) is a medical imaging technique that is used to measure processes in the body, including the brain (see Figure 1.11.4.3 for a PET scanner). This method relies on a positron-emitting tracer atom that is introduced into the blood stream in a biologically active molecule, such as glucose, water, or ammonia. A positron is a particle much like an electron but with a positive charge. One example of a biologically active molecule is fludeoxyglucose, which acts similarly to glucose in the body. Fludeoxyglucose will concentrate in areas where glucose is needed—commonly areas with higher metabolic (energy) needs. Over time, this tracer molecule emits positrons, which are detected by a sensor. The spatial location of the tracer molecule in the brain can be determined based on the emitted positrons. This allows researchers to construct a three-dimensional image of the areas of the brain that have the highest metabolic needs, typically those that are most active. Images resulting from PET usually represent neural activity that has occurred over tens of minutes, which is very poor temporal resolution for some purposes. PET images are often combined with computed tomography (CT) images to improve spatial resolution, as fine as several millimeters. Tracers can also be incorporated into molecules that bind to neurotransmitter receptors, which allow researchers to answer some unique questions about the action of neurotransmitters. Unfortunately, very few research centers have the equipment required to obtain the images or the special equipment needed to create the positron-emitting tracer molecules, which typically need to be produced on site.

Figure 1.11.4.3: A PET scanner.

Using Indirect Functional Imaging Techniques to Study a Disorder: Autism Spectrum Disorder

PET and fMRI studies of ASD have found different levels of neuronal activity in the amygdala and the hippocampus compared to subjects without ASD. These areas are notable because they are a part of the “social brain.” These studies have largely focused on patients with ASD when they are viewing faces. As the viewing of faces is a large part of socializing (for example, reading expressions and making eye contact) and socializing is one area where many autistic patients have issues, these studies help provide further information for doctors and researchers to use. (See Philip et al. (2012) for a review of the fMRI studies of ASD.)

Summary

The use of indirect functional imaging techniques has allowed researchers and doctors to see which parts of the brain are active during various tasks. Both fMRI and PET allow researchers to measure blood flow in order to make conclusions about changes in brain activity. These techniques have excellent spatial resolution, but poor temporal resolution.

1.11.5: Other Non-Invasive Techniques

Learning Objectives

1. Describe how transcranial magnetic stimulation (TMS) is different from other functional imaging techniques.
2. Differentiate between depolarization and hyperpolarization with respect to TMS.

Overview

This section is frequently combined with one of the previous sections in many textbooks because many of the researchers who do functional brain imaging work also conduct TMS work (the subject of this section). However, this technique is different from the previous techniques in many important ways. In this section, we will discuss what TMS is, when it is used, and how it is different from the previous imaging techniques.

Transcranial Magnetic Stimulation

Another technique that is worth mentioning is transcranial magnetic stimulation (TMS). TMS is a noninvasive method that causes **depolarization** or **hyperpolarization** in neurons near the scalp. In TMS, a coil of wire is placed just above the participant's scalp (as shown in Figure 1.11.5.1). When electricity flows through the coil, it produces a magnetic field. This magnetic field travels through the skull and scalp and affects neurons near the surface of the brain. When the magnetic field is rapidly turned on and off, a current is induced in the neurons, leading to depolarization or hyperpolarization, depending on the number of magnetic field pulses. Single- or paired-pulse TMS depolarizes site-specific neurons in the cortex, causing them to fire. If this method is used over primary motor cortex, it can produce or block muscle activity, such as inducing a finger twitch or preventing someone from pressing a button. If used over primary visual cortex, it can produce sensations of flashes of light or impair visual processes. This has proved to be a valuable tool in studying the function and timing of specific processes such as the recognition of visual stimuli. Repetitive TMS produces effects that last longer than the initial stimulation. Depending on the intensity, coil orientation, and frequency, neural activity in the stimulated area may be either attenuated or amplified. Used in this manner, TMS is able to explore **neural plasticity**, which is the ability of connections between neurons to change. This has implications for treating psychological disorders as well as understanding long-term changes in neuronal excitability.

Note that TMS is different from the previous techniques in that we are not taking images of what the brain is doing. TMS disrupts or stimulates the brain and actively changes what the brain is doing.

Using Transcranial Magnetic Imaging to Study a Disorder: Autism Spectrum Disorder

TMS studies, as with most research techniques, can come in the form of basic research (research intended to inform our understanding) and applied research (research intended to solve a problem). Basic research in neuroscience is typically driven by research questions aimed at a general understanding of how the brain and nervous system work. Some TMS studies have used TMS to reduce brain activity in the right amygdala during the processing of faces with negative emotions (Baeken et al., 2010). Although this research wasn't specific to autism, it is not hard to see the connection between understanding how the amygdala works and ASD. Furthermore, studies have tried to use TMS to treat ASD. Studies thus far have focused on using TMS to change activity levels and possibly stimulate neural plasticity. There was even a transcranial magnetic stimulation therapy for autism conference held in 2014 to discuss the use of the tool in the treatment of ASD. Indeed, there are myriad of possibilities for how this tool can be used in the future. (See Oberman et al. (2015) for a review of TMS treatments for ASD.)

Summary

TMS is a technique where researchers and doctors are able examine the changes in function that are produced when a brain area is excited or inhibited. For research purposes, it has been useful to help us map the brain. For clinical purposes, TMS is being studied more and more to understand whether it can cause alterations in the neural networks that can lead to benefits for people with various disorders.

1.11.6: Invasive Techniques

Learning Objectives

1. Describe what single cell recordings, lesion studies, direct cortical stimulation, split-brain studies, and the Wada procedure each refer to.
2. Explain the pros and cons of single cell recordings.
3. Describe when lesion studies, direct cortical stimulation, split-brain studies, and the Wada procedure may be used.
4. Discuss the limitations of lesion/surgery studies.

Overview

In this section, we will discuss some of the other ways that researchers and doctors study the brain. These techniques are different from what was previously discussed in that they are more invasive, techniques that require entering the brain as opposed to taking measurements from the skull. Each of the following techniques are not used on everyday "healthy" human volunteers. Rather, these techniques are typically used when there is something going on in the brain of interest and doctors/researchers need to investigate.

Single Cell Recordings

One technique that is used to study animals in neuroscience, known as **single cell recordings** allows for us to record the activity of a cell, at least in theory. The idea of single cell recordings is that we can place a very tiny recording device, known as a microelectrode, into a single neuron and then we can try and figure out what will “activate” that particular neuron. For example, in the visual system, you may find a neuron that activates when a line moves in a certain direction in a certain location. We would then conclude that this neuron processes moving lines from a particular location.

Furthermore, single cell recordings have excellent spatial and temporal resolution. The researcher can tell exactly where the activity is coming from and exactly when the activity is occurring.

However, single cell recordings are usually extracellular (outside of the cell). That is, they don’t record from inside a single cell but, rather, they record from outside a few cells. Also, consider that the neuron that responds to a line in a particular location that is moving in a particular direction likely does not respond to much else. So, it is extremely difficult to determine what exactly each cell does through single cell recordings. Recording from one area ignores what is happening everywhere else in the brain.

Lesion Studies

A **lesion** is a site of damage in the brain. In neuroscience, we conduct lesion studies on both animals and human subjects. In animals, lesions can be made in a specific area by the researcher. Researchers are able to correlate the deficits in function with the area of damage. For example, if a researcher damages area X, and now the animal is unable to enter into REM (rapid eye movement) sleep, one can reasonably conclude that area X serves some function related to REM sleep. Although the same can be said for lesion studies of humans, accidents, or medical necessities are generally the source of human lesion subjects. You'll recall that we began this chapter by mentioning the tragic - but educational - case of Phineas Gage.

Lesion studies can allow for very specific conclusions to be made about very specific brain areas. However, in human subjects, many of the lesion patients have damage to multiple areas. In general, this makes it more difficult to make conclusions about the function of the brain areas. If the person has damage to areas X, Y, and Z, and is unable to enter into REM sleep, we are uncertain whether the area that is related to REM sleep is area X, Y, or Z or some combination of them.

Neurosurgical Techniques

Another way the brain has been studied by neuroscientists is through various techniques that are employed before or during brain surgery. One such technique, **direct cortical stimulation**, occurs when a researcher applies a small electrical current directly to

the brain itself. This stimulation can cause excitation or inhibition depending on how much stimulation is given. In order to do direct cortical stimulation, the subject must have their brain exposed during surgery. One may reasonably ask the question, “Why would we ever do this?” Well, when someone is having brain surgery, there is likely a reason. For example, if a patient has a tumor in a medial portion of the brain, doctors may have to go through healthy brain tissue in order to reach the tumor so that they can remove it. Doctors must choose carefully which part of the healthy brain tissue they will damage in order to get to the tumor. One way of figuring out which area would do the least damage is to do a technique known as **cortical mapping**. During cortical mapping, direct cortical stimulation is applied to various parts of the healthy brain tissue to map out their functions. This allows doctors to choose the path of least damage.

Alternatively, cortical mapping can now occur through surgically implanted subdural strip and grid electrodes that will allow the researchers/doctors to stimulate the brain areas in between surgeries, as opposed to during surgery. Additionally, in recent years, researchers have been examining whether TMS is an appropriate (and non-surgical) substitution for direct cortical stimulation.

Split Brain Studies

Sometimes when surgeons perform surgery to improve the lives of their patients, they can unintentionally create other issues. One famous example of this involves patients who were subjected to a procedure that effectively disrupts the communication between the two sides of the brain. Split-brain research refers to the study of those who received this treatment and the knowledge resulting from this work (Rosen, 2018). Under what circumstances would such a seemingly radical procedure be used - and what are its effects?

In order to treat patients with severe epilepsy, doctors cut the corpus callosum in the brain, which is the main structure that connects the two hemispheres. Doing this kept the electrical activity that was causing the epileptic seizures confined to one hemisphere and helped get the epilepsy under control. However, this also disconnected the two hemispheres from each other, which led to some interesting studies, where researchers were able to study the functions of each hemisphere independently. These studies will be discussed later when we cover lateralization of functions.

Wada Procedure

One additional way to study the contributions of each hemisphere separately is through a procedure known as a Wada. In a Wada procedure, a barbiturate (a depressant drug used for various purposes including sedation) is used to put one half of the brain “to sleep” and then the contributions of the other hemisphere can be studied. Wada procedures are typically used for similar purposes as are cortical mapping techniques such as direct cortical stimulation. But, instead of mapping specific functions to specific areas (as with direct cortical stimulation), the Wada procedure maps functions to hemispheres. Usually, the Wada is used to identify which hemisphere is responsible for language processing and memory tasks. Although scientists know that language functions are usually in the left hemisphere, it is not always the case (particularly in left-handed individuals), so the Wada will help determine which hemisphere is dominant for language functions. For memory functions, both hemispheres play a significant role, but during the Wada, doctors are able to determine which hemisphere has stronger memory function.

One Major Concern With Lesion/Surgery Studies

One thing to remember about all studies of lesion or surgical patients is that the ability to generalize to the population during these studies may be questionable. It is important to keep in mind that that the reason these patients are studied is because they had some sort of issue with their brain. It is reasonable to wonder whether their brains are representative of “normal subjects,” that is, subjects who do not have lesions or other issues.

For example, perhaps someone with epilepsy, after having years of seizures, has a different brain organization than someone without epilepsy. In that circumstance, what we learn from them in a split brain study may not be applicable to a non-epileptic population.

Summary

There are many ways for researchers and doctors to learn about the brain and how it functions. As discussed in this section, we can use animals to study the brain and nervous system and try to draw parallels between what we learn about them and how our own brains work. We also discussed how people with brain lesions or other brain disorders (such as epilepsy) have led scientists to develop techniques to help them function, and how these techniques (split-brain surgeries or Wada procedures) have provided

us with valuable information about the brain as well.

1.11.7: Ethical Considerations

Learning Objectives

1. Explain the "Three R's".
2. Explain why research is still conducted on nonhuman animal subjects.
3. Describe the Tuskegee Syphilis Study and explain the ramifications of studies like these on research.

Overview

In this section, we will discuss the ethics of conducting research, both on nonhuman animal subjects and on human subjects. We will discuss a handful of examples of ethical violations and how these violations have led to negative outcomes in some situations.

Ethics in Neuroscience Research

Research has a very complicated history with respect to ethics. This is true when discussing our treatment of nonhuman animal subjects and our treatment of human subjects as well. Let's start by discussing the ethical considerations for nonhuman animal subject research.

Nonhuman Animal Subject Research

One area of controversy regarding research techniques is the use of nonhuman animal subjects. One of the keys to behaving in an ethical manner is to ensure that one has given informed consent to be a subject in a study. Obviously, animals are unable to give consent. For this reason, there are some who believe that researchers should not use nonhuman animal subjects in any case.

There are others that advocate for using nonhuman animal subjects because nonhuman animal subjects many times will have distinct advantages over human subjects. Their nervous systems are frequently less complex than human systems, which facilitates the research. It is much easier to learn from a system with thousands of neurons compared to one with billions of neurons like humans. Also, nonhuman animals may have other desirable characteristics such as shorter life cycles, larger neurons, and translucent embryos. However, it is widely recognized that this research must proceed with explicit guidelines ensuring the safe treatment of the animals. For example, any research institution that will be conducting research using nonhuman animal subjects must have an Institutional Animal Care and Use Committee (IACUC). IACUCs review the proposed experiments to ensure an appropriate rationale for using nonhuman animals as subjects and ensure ethical treatment of those subjects.

Furthermore, many researchers who work with nonhuman animal subjects adhere to the Three R's: Replacement, Reduction, and Refinement (Russell & Burch, 1959).

Replacement suggests that researchers should seek to use inanimate systems as a replacement for nonhuman animal subjects whenever possible. Furthermore, replacement is also suggested to replace higher level organisms with lower level organisms whenever possible. The idea is that instead of choosing a primate to conduct the study, researchers are encouraged to use a lower level animal such as an invertebrate (a sea slug, for example) to conduct the study.

Reduction refers to reducing the number of nonhuman animal subjects that will be used in the particular study. The idea here is that if a study can learn sufficient information from one nonhuman animal, then they should only use one.

Finally, refinement is about how the nonhuman animals are cared for. The goal is to minimize discomfort that the subject experiences and to enhance the conditions that the subject experiences throughout their life. For a full discussion of the Three R's, see Tannenbaum and Bennett (2015).

In conclusion, many researchers argue that what we have learned from nonhuman animal subjects has been invaluable. These studies have led to drug therapies for treating pain and other disorders; for instance, most drugs are studied using animals first, to ensure they are safe for humans. Animal nervous systems are used as models for the human nervous systems in many areas.

Sea slugs (Aplysia californica) have been used to learn about neural networks involved in learning and memory. Cats have been studied to learn about how our brain's visual system is organized. Owls have been used to learn about sound localization in the auditory system. Indeed, research using nonhuman animal subjects has led to many important discoveries.

Human Subject Research

What about research on human subjects? We do not have to go very far back in history to find situations where researchers behaved in unethical ways towards their human subjects. One of the most famous ethical violations in history is that many experiments were conducted using concentration camp prisoners as subjects during the holocaust.

Throughout the years, psychologists have engaged in various studies that have pushed the envelope of ethical research, such as Milgram's study of obedience or Zimbardo's Stanford prison study. Studies such as these have led to the development of strict ethical guidelines for human research. As with research on nonhuman animal subjects, there is a committee known as an Institutional Review Board (IRB) whose role is to approve research proposals. These committees ensure that there is an appropriate reason for completing the research with human subjects and that the safety of the human subjects are appropriately considered.

To further complicate matters, here in the United States, we have our own history of when ethical violations intersected with racial/ethnic divides.

Indeed, members of some groups have historically faced more than their fair share of the risks of scientific research, including people who are institutionalized, are disabled, or belong to racial or ethnic minorities. A particularly tragic example is the Tuskegee syphilis study conducted by the US Public Health Service from 1932 to 1972 (Reverby, 2009). The participants in this study were poor African American men in the vicinity of Tuskegee, Alabama, who were told that they were being treated for “bad blood.” Although they were given some free medical care, they were not treated for their syphilis. Instead, they were observed to see how the disease developed in untreated patients. Even after the use of penicillin became the standard treatment for syphilis in the 1940s, these men continued to be denied treatment without being given an opportunity to leave the study. The study was eventually discontinued only after details were made known to the general public by journalists and activists. It is now widely recognized that researchers need to consider issues of justice and fairness at the societal level.

“They Were Betrayed”

In 1997— 65 years after the Tuskegee Syphilis Study began and 25 years after it ended— President Bill Clinton formally apologized on behalf of the US government to those who were affected. Here is an excerpt from the apology:

So today America does remember the hundreds of men used in research without their knowledge and consent. We remember them and their family members. Men who were poor and African American, without resources and with few alternatives, they believed they had found hope when they were offered free medical care by the United States Public Health Service. They were betrayed.

Read the full text of the apology at http://www.cdc.gov/tuskegee/clintonp.htm.

Figure : President Bill Clinton greets a survivor of the Tuskegee Syphilis Study on African-American men.

The racism behind the unethical behavior in the Tuskegee study (and other studies) has led to a general distrust of research from some minorities. This distrust in research has led to a lack of volunteers from minority communities in research. Distrust in research also has other consequences, and as recently as 2021 has been cited as a contributing factor for the disproportionate impact of the COVID-19 pandemic on minority communities (Carson, et all., 2021). Unfortunately, when a large portion of the research conducted is on Caucasian samples, it is unclear whether or not the results generalize to non-Caucasian groups. Given the complexities of the human brain, researchers continue to push for a sample that is truly representative of the population at large to ensure that their research results are generalizable.

Summary

In this section, we discussed the ethical considerations of conducting research on nonhuman animal subjects and human subjects. We discussed what rules and guidelines have been put in place to ensure ethical conduct from researchers with their subjects. We also discussed some examples of violations of ethical research practices and the consequences of those violations.

2.1: Senses Overview

Senses Overview

Organisms such as humans have been identified as having five basic senses. The five basic senses that are most commonly identified in humans are sight, hearing, touch, smell, and taste. These senses help individuals understand and make sense of the environment around them. How do the senses work? Organisms and humans have sensory receptors which are specialized neurons that react to specific types of stimuli in the environment. When a stimulus is detected by a sensory receptor, a sensation response has occurred**.** There is typically a specified area or space in which a given sensory receptor can identify or respond to a stimulus, be it far away or in close proximity to the body; that is the receptor's **receptive field**. Think of everyday experiences organisms may have with the environment around them and how different receptive fields are different for the different senses. For example: for the sense of touch, a stimulus must come into contact with the body. For the sense of hearing, a stimulus can be a moderate distance away (some baleen whale sounds can propagate for many kilometers). For vision, a stimulus can be very far away; for example, the visual system perceives light from stars at enormous distances. A sensory receptor identifies stimuli in the environment and the conversion from sensory stimulus energy to action potential is known as **transduction**. Transduction in the nervous system typically refers to stimulus-alerting events wherein a physical stimulus is converted into an action potential (see image below), which is transmitted along axons towards the central nervous system for integration. It is a step in the larger process of sensory processing (see Figure 2.1.1).

Informationabout reusing

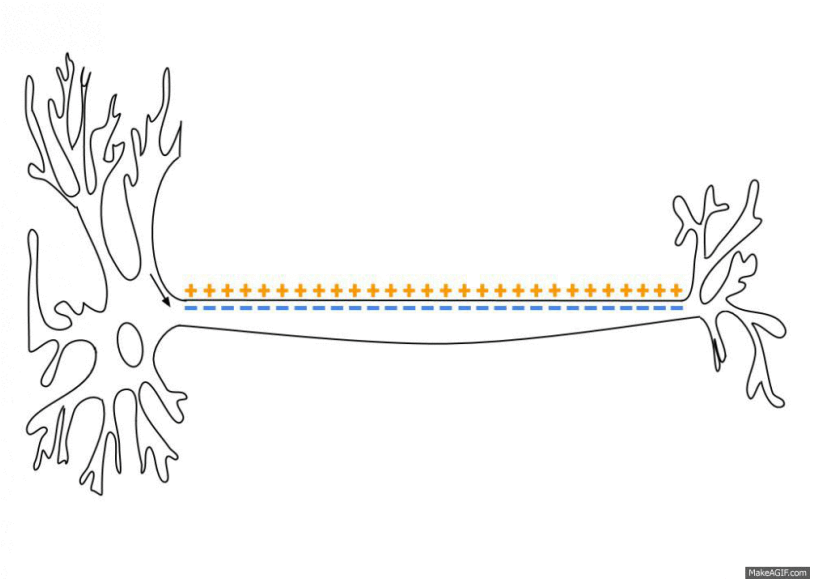

Figure 2.1.1: As an action potential (nerve impulse) travels down an axon there is a change in polarity across the membrane of the axon. In response to a signal from another neuron, sodium- (Na^+) and potassium- (K^+) gated ion channels open and close as the membrane reaches its threshold potential. Na^+ channels open at the beginning of the action potential, and Na^+ moves into the axon, causing depolarization. Repolarization occurs when the K^+ channels open and K^+ moves out of the axon, creating a change in polarity between the outside of the cell and the inside. The impulse travels down the axon in one direction only, to the axon terminal where it signals other neurons. By Laurentaylorj - Own work, CC BY-SA 3.0, https://commons.wikimedia.org/w/inde...curid=26311114

This chapter will later go into more depth about the difference between sensation and perception but the initial part of the chapter will focus on sensation. In short, senses help organisms identify a familiar sound, or recognize smoke when there is a fire. The receptors are different for each sense and they are specialized according to the type of stimulus they sense. For example, touch receptors, light receptors, and sound receptors are each activated by different stimuli. Touch receptors are not sensitive to light or sound; they are sensitive only to touch or pressure. However, stimuli may be combined at higher levels in the brain, as

happens with olfaction, contributing to our sense of taste. These senses will be discussed in more detail throughout this chapter along with a brief introduction into how these senses at times work together to help individuals have a deeper understanding of the environment around them and how this deeper understanding can help individuals respond to that environment.

2.2.1: Introduction

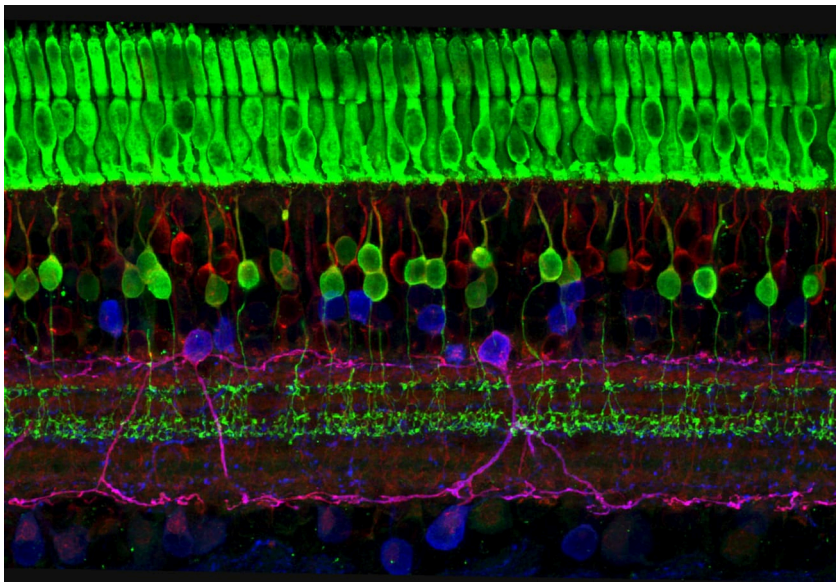

Figure 6.1 Vision begins in the retina, a layered structure where photoreceptors absorb light to start a chain of activity that ends in the brain. Image Credit: Wei Li, National Eye Institute, National Institutes of Health. Public domain

Meet the Author

Richard Olivo, PhD

Meet the author

For most people, vision is not only their most important sense, it is the sensory system that defines the world around them. If we weren't such visual animals, humans wouldn't move easily through the space around us, recognize other people, identify familiar objects, and do numerous other tasks that seem effortless. Movies and videos wouldn't be persuasive representations of the world. Our visual system acts so immediately and fluently that it is difficult for us to realize that constructing the visual world is an extremely difficult task that our brain accomplishes through multiple steps that begin in the eye and continue in major regions of the cerebral cortex. Our goal in this chapter will be to follow those steps, beginning in the retina and proceeding through the primary visual cortex and adjacent areas in the occipital lobe, and continuing in the inferotemporal cortex. We will first encounter photoreceptors in the retina, specialized neural cells that catch light energy, and we will end with cortical neurons that respond to faces, places, and complex visual shapes.

An analogy can help us understand how unlikely vision would seem to us if we didn't have a sophisticated visual system ourselves. In the 1940s, scientists discovered how bats could fly freely in the dark and catch flying insects without using vision. The bats use echolocation: they emit ultrasonic screeches and then detect the echoes of sounds reflected from tree branches and their insect prey. It's hard to imagine what it might be like to perceive surroundings through echolocation, but our vision does something similar. The sun or artificial sources flood our surroundings with light, and we detect reflections of that light from the surfaces around us. Our brain processes that sensory information to construct a mental image of the world—something we might not believe could be done if we didn't do it ourselves.

2.2.2: An Overview of the Visual System

Learning Objectives

By the end of this section, you should be able to

- 6.1.1 Describe the region of the electromagnetic spectrum that is perceived by our visual system, and the relative energy of photons at long and short wavelengths.
- 6.1.2 Describe the major parts of the eye and their role in focusing light to create a clear image.

In this section, we will meet the range of the electromagnetic energy spectrum that we call "light," and see how the structure of the eye provides an optical system that creates a sharply focused image of the visible world on the sensory structure at the back of the eye, the retina.

We Capture Photons of Light Reflected from Objects Around Us

Light is a form of electromagnetic radiation, energy packaged in particles called photons. Physicists understand that light is both a particle and an electromagnetic wave, and although light can be described by the energy in each photon, light is more typically described by its wavelength on the electromagnetic spectrum. Electromagnetic wavelengths stretch from long wavelength, low energy radio waves to short wavelength, high energy gamma rays. (Figure 6.2)

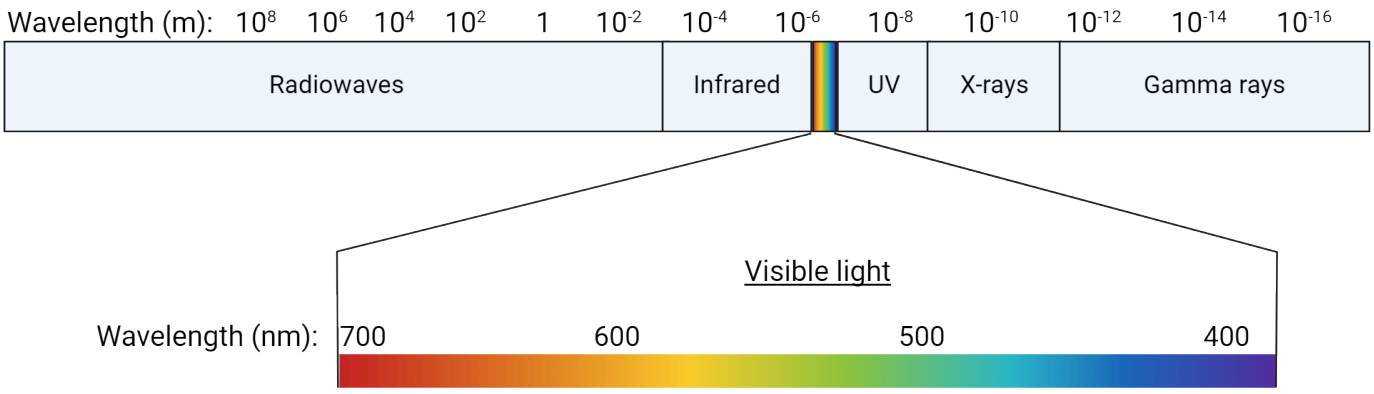

Figure 6.2 Light is a component of the electromagnetic spectrum

Sunlight includes wavelengths from infrared to ultraviolet (UV) that penetrate the atmosphere, but only the middle of that range penetrates water, which is where vertebrate vision first evolved. This is the visible spectrum that our eyes can detect. Different components (wavelengths) of the visible spectrum are absorbed or reflected by the surfaces of objects and our visual system interprets the reflected wavelengths as an object's color and shape. Shorter wavelengths within the visible spectrum we call blue while longer ones look red. White light combines wavelengths from the entire visible spectrum. Bright lights produce many photons per second, while dim lights emit few photons per second.

Anatomy of the Eye

The eye is the primary sensory structure that intercepts electromagnetic waves in the visible spectrum, eventually allowing us to perceive light. Figure 6.3 shows the major parts of the eye.

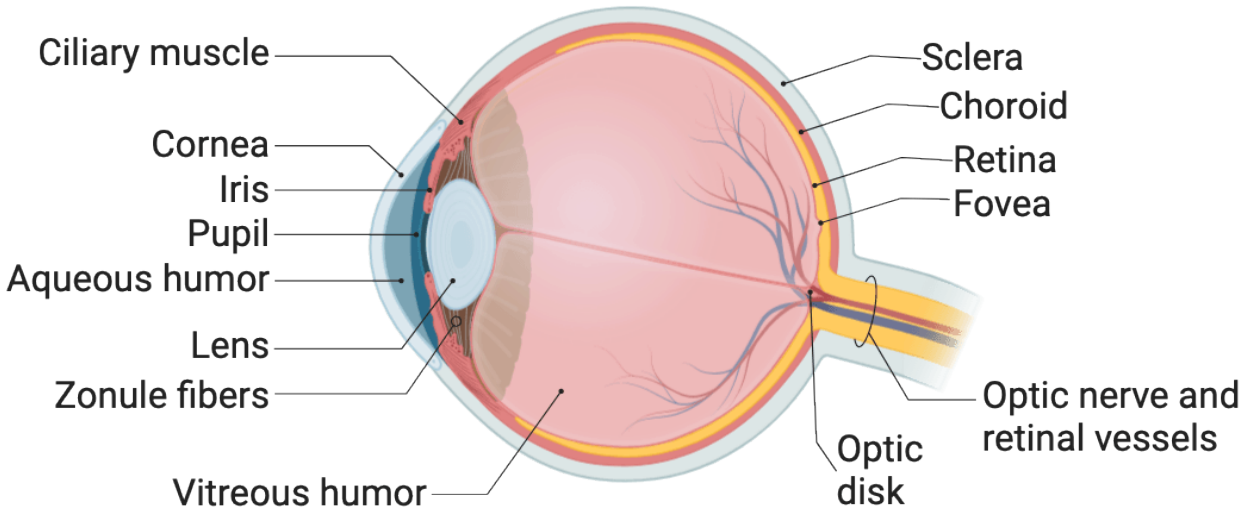

Figure 6.3 Anatomy of the human eye

At the front of the eye, the eye's optics are like the lens of a camera. The rays of light reflected from objects spread out in space. The cornea and crystalline lens intercept the arriving rays of light and bend them to form a focused image on the retina at the rear of the eye. Interestingly, because lenses invert images, the projection of the world on the retina is upside-down and left-right reversed. Figure 6.4 shows how light reflected from objects diverges in space but is refocused and flipped around for its projection on the retina.

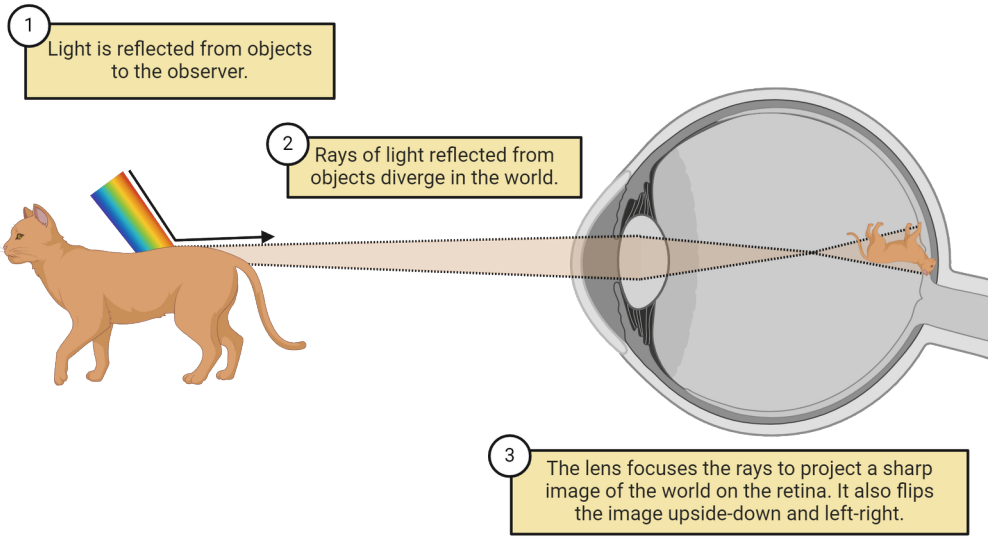

Figure 6.4 Objects reflect rays of light that reach the eye

The ciliary muscle and zonule fibers pull on the lens to flatten it and shift the focus to distant objects; when relaxed, the lens rounds up to focus on nearby objects. A clear liquid, the aqueous humor, fills the space between the cornea and the lens, and a clear, jelly-like vitreous humor fills the globe of the eye. Blood vessels spread over the inner surface of the eye next to the vitreous humor.

At the back of the eye, photoreceptors (rods and cones) embedded in the retina respond to the light hitting them, and several layers of nerve cells process the image, responding to borders between light and dark. The final retinal neurons, called retinal ganglion cells, send their axons out of the eye, bundling together to form the optic nerve, which transmits visual information to the brain. The optic disk is the region where the ganglion cell axons leave the eye and blood vessels enter. There are no photoreceptors in the optic disk, which creates a "blind spot" in our vision, although we are normally unaware of it. The fovea at the center of the retina is a region of tightly packed photoreceptors that provide our highest visual acuity. When we look at an

object, we turn our head and eyes to project the object's image onto the fovea, where we perceive details most clearly.

The remaining structural features include the choroid, a layer behind the retina with blood vessels that nourish the retina and a screening pigment to absorb stray light and prevent internal reflections. Behind that is the tough white of the eye, the sclera.

Correcting Optical Flaws: Myopia, Hyperopia and Presbyopia

Sharp vision requires the image projected on the retina to be in good focus, but for many people, the focus is in front of the retina (myopia) or behind the retina (hyperopia) (Figure 6.5). Corrective lenses restore sharp focus on the retina. Although in some cases people are born with an eye that is too short or too long for good focus, and thus need to wear corrective lenses from an early age, there is also some indication that constant close-up work can affect the continued development of the eye's shape and lead to myopia.

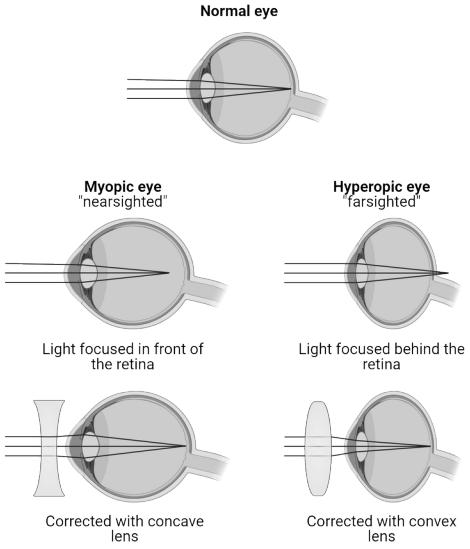

Figure 6.5 Correcting optical flaws

Even people who do not need corrective lenses when they are young eventually require reading glasses as they age. This condition is called "presbyopia," literally "old eyes," and it results from the lens of the eye becoming less flexible as people age. The lens normally becomes rounder to focus on nearby objects, but as people age, the lens becomes more rigid and is unable to change its shape to focus on nearby objects such as pages of text. At that point, corrective lenses are needed to supplement the lens's ability to focus.

2.2.3: The Retina

Learning Objectives

By the end of this section, you should be able to

- 6.2.1 Describe the layers of the retina and the five major cell types
- 6.2.2 Describe the functional differences and anatomical distributions of the two kinds of photoreceptors: rods and cones
- 6.2.3 Describe the steps in phototransduction
- 6.2.4 Explain how cones transduce color information by using different visual pigments with maximal sensitivity to different wavelengths of light

In this section, we will explore the retina, and meet its five major types of neurons. We will see that vision begins with specialized sensory receptors, the rods and cones, which capture light energy and create a neural signal, a process called phototransduction. We will learn that rods function best in dim light while cones are responsible for our vision in bright light, our high-acuity detailed vision, and color vision. We will encounter the surprising steps in phototransduction between capture of a photon and closing of membrane channels that produce the subsequent change in the electrical potential of a rod or cone. Finally, we will discover that our color vision depends on three types of cones that differ in the absorption spectrum of the molecules that capture photons.

The Retina Is Composed of Several Neural Cell Types

The retina (Figure 6.6) arranges five types of nerve cells in distinct layers. The retinal processing chain for conscious vision begins with the receptors (rods and cones) that absorb light. The rods and cones make synapses with bipolar cells, which connect in turn to ganglion cells. Horizontal cells support visual processing with lateral synaptic connections to receptors and bipolar cells. Amacrine cells provide lateral connections in the synaptic layer between bipolar and ganglion cells. Ganglion cell axons spread across the inner retinal surface, gathering as a bundle to leave the eye as the optic nerve. The figure does not show the pigment epithelium above the receptors, or the extensive array of blood vessels that spread over the retina next to the ganglion cells.

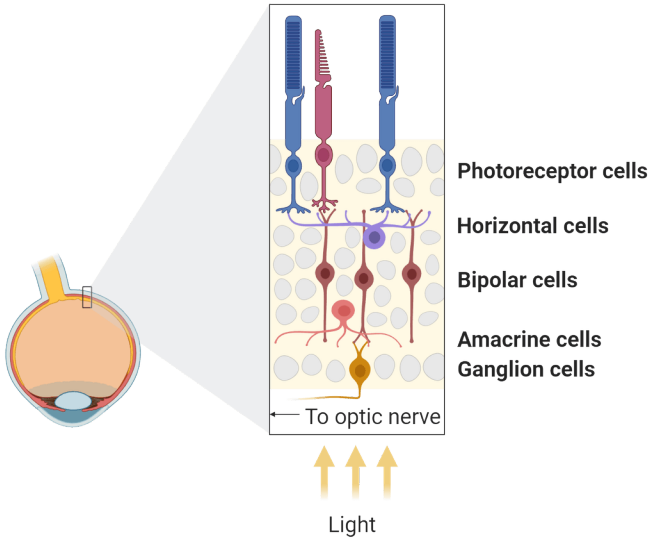

Figure 6.6 Retina structure

Embryologically, the retina is an outpocketing of the brain, and because it is more accessible than the developed brain and arranged in clear layers of defined neuronal cell types, it has been the subject of many experimental studies. This began in the 1890s when Cajal published images of retinas stained by the Golgi method, and identified many of the cell types. Since all vertebrate retinas have the same general structure, retinas with relatively large cells have been the most intensively studied, such as the retina of the mudpuppy, a large amphibian related to frogs and salamanders.

The human retina shown in Figure 6.7 has relatively small cells, but it is clear they are arranged in distinct layers. Although the eye is sometimes cited as evidence for “intelligent design,” the retina is actually a poor optical design because light must pass through several layers of neurons to reach the photoreceptors. These layers scatter the light and blur the image. It is never possible to know exactly why evolution produced a particular structural outcome, but two theories have suggested why the receptors are placed in an optically poor position, facing away from the light. One possibility is that because the receptors are metabolically very active, they require a dense blood supply, which they receive by facing the blood vessels in the choroid layer. A second possibility is that receptors evolved from ciliated cells that lined the embryonic neural tube (the “connecting cilium” is a group of microtubules arranged like a cilium that are still present in photoreceptors). As additional retinal layers are added during development, the receptors remain in an optically poor position. The fovea compensates for this “unintelligent” optical design by pushing aside the neural layers at our center of gaze, where tightly packed cones provide our sharpest visual acuity.

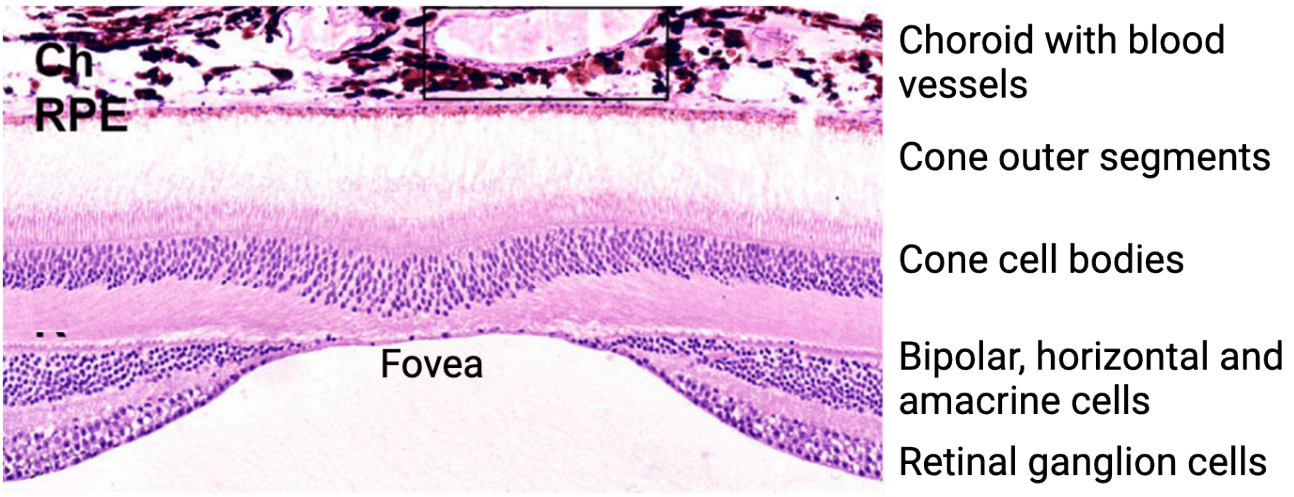

Figure 6.7 Fovea structure In the fovea, inner layers are pushed aside so light can hit photoreceptors directly.Image credit: Gregory S. Hageman, Karen Gaehrs, Lincoln V. Johnson and Don Anderson. AGE-RELATED MACULAR DEGENERATION (AMD) BY GREGORY S. HAGEMAN, KAREN GAEHRS, LINCOLN V. JOHNSON AND DON ANDERSON. In: Webvision, http://webvision.med.utah.edu/ CC BY-NC 4.0

Rods and Cones Capture Photons of Light

In 6.2 The Retina we introduced photoreceptors, the specialized neurons that respond to light. Photoreceptors (Figure 6.8) have an outer segment of discs, or infolded membrane in which millions of visual pigment molecules are embedded. These pigment molecules give photoreceptors the ability to capture light and will be discussed more below. Photoreceptors also have an inner segment with mitochondria, the nucleus, and other structures typical of all cells (see Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy). The synaptic terminal is the photoreceptor’s output region, where it connects to bipolar and horizontal cells.

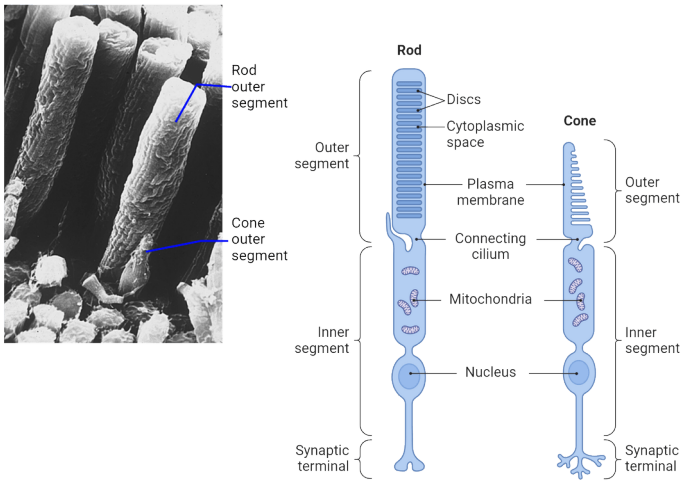

Figure 6.8 Morphology of photoreceptors "Image credit: Deric Bownds, U Wisconsin, personal communication to R. Olivo.

Our photoreceptors come in two types, each with a unique function in vision: cones and rods. The human eye has about 6 million cones, concentrated in the fovea and central retina but also distributed sparsely in the retinal periphery. Cones are responsible for high-acuity color vision in daylight. The human retina also has about 120 million rods, which are absent from the fovea but distributed across the rest of the retina. Rods serve low-acuity vision in dim light (such as moonlight), and under optimal dark-adapted conditions a rod can respond to as little as a single photon of light. In daylight and typical artificial light, the rods no longer respond because the bright light saturates their response, and only the cones signal differences in brightness.

Rods and Cones Depolarize in the Dark and Hyperpolarize in the Light

When neurobiologists first succeeded in recording from rods and cones with intracellular electrodes, they were puzzled by what they found. Most sensory receptors, including invertebrate photoreceptors, depolarize in response to a stimulus, but vertebrate photoreceptors hyperpolarize (become more negative) in response to light. Figure 6.9 shows an example of the kind of data one of these experiments generated, where a photoreceptor's intracellular electrical response was recorded while light was flashed on it. Dim flashes elicited a small hyperpolarization, and bright flashes evoked a large hyperpolarization. The receptors in the dark also had a surprisingly depolarized resting potential, about -40 mV instead of the -60 mV more typical of nerve cells (see Chapter 2 Neurophysiology). Everything seemed backward!

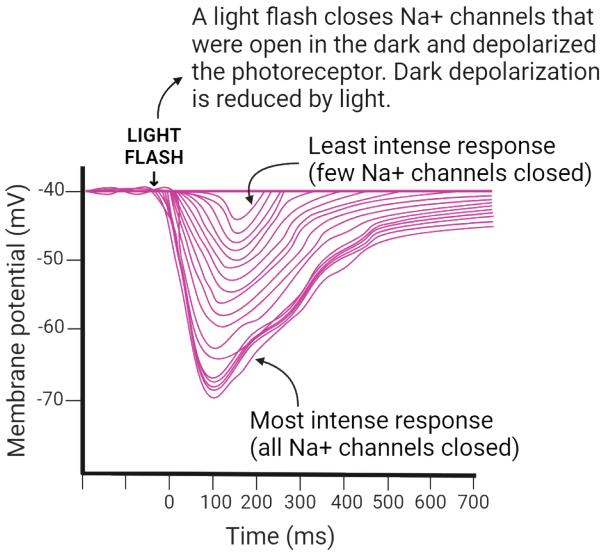

Figure 6.9 Rod and cone membrane potential changes

Later work unraveled the mystery. In the dark, channels in the outer segment are open and admit positive Na+ ions, creating a depolarized resting potential. Capturing photons of light leads to closing some of these sodium channels, which diminishes the resting depolarization, an apparent hyperpolarization. With brighter lights and more photons captured, more of the channels close, leading to greater degrees of hyperpolarization. In a way, we can think of the response to light as allowing the photoreceptors to return to their “real” resting potential (the potential when the sodium channels are closed, about -60 mV like other neurons). Light interrupts the depolarization that occurs in the dark. Like all other neurons, photoreceptors release their transmitter (glutamate) when they are depolarized, so photoreceptors continually release transmitter in the dark, and light interrupts transmitter release. In the next section, we will discuss how photoreceptors keep Na+ channels open to become depolarized in the dark and how light exposure cancels that.

Phototransduction

Eventually, researchers worked out how the capture of photons by visual pigment molecules in the disk membranes of photoreceptors led to closing sodium ion channels in the cell membrane. We call this process of turning photons into an electrical signal "phototransduction" (Figure 6.10). Here, we will describe this process in rods. Cones use similar processes but differ in the wavelengths of light that they absorb, which will be discussed in the next section.

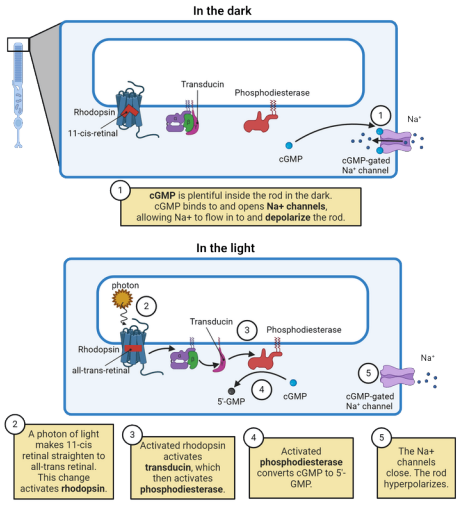

Figure 6.10 Phototransduction

In rods, rhodopsin molecules are the visual pigment packed into the disk membranes. Rhodopsin molecules consist of two components: opsin, a large protein, and 11-cis retinal, a small subunit that is derived from Vitamin A. In the dark, the 11-cis retinal has a bent side chain. Capturing a single photon provides the energy to straighten the side chain to its straight, “all-trans” shape. This in turn activates the opsin protein, which leads to a series of steps that reduce the level of cGMP, a messenger molecule in the cytoplasm. While the intermediate steps may seem detailed, the important point is that light leads to closure of sodium channels that are open in the dark.

As Figure 6.10 shows, cGMP is normally abundant in the dark and attaches to Na+ channels in the cell membrane, keeping them open. In the dark, Na+ ions enter the cell and create a depolarized resting potential. The action of light reduces the level of cGMP, which leads to closure of Na+ channels and less depolarization (which appears as hyperpolarization). The more photons that each photoreceptor catches, the lower its level of cGMP and the more Na+ channels that close. In bright light, when most or all of the Na+ channels are closed, the cell is essentially at its “real” resting potential: strongly hyperpolarized from its resting state in the dark.

Color Vision in the Retina: Three Kinds of Cones

Rhodopsin, the visual pigment that catches photons and begins the process of phototransduction, is found in rods (“rod opsin”), but our retinas have three other visual pigments found in three types of cones. These pigments differ slightly in their opsin protein but work in similar ways. The different opsins give the pigments different absorption spectra, making them effective in catching

photons at different peak wavelengths. Figure 6.11 shows the peak absorbance for the 4 major visual pigments found in human photoreceptors. For example, rhodopsin in rods has its absorption peak at 498 nm, in the middle of the spectrum, while the three cone pigments have peaks in the short wavelengths (S or "blue cones," peak at 420 nm), middle wavelengths (M or green cones, 534 nm), or long wavelengths (L or red cones, 564 nm). The middle and long wavelength pigments differ only slightly because they diverged only recently in evolution, giving humans and old-world monkeys three cone types. Most mammals such as dogs, cats and new-world monkeys have only two types of cones, one for short wavelengths (blue) and one for long wavelengths (yellow). Thus, the color vision of most mammals is different from ours, and your pet dog or cat does not see colors the same way you do.

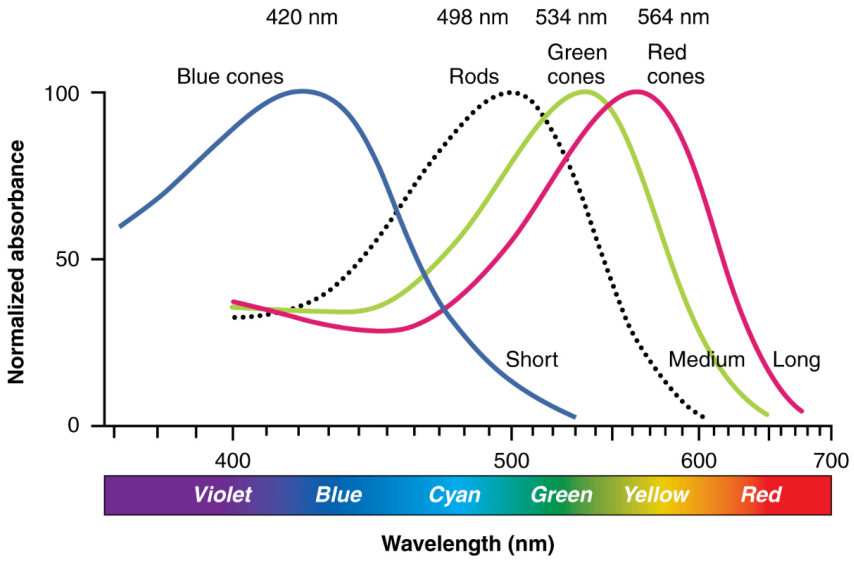

Figure 6.11 Absorption spectra of the four visual pigments in the human eye Three visual pigments in three kinds of cones underpin our trivariant color vision. Image credit: Image by OpenStax - Anatomy & Physiology, https://openstax.org/books/anatomy-a...ory-perception, CC BY 4.0

Although each absorption spectrum indicates that a single pigment can catch photons in a range of wavelengths, one pigment cannot distinguish between a small number of photons at the pigment's best wavelength and many photons at a wavelength that the pigment does not absorb well. Both stimuli could result in the same total number of photons being caught, and any photon that is caught initiates phototransduction in the same way. (Figure 6.12)

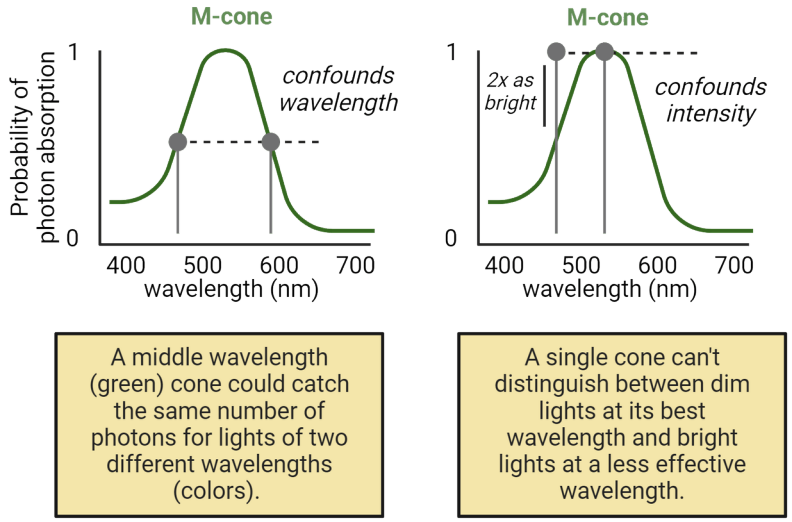

Figure 6.12 One visual pigment cannot discriminate colors Image credit: Image redrawn from: Patterson SS, Neitz M and Neitz J (2019) Reconciling Color Vision Models With Midget Ganglion Cell Receptive Fields. Front. Neurosci. 13:865. doi: 10.3389/fnins.2019.00865. CC BY 4.0

To distinguish light of two wavelengths, it is necessary to compare the responses of nearby cones with different pigments. For example, if the blue-absorbing cones in a patch of the retina catch many photons but nearby green or red cones catch only a few, then the light is at the blue end of the spectrum.

Since we have three types of cones, our color vision has three primary colors. Together, they can generate the appearance of any possible color. Looking at a TV or computer screen with a magnifying glass will reveal blue, green and red pixels (Figure 6.13). By controlling the brightness of each pixel, the screen simulates any real-world color. Red and green pixels together give us the sensation of yellow, and all three types together appear white. It's as if each pixel type is activating one of the three cone types. In combination, the RGB pixels evoke responses in the cones that are equivalent to their response to any real-world color.

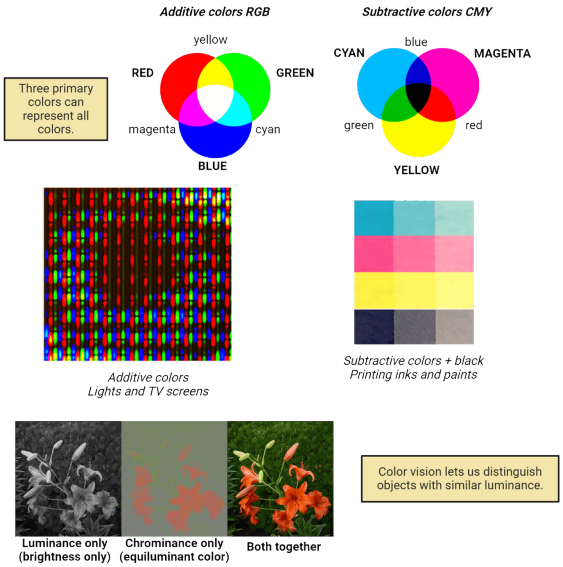

Figure 6.13 Primary colors image credit: "Luminance-hrominance image: By Algr, CC BY-SA 3.0, https://commons.wikimedia.org/w/inde...curid=31044071; RGB color model: By pd4u, CC0, https://commons.wikimedia.org/w/inde...curid=65835679; CMY color model: By Jipre, CC0, https://commons.wikimedia.org/w/inde...curid=14670042"

For lights and TV screens, where photons are added together to make the final mixture, red, green and blue are the primary colors. But surfaces covered in paints and inks subtract photons from the illuminating light, reflecting the non-absorbed photons. For example, a yellow paint patch in white light absorbs blue photons and reflects red and green, which appear to us as yellow. The three primary colors for subtractive surface colors are cyan, magenta and yellow (CMY). As explained in our example, yellow absorbs blue, reflecting green and red, while magenta absorbs green and reflects red and blue, and cyan absorbs red and reflects blue and green. For printing inks (Figure 6.13), the three primary inks together should appear black, but in practice the mixture often looks muddy, and a fourth ink, a true black, is usually added. Test strips of the four primary printing inks in different densities can often be found on printed materials, including the hidden flaps of cookie packages.

As shown in the bottom of Figure 6.13, color allows us to distinguish objects that have equiluminant surfaces (surfaces that would appear equally bright in a grayscale image) but reflect different wavelengths. The relatively recent evolution of separate red and green cones in primates (including humans) from a single yellow-absorbing cone further improves discrimination. Detecting red apples in the midst of green leaves would be difficult without our trichromatic color vision.

Color Blindness

Some people carry a genetic variation that gives them only two cone types instead of three, or they produce an anomalous version of one of the cone pigments. As a result, they make color matches that differ from those made by typical trichromats, who have three types of cones. They are not actually "blind" to a color, but rather can't distinguish some colors that trichromats see as different. Color blindness affecting the red or green genes is the most common, occurring in about 8% of males and only 0.4% of females (Neitz & Neitz, 2011). The red and green genes are both on the X chromosome (further evidence that they were duplicated recently in evolution). Since XY biological males have only one X chromosome, they cannot compensate for a defective gene, unlike XX females who have two different X chromosomes, one from each parent. Blue blindness is very rare, since the blue gene is on a chromosome for which everyone has two copies.

2.2.4: Visual Processing Begins in Bipolar, Horizontal, Amacrine and Ganglion Cells

Learning Objectives

By the end of this section, you should be able to

- 6.3.1 Describe the direct pathway for transmitting information from photoreceptors to the brain
- 6.3.2 Define the difference between on-center and off-center bipolar cells and how they help detect edges
- 6.3.3 Explain how horizontal cells facilitate the center-surround nature of bipolar cell receptive fields
- 6.3.4 Describe the difference in how on-center and off-center retinal ganglion cells respond to light in their receptive fields
- 6.3.5 Define the major types of retinal ganglion cells and their contribution to visual perception
- 6.3.6 Describe how retinal ganglion cells contribute to detecting color edges through the use of opponent color responses

In many ways, the millions of rods and cones spread across the retina are like the pixels of a digital camera. Each photoreceptor reports on the number of photons it is catching from the image projected on the retina. It is tempting to imagine that this is the information that the optic nerve transmits to the brain for further processing, but that is not what happens. The retina's layers of nerve cells between the photoreceptors and the ganglion cells transform the information from a report on color and brightness to a report of color and brightness borders in the region served by each ganglion cell. In this section, we will learn about how the cells of the retina provide the first step in visual processing, detecting the edges of objects.

Bipolar Cells

Take a moment to remind yourself of the cellular architecture in the retina, from Figure 6.6 in the previous section. From the photoreceptors, the next synaptic partners in the pathway out of the eye are bipolar cells. This is where detecting borders begins. Bipolar cells gather information from the photoreceptors that synapse directly onto them and also from additional photoreceptors in a surrounding region, creating a circular region with a center and a surround that together are the bipolar cell's receptive field (see Feature Box on the concept of receptive fields). This arrangement is diagrammed on the left side of Figure 6.14. As mentioned, photoreceptors in the center of the receptive field synapse directly onto the underlying bipolar cell, while receptors that contribute to the surround connect to horizontal cells that modulate the synapses from central photoreceptors, thereby canceling the bipolar cell's response to the center. (Photoreceptors make multiple synapses, so one receptor can contribute to the center of one bipolar cell's receptive field but also help form the surround for other bipolar cells.) Contrast between the light falling on the center and the surround is required for a bipolar cell to respond. Uniform illumination is not effective.

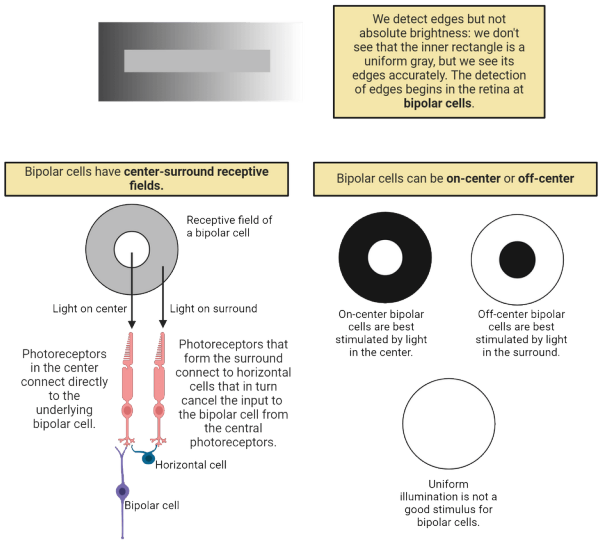

Figure 6.14 Bipolar cell types

We are actually not very good at perceiving brightness. In the gray rectangle in the top of Figure 6.14, we don't see that the inner rectangle is a uniform gray, but we see its edges accurately. Similarly, we make poor judgments of absolute brightness (if you are now in a room lit by artificial light, is the room brighter than the light outdoors on a cloudy day? it's hard to know the answer.). On the other hand, we are very good at detecting and remembering edges. A cartoon drawn with just a few lines can easily represent a face or an object for us.

The center-surround receptive fields of bipolar cells provide the first processing step that ignores absolute brightness in favor of detecting contrasting borders between light and dark. This arrangement is sensitive to contrast because bipolar cells respond in opposite ways to input from photoreceptors in the center of their receptive field compared to photoreceptors in the receptive field surround. To better understand how this works, we need to consider the two types of bipolar cells, on-center and off-center bipolar cells.

About half of bipolar cells are on-center, where the bipolar cell depolarizes to light covering the center of the receptive field if a darker region surrounds the center, or off-center, which is the reverse. In an on-center cell, the bipolar cell is directly affected by responses of the photoreceptors that synapse on it directly. The photoreceptors in the surround do not synapse directly on the bipolar cell. Instead, they synapse on horizontal cells, a type of interneuron that serves as a bridge between photoreceptors and bipolar cells. Activating horizontal cells cancels the bipolar cell's response to the center stimulus.

Although the complete neural circuit is more than we will explore here, it still may surprise you that light in the center of the receptive field depolarizes on-center bipolar cells but has the opposite effect on off-center bipolar cells. How can there be two types of bipolar cells, both of which receive direct synapses from photoreceptors in the center of their receptive fields? The cells differ because they have different molecular receptors for the neurotransmitter glutamate that is released by rods and cones. Recall that neurons release transmitter only when they are depolarized (see Chapter 2 Neurophysiology), and also that rods and cones are depolarized in the dark. This means that in the dark, the depolarized rods and cones release glutamate continually onto the bipolar cells they connect to. For an off-center bipolar cell, a dark patch of a visual scene falling in the center of the receptive field will depolarize the receptors and lead to the release of glutamate. The receptor for glutamate in off-center bipolar cells depolarizes the cell, so if the photoreceptors in the center are in the dark, the off-center bipolar cell receives transmitter and is depolarized: an off response.

On-center bipolar cells have a different receptor for glutamate, one that leads to activation of a second messenger that closes depolarizing channels. Light on the center of the receptive field interrupts the release of transmitter from photoreceptors, which stops activation of the messenger that closes depolarizing channels in the bipolar cells. Those channels then open, and the bipolar cell depolarizes, producing an on-response. Thus, because they have different receptors for the neurotransmitter glutamate, on-center and off-center bipolar cells have different responses to light in the center of their receptive field.

While it's helpful to understand the mechanisms for on and off responses, let's return to the important task that bipolar cells accomplish: responding to contrast between light and dark regions of the image while ignoring uniform illumination. If we imagine the image background as a medium gray, the two types of bipolar cells would depolarize in response to either dark spots or bright

spots covering the center of their receptive fields. Although uniform illumination is not a good stimulus, a border between light and dark falling on the receptive field works well if it puts light or dark on the center and the opposite illumination on at least part of the surround. The bipolar cells' response to contrast is conveyed to the next stage of retinal processing, the ganglion cells. Since the distances are very short, action potentials are not necessary to transmit signals, and bipolar cells are "non-spiking," making only graded changes in potential. The bipolar cells release varying amounts of their transmitter, which is also glutamate, depending on how depolarized they are.

The Concept of Receptive Fields

We referred above to the center-surround receptive field of a bipolar cell, but the concept of receptive fields actually began more than a century ago to describe areas of the skin that activate individual touch receptors (see Chapter 9 Touch and Pain). A single touch receptor axon typically branches to innervate a small patch of skin, and touching anywhere in that patch of skin will generate action potentials in that sensory axon. The patch of skin was called the sensory axon's "receptive field." Later, the concept was expanded to include sensory systems (like vision) where some regions of the receptive field might excite the neuron while other regions inhibit responses. The concept was further expanded to apply to neurons in the brain linked by a synaptic network to receptors that might be many synapses away. In the visual system, as we will see in later sections, a cortical neuron's receptive field describes the pattern on the retina (or a screen in front of the animal) that optimally excites or inhibits the neuron, even if the neuron is deep in the brain and far removed from the initial sensory receptors that contribute to its response. A neuron's receptive field is a succinct description or diagram of the pattern of stimuli that determine the neuron's response.

Retinal Ganglion Cells

Like the bipolar cells that drive them, retinal ganglion cells have center-surround receptive fields and are either on-center or off-center, characteristics they inherit from the bipolar cells that excite them. On-center ganglion cells are driven by on-center bipolar cells, and off-center bipolar cells drive off-center ganglion cells. Because the ganglion cell axons transmit signals a significant distance to the brain, retinal ganglion cells do make action potentials, and they are the first cells in the retinal processing chain that do so. In Figure 6.15, an on-center ganglion cell on the left responds with a burst of action potentials to a bright spot on its receptive field center, and also to a dark ring on the surround. Both patterns represent contrast between the center and the surround. The ganglion cell also responds to reverse patterns, but they inhibit the cell's spontaneous firing instead of exciting firing. A dark spot on the center or a bright ring on the surround inhibits an on-center ganglion cell. Since uniform light does not activate bipolar cells, it also does not activate ganglion cells.

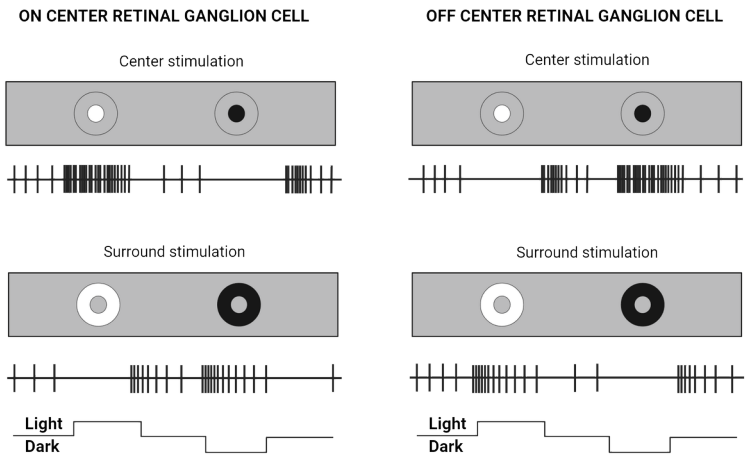

Figure 6.15 Retinal ganglion cell receptive fields

The off-center ganglion cell on the right in Figure 6.15 has the opposite responses. A dark spot on the center or a bright surround excites the cell, while the opposite patterns inhibit it. In all cases, a boundary between light and dark is necessary to generate a

response in ganglion cells. It is that information about borders and edges, not brightness, that is carried to the brain in the optic nerve.

The optic nerve projects to several different destinations in the brain because it carries axons from several types of ganglion cells. The on- and off-center ganglion cells that are responsible for conscious visual perception provide more than 80% of the axons in the optic nerve. Those important ganglion cells can be further divided into two groups, relatively few large ganglion cells with large receptive fields and large axons that conduct signals rapidly (the “magnocellular” cells), and very abundant smaller cells with small receptive fields and medium diameter axons that conduct more slowly (the “parvocellular” ganglion cells). Magnocellular and parvocellular axons connect to neurons in different layers of the lateral geniculate nucleus of the thalamus, which we will discuss in 6.4 The Thalamus and Primary Visual Cortex.

The difference in receptive field sizes of magnocellular and parvocellular ganglion cells gives them different roles in conscious visual perception. The abundant parvocellular cells with small receptive fields provide detailed, high-acuity vision, including details of the image that falls on the fovea. If you look straight ahead at a scene, the center will appear sharp, but if without moving your eyes you pay attention to objects near the edge of your visual field, you will discover that peripheral vision is quite blurry. If you wish to inspect peripheral details, you move your eyes to project those details on the fovea, where vision is sharp. Our brains create the illusion that the entire scene is sharply focused, but in fact, peripheral regions served by ganglion cells with large receptive fields are not sharp at all. However, magnocellular cells are very sensitive to motion. If you wiggle your fingers near the edge of your peripheral vision, you will easily detect their motion even though they are blurry. The large diameter axons and rapid conduction velocity of magnocellular ganglion cells helps convey information about motion quickly to the brain.

Two other types of retinal ganglion cells convey responses to light but do not contribute to conscious visual perception. One evolutionarily older class of ganglion cells, less than 10% of all ganglion cells, has wide receptive fields and narrow axons, and projects to the superior colliculus. These ganglion cells contribute to generating eye movements as we watch a scene. The highest visual area in the brains of fish and amphibians, the optic tectum, is the precursor of the superior colliculus in mammals, but it has been superseded by the evolutionarily new visual pathway for visual perception that leads to the thalamus and the visual cortex. Another category of specialized ganglion cells, about 1% of the total, are the intrinsically photosensitive ganglion cells (ipRGCs). These cells contain the pigment melanopsin, which makes them directly responsive to light. They do not contribute to visual perception (and are sometimes called “non image-forming” cells, NIFs), but most of them project to the suprachiasmatic nucleus and help control circadian rhythms (see Chapter 15 Biological Rhythms and Sleep). A few ipRGCs project instead to the brain nucleus that controls the pupillary reflex, which constricts the iris in response to bright light.

The retina is carpeted in these multiple types of ganglion cells, and the receptive fields overlap within and between types. Any visual pattern falling on the retina will activate many ganglion cells, with the specific responses depending on the portions of the image that fall within each ganglion cell’s receptive field. There are between one and two million retinal ganglion cells in each human retina. Receptive field centers can be as small as a single cone in the fovea, where the parvocellular ganglion cells are dense, or much larger in the periphery where the ganglion cells are spread out and have large receptive fields.

Color Vision in the Retina: Opponent Color RGCs

Many experiments to record electrical activity from retinal cells were first performed in fish and amphibians because their retinal cells are much larger than in mammals, making them easier to penetrate with sharp microelectrodes. The goldfish retina was also the site of the first measurements of absorption spectra for individual cones, revealing three types as in our retinas. Meanwhile, research on color vision in people mostly involved a controversy among psychologists about whether three primary colors explained color vision, or whether vision involved pairs of complementary colors. This controversy continued for many years because both sides turned out to be right. At the receptor level, three cone types account for the three primary colors, but retinal ganglion cells receive input from cones representing opposing pairs of color and thereby respond to pairs of complementary colors.

Early recordings from retinal ganglion cells in the goldfish retina showed excitation to one color but inhibition to its complementary color, establishing the concept of opponent colors. Soon after, recordings were made from lateral geniculate neurons in monkeys, which have receptive fields like ganglion cells, and this settled the debate about color vision in humans. Figure 6.16 shows responses of a goldfish retinal ganglion cell to blue-green light, which excited bursts of action potentials, and to red light, which inhibited the cell’s spontaneous firing. Other ganglion cells were the reverse, excited by red and inhibited by green. Later, other ganglion cells were found that had opponent responses to blue and yellow. This corresponded to observations about human vision, where we can’t imagine a reddish-green or a yellowish-blue because those pairs are opponent colors.

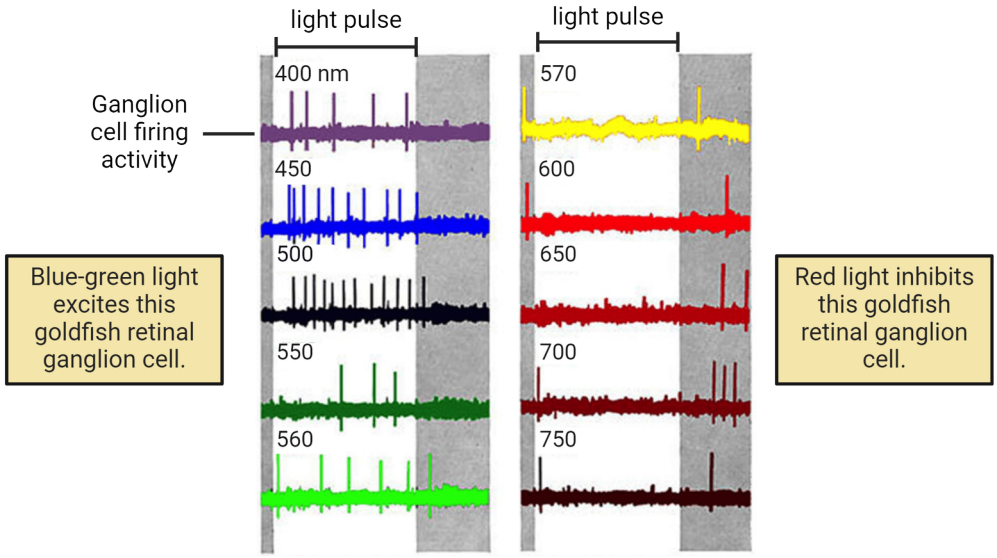

Figure 6.16 Opponent color retinal ganglion cells firing in goldfish retina Image credit: Reproduced with author permission: Kolb, Helga & Fernandez, Eduardo & Nelson, Ralph. (2007). Webvision: The Neural Organization of Retina and Visual System (From Webvision, http://webvision.med.utah.edu/). Section: Anatomy and Physiology of the Retina, Ch: Visual Responses of Ganglion cells. Ralph Nelson. Fig 17

Across many vertebrate retinas, including fish, color vision at the ganglion cell level was found to fall into the three categories shown in Figure 6.17.

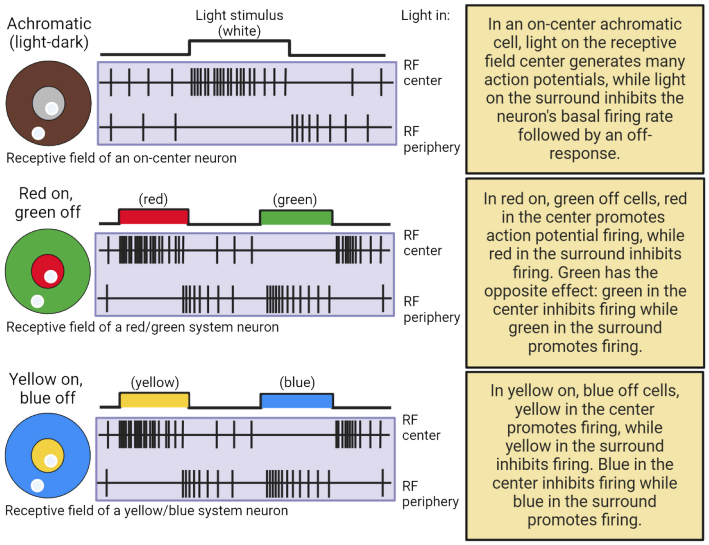

Figure 6.17 Opponent color retinal ganglion cells receptive fields

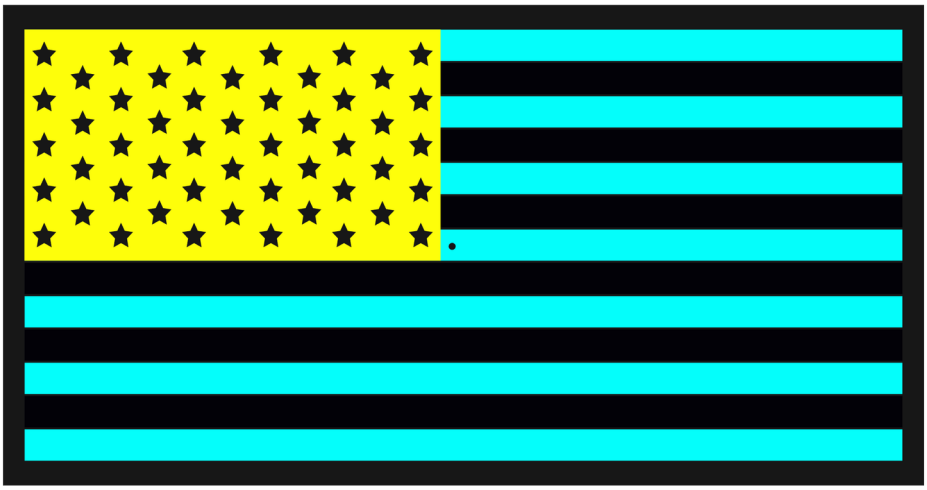

One class of ganglion cells pools the responses of different cone types, responding to light or dark on their receptive fields but not to differences in color. These are the achromatic ganglion cells where a spot of white light in the center of an on-center receptive field excites the cell, while a white spot in the surround inhibits the cell and produces a brief burst of activity when the light goes off, an “off response.” The example in Figure 6.17 is an on-center, off-surround ganglion cell like the neurons we discussed in the previous section.

Another class, red/green ganglion cells, are excited by a red spot in the receptive field center, while a green spot in the center inhibits the cell and produces an off response. The responses in the surround are reversed: red inhibits and green excites. These are opponent-color cells, and the strongest response for this example would be to a red stimulus in the center surrounded by a green ring. Other red/green cells would have the reverse organization, excited by a green spot in the receptive field center against a red surround. These cells would respond well to a border between red and green areas.

A third class, blue/yellow ganglion cells, is organized in a similar way, but now the best stimulus for the example shown would be a yellow spot against a blue background. (Recall that yellow excites both red and green cones.) The reverse type also exists, responding best to a blue spot against a yellow background. These are all examples of “double-opponent” cells, where the center and surround have opposite responses to color spots. In the human retina, the ganglion cells are red/green or blue/yellow, but the receptive fields are usually not divided into a center and surround. Instead they are “single opponent” cells, still excited by one color and inhibited by its complementary color, but across the entire receptive field.

The number of cones contributing to the response of a single retinal ganglion cell varies with the cell’s location in the retina. In the fovea, where we have the highest visual acuity, a ganglion cell’s receptive field center may be as small as a single red or green cone. In the retinal periphery, ganglion cell receptive fields are larger, driven by clusters of cones, and visual acuity is much lower.

You can experience opponent color organization in your own visual system by staring at Figure 6.18 and then looking at a blank page or a white wall. An afterimage will appear with colors that are the complements of the colors in Figure 6.18. Black will appear white, cyan will appear red, and yellow areas will be blue. This is an indication of opponent color organization, which begins at the ganglion cell level. Afterimages occur when prolonged exposure to one color causes an opponent-color ganglion cell to adapt, becoming less sensitive to the exposed color while retaining full sensitivity to the complementary color. Flooding the receptive field with white light would ordinarily activate both opponent colors, but because one color system has adapted, the balance is shifted and the ganglion cell responds as if it is being exposed to the complementary color—which is what we see in the afterimage.

Stare at the dot in the center for 30 seconds, then stare at a blank wall.

Figure 6.18 Visual after-effects of opponent color retinal ganglion cells

2.2.5: The Thalamus and Primary Visual Cortex

Learning Objectives

By the end of this section, you should be able to

- 6.4.1 Describe how visual pathways divide visual information from left and right visual fields for projection to right and left cortical areas, respectively
- 6.4.2 Define the optimal stimuli for simple and complex cortical cells
- 6.4.3 Describe how LGN receptive fields combine within the receptive field of simple cortical cells to drive simple cell activity
- 6.4.4 Describe how simple cortical cell receptive fields combine within the receptive field of complex cortical cells to drive complex cell activity
- 6.4.5 Describe the retinotopic map of the primary visual cortex
- 6.4.6 Describe the functional architecture of the primary visual cortex, including ocular dominance columns, cytochrome oxidase blobs, and orientation pinwheels
- 6.4.7 List the different types of stimuli that can excite primary visual cortical cells, including their combination with color

From the retina, the main visual pathway for conscious perception goes to the lateral geniculate nucleus of the thalamus (LGN), after which LGN neurons project to the primary visual cortex. Visual information then goes to a series of extrastriate visual areas, the inferotemporal cortex, and a number of other brain regions involved in identifying, localizing, and interacting with visually perceived objects. In this section, we will sample several of these areas to see how neurons code visual information, eventually reaching neurons that are selectively responsive to objects and faces located anywhere in the visual field.

Visual Fields and the Visual Pathway

Figure 6.19 shows the first stages of the visual pathway, going from the eye through the thalamus to the primary visual cortex.

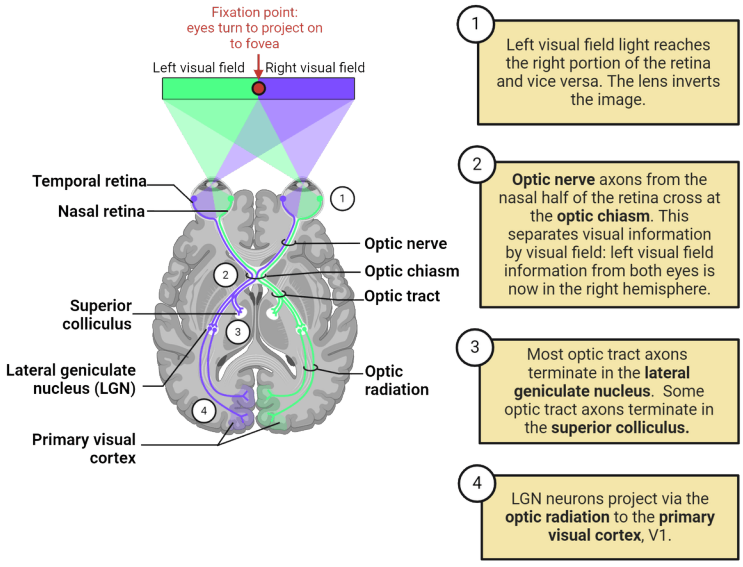

Figure 6.19 Visual pathways

Each eye is turned to project the fixation point between the left and right visual fields onto the fovea in the center of the retina. Because lenses invert images, the left visual field (shown in green) is imaged on the right side of each retina, and the right visual field (purple/blue) is imaged on the left side. Ganglion cell axons from both sides of the retina bundle together to form the optic nerve, which leads to the optic chiasm in the midline. There, the nasal (inner) half of the axons from each retina cross over, while the temporal (outer) half remains on its side of origin. Consequently, the right side of the brain (green) receives axons from the

right half of each retina, and the left brain (purple) receives axons from the left retinas. Because the left retina views the right visual field, each hemisphere of the brain receives information about the opposite side of the visual world from both eyes. Lesions in the visual pathway on one side of the brain lead to deficits in seeing the opposite side of the visual world.

Lateral Geniculate Nucleus

The main cerebral target for the retinal ganglion cell axons is the lateral geniculate nucleus (LGN), a structure in the thalamus on the path to the primary visual cortex. The LGN is a six-layered structure. The left side of Figure 6.20 shows the LGN in a post-mortem monkey brain. The dark purple dots are cell bodies and show how distinct these six layers are. Each of these layers is unique in the input it receives. Two layers are composed of large neurons, magnocellular layers 1 and 2, and four layers are composed of smaller neurons, the parvocellular layers 3-6. Magnocellular retinal ganglion cells, which convey low resolution information and respond well to motion, send their axons to the magnocellular LGN layers. Parvocellular ganglion cells with small receptive fields, red/green opponent color responses, and high resolution connect to the parvocellular layers. There are also small intermediate koniocellular LGN layers, which were overlooked in early studies. They are the target for axons from blue/yellow ganglion cells. The neurons in each LGN layer are arranged in a two-dimensional array that matches the ganglion cell locations in the retina. This preserves a map of receptive field positions, a retinotopic map.

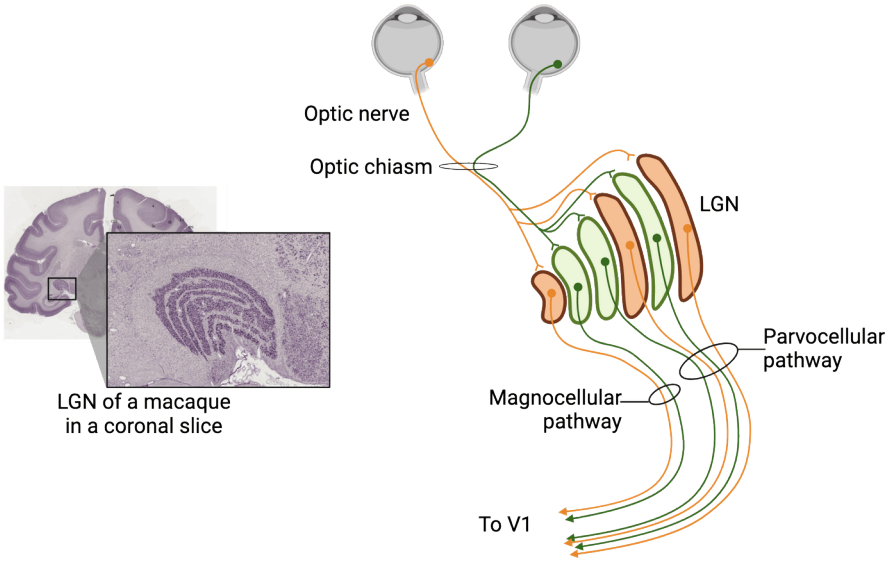

Figure 6.20 Layers of neurons in the lateral geniculate nucleus Information from the two retinas reaches separate layers of the LGN. Image credit: Primate LGN images from BrainMaps: An Interactive Multiresolution Brain Atlas; http://brainmaps.org [retrieved on 11-10-2021]

Although ganglion cells from the right half of each eye project to the LGN on the right side of the brain, the ganglion cells from each eye connect to different layers of the LGN. Thus, information from the two eyes remains separate in the LGN, and neurons driven by both eyes will not appear in the visual pathway until the next stage, the primary visual cortex.

V1 Simple, Complex and “Hypercomplex” Neurons

LGN neurons that receive input from retinal ganglion cells send their axons to the primary visual cortex (V1), a large visual area in the posterior occipital lobe and midline. This area is also called “striate” cortex because cross sections appear striated, or striped, and it is also sometimes referred to as “area 17” in reference to labels for different cortical areas based on their appearance. V1 is the first stage of visual processing in the cortex. In a collaboration that began in 1958, David Hubel and Torsten Wiesel conducted an extensive research program to discover how V1 cells respond to visual stimuli (more about them and their experiments can be found later in this section). By recording from individual cortical neurons in experiments that often lasted for more than 24 hours, they showed that the cortex could be understood at the level of individual neurons, and that the neurons had receptive fields responsive to edges. This continued earlier stages in the perception of objects and scenes. Hubel and Wiesel’s experimental method was to advance an insulated needle electrode into the visual cortex to pick up extracellular action potentials from neurons along the electrode’s path (see Methods: Electrophysiology). They projected visual stimuli on a screen facing the anesthetized animal (initially cats and later monkeys), while they searched for the most effective visual stimulus. By listening to the neuron’s action potentials as they altered the projected stimulus, they mapped the neuron’s receptive field: the visual pattern that optimally

excited the cell. Once they characterized a neuron's receptive field, they advanced the electrode until it encountered another neuron, which they then mapped. In this way, they gathered data on the receptive fields of hundreds of V1 neurons in each experiment.

In addition to mapping receptive fields, they also kept data on the location of each neuron along the electrode's track, so they could later reconstruct the positions of the mapped neurons on slices of the post-mortem brain. In this way, they not only were able to classify V1 neurons into functional categories, but they also revealed the functional architecture of the primary visual cortex.

The earliest experiments recording from individual neurons in V1 used stimuli that had been effective in exciting or inhibiting retinal ganglion and LGN cells: small light or dark spots. Many cortical cells could be stimulated and mapped with small spots. But unlike the earlier neurons in the visual pathway, where receptive fields were circular with opposing center and surround regions, the cortical receptive fields had elongated excitatory and inhibitory areas organized along straight-line edges. Hubel and Wiesel found that bright bars, dark bars, or an edge between light and dark were even more effective than spots as stimuli. For a vigorous response, the straight-line stimulus had to be at an appropriate angle of orientation aligned with the receptive field edge, and positioned exactly within the receptive field (Figure 6.21). These first cortical cells with receptive fields that could be mapped with small spots they called "simple cells."

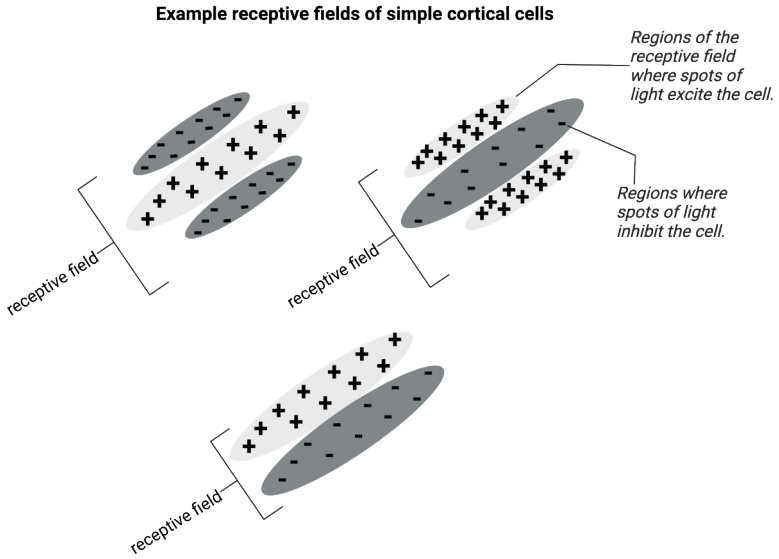

Figure 6.21 V1 simple cortical cells A simple cell responds to a small spot of light in its receptive field with excitatory "on" responses in some regions, or with inhibitory "off" responses in adjoining regions.

Hubel and Wiesel also discovered a second group of cortical cells that could not be stimulated with small spots. They named these cells complex cells. At first, they were a puzzle to the experimenters. Hubel has told the story of how they accidentally discovered what was special about complex cells. After struggling for hours without finding an effective stimulus for the neuron they were recording from, they slid a glass slide out of the projector, and as the faint dark edge of the slide moved across the screen, the neuron suddenly fired vigorously. It soon became clear that complex cells would respond to edges but not to spots. Their receptive fields could not be divided into static excitatory and inhibitory areas. Instead, complex cells responded to an appropriately oriented straight-line edge at any position in the receptive field. If the angled light or dark bar swept across the receptive field, the cell would respond continuously. (Figure 6.22) Many complex cells were also directionally selective, responding to an edge moving in one direction but not the reverse. This was different from simple cells, where an appropriately oriented edge would be effective at only one exact position; complex cells would respond to the stimulus at any position. This seemed to be a step beyond simple cells, hence the name "complex."

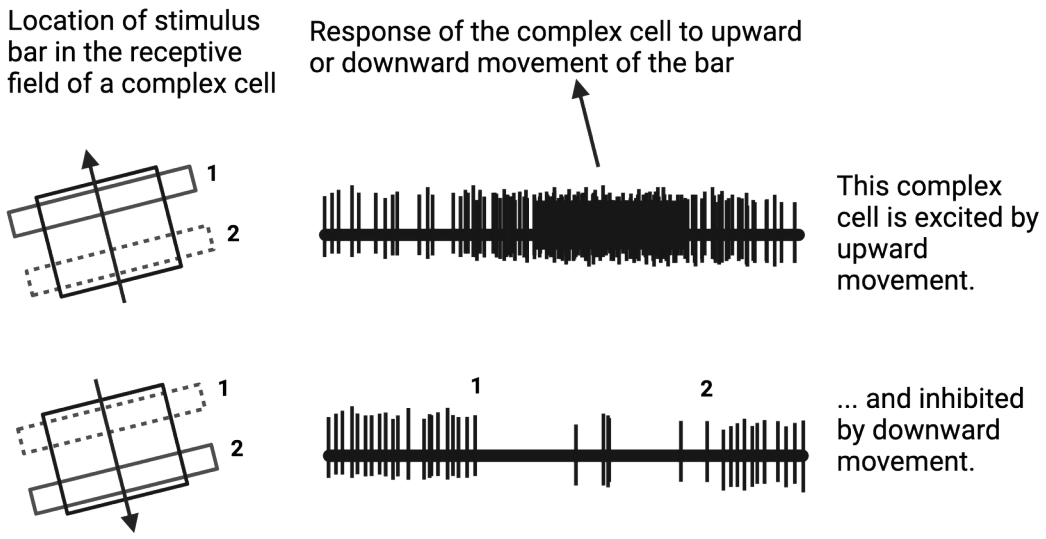

Figure 6.22 V1 complex cells respond to orientation and direction Complex cells respond to an appropriately oriented edge of light anywhere in their receptive field, not just at one exact position like simple cells. Many complex cells are directionally selective.

Hubel and Wiesel recorded videos that showed how they mapped receptive fields of simple and complex cells. The videos show the screen in front of the animal on which stimuli are projected, and we hear the action potentials (as clicks) produced by the neuron they are mapping. Although the video quality is not the best, these historically important videos show how V1 neurons respond selectively to projected visual stimuli.

Other neuroscientists explored responses of V1 neurons to other visual stimuli in addition to the projected bright or dark bars and edges that Hubel and Wiesel used. One group of stimuli, which are generated on a computer screen, are sinusoidal luminance gratings. These look like soft-edged stripes, and are discussed in the Feature Box on spatial frequency selectivity. Theoretically, any image can be broken down into its component spatial frequencies, which makes these stimuli of particular interest. V1 neurons actually respond more vigorously to appropriately oriented spatial frequency gratings than they do to simple bars or edges, and a neuron's preferred spatial frequency is now considered a significant characteristic of its receptive field.

Building Simple and Complex Receptive Fields

Hubel and Wiesel were interested in how information from LGN neurons with center-surround receptive fields could be transformed into the elongated receptive fields of cortical cells. They proposed that a simple cell in V1 receives excitatory synaptic input from a group of LGN neurons that have overlapping receptive fields located in a staggered straight line. Activating any one of the LGN cells with an appropriate light or dark spot would slightly excite the simple cell, but activating all of the LGN neurons with an oriented edge that covered all their receptive field centers would excite all of the LGN cells. This would elicit a vigorous response from the simple cell. Later experiments that recorded simultaneously from LGN and V1 neurons confirmed this scheme. Figure 6.23 shows the proposed cellular anatomy of these connections on the left, with multiple LGN neurons converging to excite a single V1 simple cell. The receptive field perspective on the right shows how a bar of light would provide the most effective stimulus for a V1 simple cell receptive field.

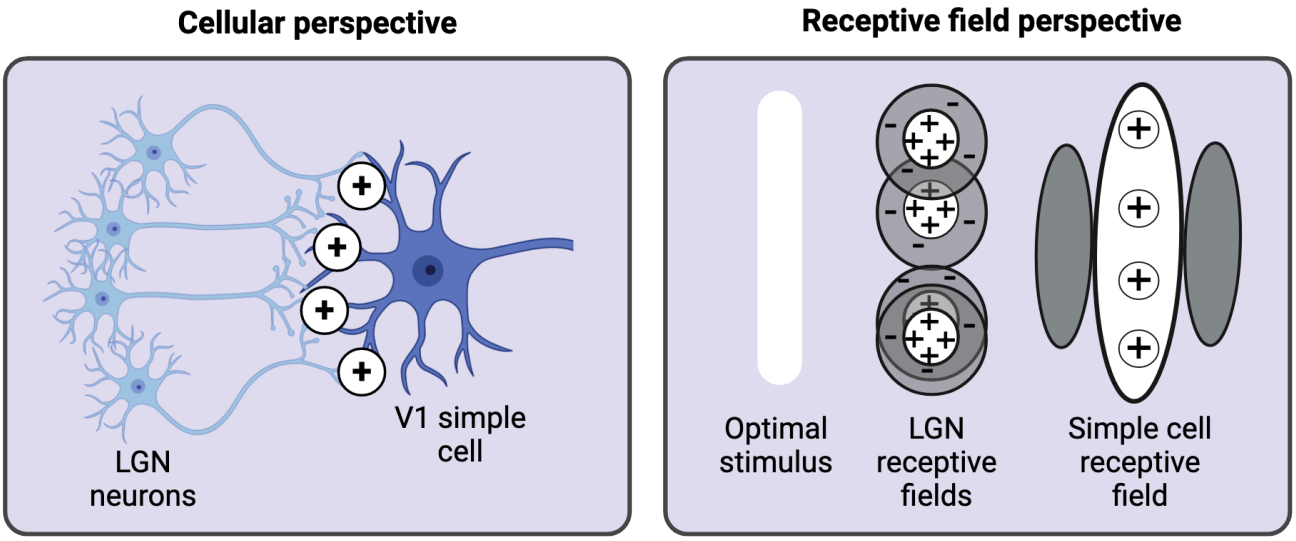

Figure 6.23 Simple cell connections to LGN neurons A bar of light maximally excites the simple cortical cell.

Hubel and Wiesel further proposed that complex cells were excited by the activity of a group of simple cells that had overlapping but similar receptive fields (Figure 6.24). An edge at an appropriate angle and position would excite one or more of the simple cells, thereby exciting the complex cell. But the stimulus could be at any position in the receptive field and still excite the complex cell. A moving edge crossing the receptive field would lead to continuous excitation. Directional selectivity could be imposed by additional circuitry that enhanced the complex cell's response to movement in one direction but suppressed the response to the opposite direction.

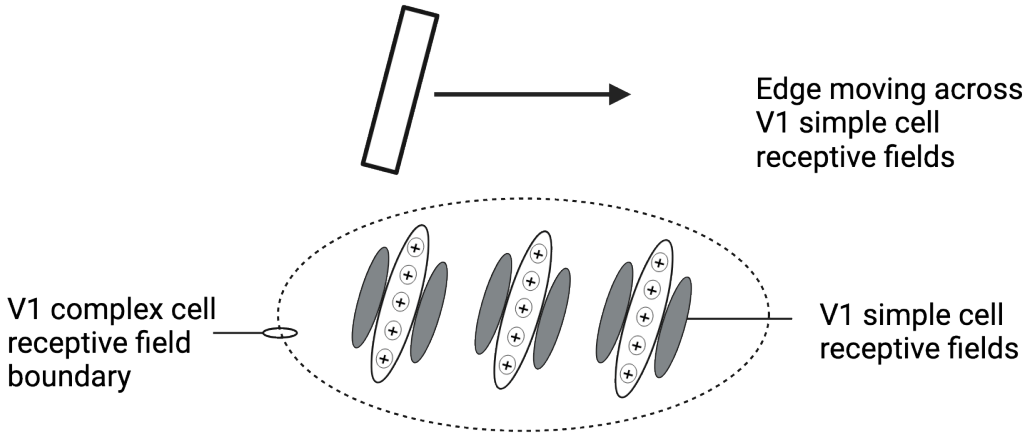

Figure 6.24 V1 complex cells respond to simple cells A vertical-edge stimulus moving across a series of simple cell receptive fields can continually activate a complex cell.

As Hubel and Wiesel continued their exploration of complex cells' responses, they found an additional characteristic. Making an appropriate stimulus bar longer so it spilled beyond the receptive field had no effect on the responses of many complex cells, but it decreased the response of other complex cells (Figure 6.25). This effect, where a stimulus bar extending beyond the receptive field actually inhibits a cortical cell's response, is referred to as endstopping. They named the new category "hypercomplex cells." Later research suggested that endstopping was a variable characteristic of every complex cell, and most neuroscientists no longer regard hypercomplex cells as a separate category. Figure 6.25 shows examples of complex cells with weak endstopping (top) and strong endstopping (bottom). Notice how both examples respond more and more to a stimulus as it elongates to fill the receptive field, but one stops responding when the stimulus extends beyond the receptive field. That complex cell shows endstopping in action.

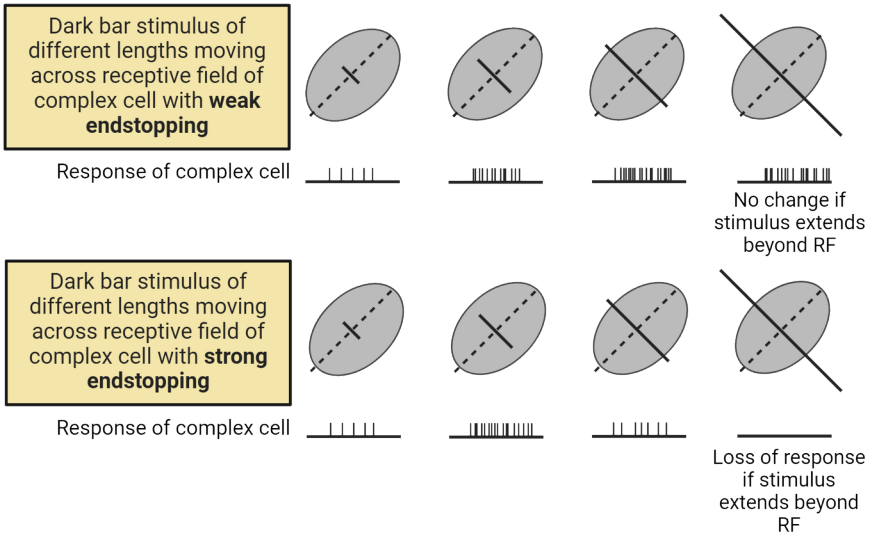

Figure 6.25 Endstopping

The functional purpose of endstopping has been puzzling, but one possible explanation is that it would make complex cells respond selectively to curved edges. A long curve falling in the receptive field would excite an end-stopped neuron if the segment within the receptive field had an appropriate orientation angle, but the part of the curve falling outside the receptive field would have a different angle that would not trigger endstopping. In contrast, long straight lines would retain the same orientation angle outside the receptive field and would activate inhibitory endstopping.

Spatial Frequency Selectivity

Neurons in V1 respond selectively to sinusoidal luminance gratings, which is yet another characteristic of a neuron's receptive field. These gratings look like evenly spaced stripes with soft edges. Three examples are shown at the top of Figure 6.26. They are called "sinusoidal" because the grating's brightness changes from light to dark and back again with a profile of intensity that resembles a sine wave. Gratings are specified by how many stripes fit in one degree of visual angle. Low spatial frequency gratings have broad stripes and appear blobby, while high spatial frequencies have narrow stripes and convey fine detail.

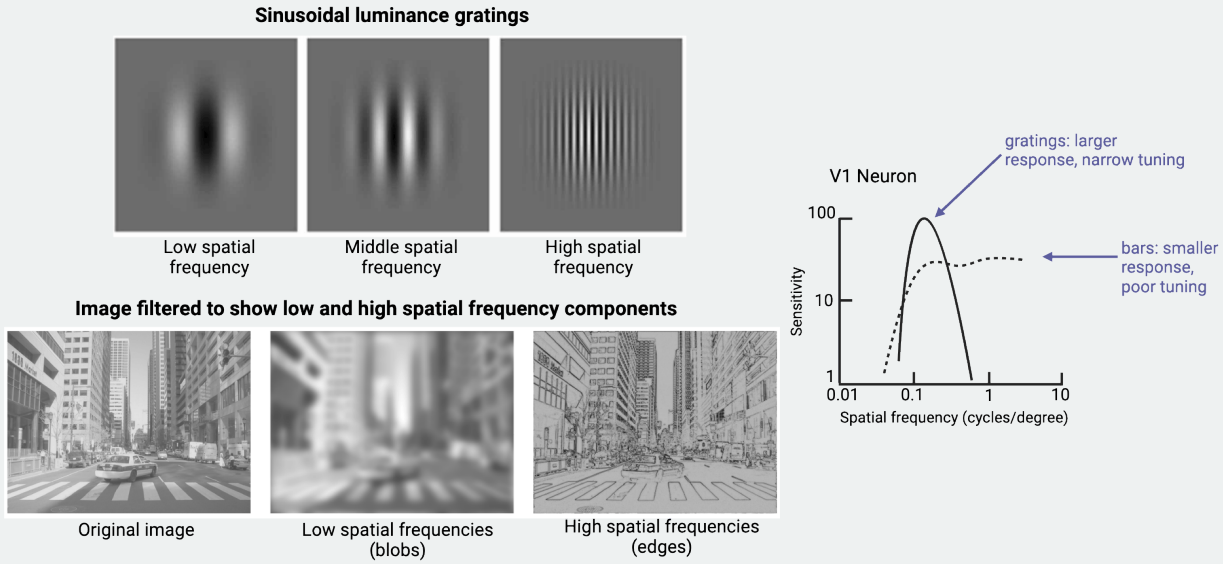

Figure 6.26 Spatial frequency selectivity Stimulating a V1 neuron with a series of spatial frequency gratings or a set of bars of different widths shows that the best SF grating is more effective than the best bar, and the neuron is more narrowly tuned for spatial frequency than for bar width. Image credit: Street scene from Berman D, Golomb JD, Walther DB (2017) Scene content is predominantly conveyed by high spatial frequencies in scene-selective visual cortex. PLoS ONE 12(12): e0189828. https://doi.org/10.1371/journal.pone.0189828 CC BY 4.0.

Selectivity for spatial frequency seems important because any real image can be computationally decomposed into its component spatial frequencies ("Fourier analysis"). The street scenes in the middle of the figure illustrate the contributions of low and high spatial frequencies to a real image. The original image (left) contains a full range of spatial frequencies, but if just the low spatial frequencies are presented (center), the scene appears blobby and out of focus. Alternatively, the high spatial frequencies show the scene's edges and reveal fine detail (right).

Interestingly, if a V1 neuron is stimulated with a series of appropriately oriented sinusoidal luminance gratings, the neuron will respond best to a particular spatial frequency and the response will fall off sharply at non-optimal frequencies. This makes the neuron narrowly tuned to its best spatial frequency. If instead the same neuron is stimulated with bars of different widths, the most effective bar does not elicit as strong a response as the best grating, and the tuning is not very sharp (narrower bars continue to excite the neuron). This is shown at the right of Figure 6.26, which plots relative sensitivity vs. spatial frequency. In their studies of V1 neurons, Hubel and Wiesel displayed rectangular bars of light from a slide projector on a screen in front of the animal, but most experimenters now use sinusoidal luminance gratings on a computer screen.

Binocular Units

We noted earlier that information from the right side of each retina ends up on the right side of the brain, but axons from the two retinas synapse in separate layers of the lateral geniculate nucleus. This means that LGN neurons projecting to the primary visual cortex will be driven by one eye or the other but not both. In V1, however, binocular neurons are found that are driven by both eyes (Figure 6.27). Covering one eye and then the other while the animal views the stimulus screen shows whether the V1 neuron responds best to the left eye, the right eye, or often to both eyes together. If one or the other eye is more effective than the other alone, this is classified as "ocular dominance," yet another characteristic of a V1 neuron's receptive field.

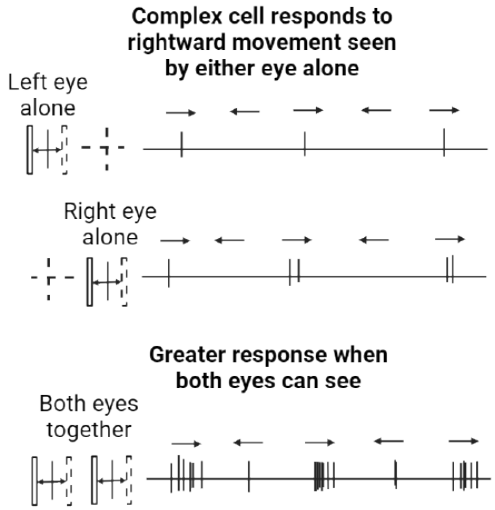

Figure 6.27 V1 biocular units

It was also possible to demonstrate that these binocular neurons contribute to stereo vision. For some neurons, moving an appropriately angled edge in space in front of the animal generated a strong response only if the stimulus was at a particular distance. Moving it nearer or farther decreased the neuron's response. Such neurons would report on the depth of edges in the visual scene. You can demonstrate stereoscopic depth perception in your own vision by moving a finger on your outstretched arm close to you and far away while closing one eye and then the other. You automatically perceive the distance of your finger as its relative position on your two retinas changes, affecting depth-sensitive neurons in your visual system. But automatic stereo vision operates only for near distances. For outdoor scenes, for example, there are other cues to depth such as occlusion (which objects are in front of others) and atmospheric haze, while relative positions of distant objects on our two retinas are no longer significant.

People Behind the Science: David Hubel and Torsten Wiesel

Hubel and Wiesel began their collaboration at Johns Hopkins University in 1958 working in the laboratory of Steven Kuffler, who had discovered receptive fields of retinal ganglion cells. Their goal was to record from neurons in the visual cortex. Both were immigrants to the US, Hubel from Montreal Canada and Wiesel from Sweden. Their experiments employed an electrode that Hubel had designed, a stiff tungsten wire sharpened to a pointed tip and insulated except for the tip. A miniature hydraulic drive bolted to the animal's skull held the electrode and allowed it to be slowly advanced into the cortical tissue, where it recorded extracellular action potentials from neurons. At first, they used the stimulus arrangement that Kuffler had used to map the receptive fields of ganglion cells, adapting it to record from the cortex by draping a bedsheet across the ceiling on which they could project spots of light. Hubel has described how awkward this was, and they soon switched to the arrangement they subsequently used for all future experiments. An anesthetized cat faced a screen on which the visual stimuli were projected, while the experimenters listened to action potentials from a neuron as they attempted to find the optimal visual stimulus to evoke a maximal response. Listening to neuronal activity provided an effective way of monitoring responses. The electrical signal was amplified and sent to a loudspeaker, where the action potentials sound like clicks. This made it easy to detect when a neuron is responding well. You can experience Hubel and Wiesel's method of mapping receptive fields in a series of videos that they made to demonstrate their work. Although the 1960s image quality is poor by modern standards, these historically important videos let you hear a V1 neuron's action potentials while you see the projection screen as the experimenters search for the best stimulus.

When Kuffler soon moved to Harvard, Hubel and Wiesel moved with him, and began experiments on cats and later monkeys that revealed cortical neurons that detect edges and boundaries. In addition to classifying different types of neurons by their responses to visual patterns, they also characterized the cortex's functional anatomy, revolutionary experiments that greatly advanced our understanding of the cerebral cortex and led to further discoveries.

An appreciative account of Hubel and Wiesel's work was published 50 years after their first paper: (Wurtz, 2009). Hubel's Nobel Prize address is also available; it is a very readable, informal account of their work. An online video of his Nobel lecture shows Hubel's casual speaking style.

Functional Anatomy of V1

The orderly layout of the retina is preserved in the layers of the lateral geniculate nucleus and in the surface of the primary visual cortex. This is the retinotopic map, shown in the left side of Figure 6.28. The right visual world is represented in the left visual cortex, with an orderly arrangement of receptive fields from the central retina to the periphery. Because there are many more retinal ganglion cells and LGN cells serving the fovea and central retina compared to the periphery, a disproportionately large area of cortex is devoted to the center of the visual field.

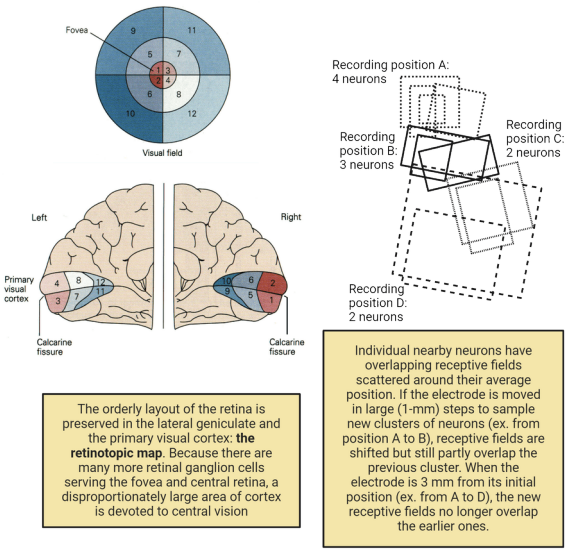

Figure 6.28 V1 visuotopic organization> Image credit: Retinotopic map by Jaygandhi786, CC BY-SA 4.0, https://commons.wikimedia.org/w/index...curid=39926315

The retinotopic map was established using several methods, including locating visual deficits (scotomas) for soldiers in World War II who had suffered head wounds that lodged shrapnel in the visual cortex. This established the overall layout of the human retinotopic map by presenting the average position in the visual world of the receptive fields of neurons from different cortical locations

Hubel and Wiesel added fine detail to the map by recording from individual neurons. A representation of their findings is shown on the right side of Figure 6.28. The receptive fields of nearby neurons overlap around their average position in visual space, but if the electrode is moved about 3 mm across the cortical surface, the receptive fields of neurons in the new location no longer overlap with receptive fields for the earlier location.

In addition to mapping hundreds of receptive fields in their experiments on V1, Hubel and Wiesel also recorded data on the location of each neuron along the electrode's track. This allowed them to later reconstruct the positions of the mapped neurons on slices of the post-mortem brain, which helped reveal the functional anatomy of the primary visual cortex. They noticed that as their electrode was advanced vertically (radially) deeper into the cortex, receptive fields of neurons along the electrode's track shared the same orientation preference. A nearby radial penetration encountered neurons that shared a different orientation preference, indicating that the cortex was organized in vertical orientation columns. They also saw broad regions that shared ocular dominance, where one eye drove a binocular neuron more strongly than the other eye. This changed from one eye to the other if the electrode was advanced horizontally (tangentially) across the cortex. They concluded that the cortex was organized in vertical columns of neurons that shared orientation and ocular dominance preferences. Later researchers used a different technique, optical recording, to reveal the two-dimensional organization of orientation and ocular dominance columns in V1. Optical recording detects differences in blood supply that reflect the level of activity of nearby neurons. In this way it resembles fMRI, but it provides finer detail and requires creating a window in the skull to permit imaging of the cortical surface. By imaging the cortex while systematically presenting a series of oriented stimuli delivered to one eye or the other, regions of maximal activity

could be identified. Using computational techniques to give each orientation preference a false color, the orientation columns were revealed to be arranged like pinwheels, while the ocular dominance columns were long stripes (Figure 6.29).

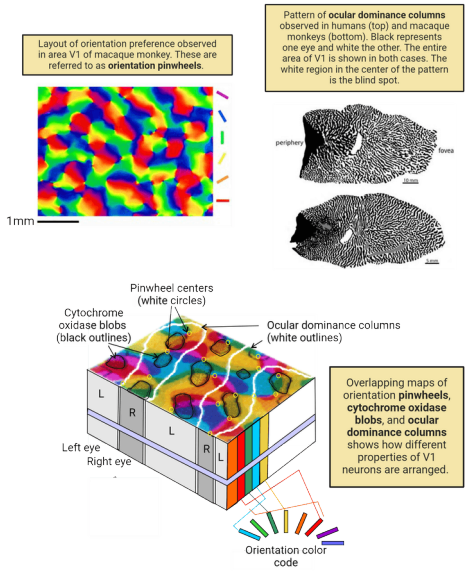

Figure 6.29 V1 orientation pinwheels and ocular dominance columns Image credit: Orientation pinwheels modified from Blasdel & Salama (1986) by Nicholas V. Swindale in 'Visual map'. http://www.scholarpedia.org/article/Visual_map CC BY-N-SA 3.0. 2D black and white ocular dominance columns image modified with permission from Adams et al. Another structural feature in the cortex had been identified earlier: cytochrome oxidase blobs in the upper layers of the cortex. Cytochrome oxidase is an enzyme associated with metabolic activity, and by using a substrate that leaves a colored reaction product, the cortex was shown to have a regular array of “blobs," small patches of neurons with high metabolic activity. The array of blobs across V1 seen in stained microscope sections became another architectural element to add to V1’s orientation and ocular dominance columns. Optical recording using achromatic (non-colored) striped gratings at various angles or gratings with alternating red and green stripes demonstrated that the cytochrome oxidase blobs coincide with regions that respond most strongly to color stimuli.

Putting all these features together created an overlapping map of orientation pinwheels, cytochrome oxidase blobs, and ocular dominance columns (shown in the bottom of Figure 6.29). The cortex has a repeating modular structure. Within each module, the blobs and the pinwheel centers are both aligned along the center of the ocular dominance columns, but they do not have a specific relation to each other. The overall implication is that as the visual cortex is built in development, a repeating subunit structure is genetically specified to organize the cortex.

The final aspect of cortical architecture to consider is cortical layers. V1 is named “striate” (striped) cortex because of the prominent layering seen in cross sections of stained cortex. There are six anatomical layers, numbered from 1 at the cortical surface to 6 adjoining the white matter. The layers turn out to have functional differences (Figure 6.30). Axons from the LGN arrive at the cortex in layer 4 and also in layer 6. Layer 4 is where simple cells are found (red dots), supporting the theory that simple cells receive direct synapses from LGN axons. Complex cells (blue) are found in Layers 2-3 and Layers 5 and 6, where they could receive connections from simple cells in the same column, again consistent with the theory that simple cells drive complex cells. Complex cells in the upper layers project to more advanced cortical areas, leading to the next stages of visual processing. Complex cells in layer 5 project to the superior colliculus, and cells in layer 6 project back to the LGN, modifying the LGN’s responses to signals from the retina.

Circuitry, architecture, and functional dynamics of visual cortex. Cereb Cortex. 1993 Sep-Oct;3(5):373-86. doi: 10.1093/cercor/3.5.373. PMID: 8260807.

Color Vision in the Cortex

Most neurons in V1 receive their input from the LGN's parvocellular, color-selective layers, but surprisingly, relatively few V1 neurons respond selectively to colors. In monkey V1, one type of color-selective receptive field has a center-surround, double opponent receptive field. This is shown in the top of Figure 6.31. The example in the figure shows a neuron that is excited by red in the center and inhibited by the opponent color in the center (green). In the surround, the responses are reversed: green excites and red inhibits. A pattern where the two colors meet at an edge is the strongest stimulus.

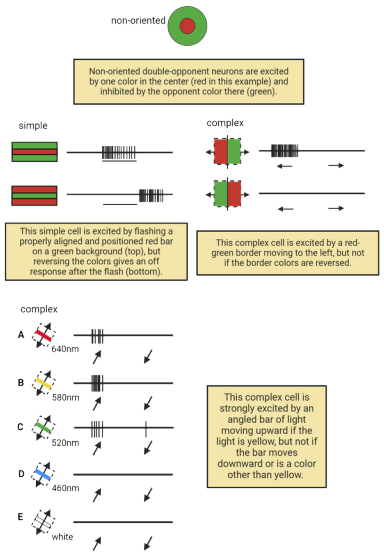

Figure 6.31 Many neurons in V1 respond selectively to colored stimuli

Other primate V1 neurons include simple and complex cells that are selective for color stimuli. The simple cell in the middle of Figure 6.31 is excited by flashing a properly aligned and positioned red bar on a green background (top), but reversing the colors elicits an off response after the stimulus ends (bottom). The complex cell in the middle of Figure 6.31 is excited by a red-green border moving to the left, but not if the border moves to the right, and not if the colors are reversed.

An interesting complex cell (bottom of Figure 6.31) is strongly excited by an angled bar of light moving upward if the light is yellow,

but not if the bar moves downward or if it is a color other than yellow. Note that white light does not excite this neuron, which means it would be overlooked in an experiment that did not test colored stimuli. These complex cells have all of the stimulus selectivities that we met earlier, such as orientation angle and movement direction, but in addition they are selective for color. Color selectivity in V1 is not well understood, and some aspects remain controversial. These and other V1 neurons provide the beginning of our visual perception of the form, color and location of objects, but V1 is just the first stage of visual processing. Processing continues in areas outside of the striate cortex: the extrastriate cortex.

2.2.6: Extrastriate Cortex

Learning Objectives

By the end of this section, you should be able to

- 6.5.1 Describe the broad functional role of the dorsal and ventral visual processing streams in the cortex
- 6.5.2 Describe the stimulus-selectivity of inferotemporal neurons and how they were discovered

Visual processing continues in several cortical regions adjacent to V1 referred to as extrastriate cortex (“extra” means outside of V1). Most of the extrastriate areas have a retinotopic map like V1, but the individual receptive fields are larger and many fields cross the visual midline. Since we detect and recognize objects placed anywhere in the visual field, especially in the fovea where we see fine detail, wider receptive fields that cross the midline would be necessary to support conscious visual perception. V1 is just the beginning of cortical visual processing, and the extrastriate cortical areas are where additional stages of visual processing occur.

Extrastriate Visual Areas Overview

The extrastriate cortex beyond V1 divides into two major pathways: a dorsal pathway concerned with stimulus position and movement, and a ventral pathway leading to the perception of objects, faces, bodies, and scenes. The two pathways were first identified through experiments with monkeys trained on tasks that required distinguishing the location of an object (“where”) or the appearance of an object (“what”). Lesions in the dorsal and ventral cortex selectively interfered with one task or the other. Later studies recording from neurons confirmed the two pathways. Figure 6.32 shows many of the extrastriate visual areas that have been discovered. The relative size of each cortical area is represented by the size of the labeled boxes, and the number of axons connecting areas is represented by the thickness of the lines between them. These connections go in both directions, with axons projecting forward from a lower to a higher area, and also feedback connections from higher areas to lower ones. In fact, except for the one-way optic nerve from the retina to the LGN, all other visual areas have both ascending and descending connections, and the descending (feedback) connections have been shown to modify the activity of neurons in lower areas. For example, V1 projects strongly to V2 and V4, but those areas also project back to V1.

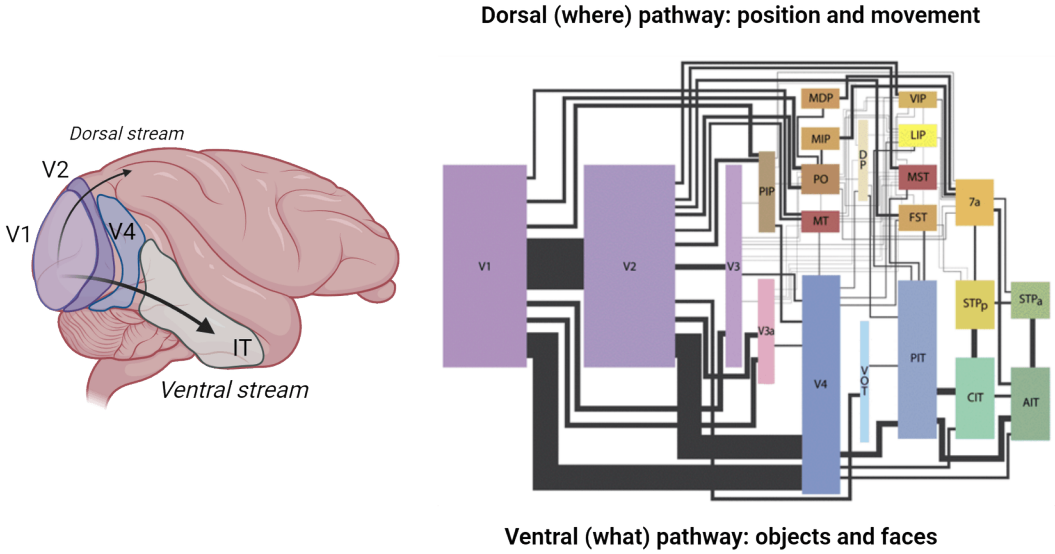

Figure 6.32 Anatomy and functional connections of extrastriate areas Image credit: Wiring diagram reprinted from Neuron, Vol. 60, Wallisch & Movshon,Structure and Function Come Unglued in the Visual Cortex, Pages No.195-197, Copyright (2008), with permission from Elsevier. www.cell.com/neuron/pdf/S089...08)00851-9.pdf

That path, V1 to V2 to V4, is the main pathway for conscious visual perception. It leads to the temporal cortex (specifically the

anterior (AIT), central (CIT) and posterior (PIT) inferotemporal cortex). These IT areas are locations for patches of neurons that respond selectively to shapes, faces, colors and places. These components of the ventral stream are discussed in the following sections.

Dorsal Stream

The dorsal stream visual pathway processing areas have received less attention than the ventral stream, but one area that has received interesting experimental attention is area MT, "middle temporal." The MT cortex is a motion-selective area organized in columns where all the neurons in a column are selective for a single direction of movement. Experiments at Stanford University showed that monkeys trained to report the direction of movement of subtle regions of random dots moving amidst stationary dots could be led to see sub-threshold movements if a column in MT was electrically stimulated (Salzman et al., 1990). The stimulation caused the neurons in that column to fire, which led the monkey to perceive movement that did not actually exist. The experiment was a direct demonstration that activity in an extrastriate area can lead to a visual perception.

Ventral Stream

The ventral "what" pathway for conscious visual perception leads from V4 to the lower ("inferior") surface of the temporal lobe, the inferotemporal cortex (IT). Receptive fields of neurons in IT are significantly different from the earlier visual areas. They are not organized in a retinotopic map, but instead are grouped by the similarity of their most effective stimuli, such as the shapes of objects or the components of faces. IT receptive fields are very large (from 25 to 70 degrees of visual angle, a substantial span of the visual field's 180 degrees), they always include the fovea, and they span the midline to include portions of both the left and right visual fields. Effective stimuli for an IT neuron can include objects, faces, or hands, independent of the size or exact position of the stimulus.

The selectivity of IT neurons represents major steps toward conscious visual perception. Neurons in the first stage of cortical processing, the simple cells of V1, have small receptive fields (about 1 degree) that require exact positioning of an oriented edge. They will detect small components of an object's outline, with thousands of V1 neurons responding to even a small object. Shifting the stimulus's position or size in the retinal image will activate a completely different population of V1 neurons. In contrast, IT neurons are flexible in their response to the position and size of the retinal image, a necessary step in perceiving objects.

Extensive experiments to record from IT neurons began in the 1980s. Among the earliest findings were that posterior IT areas, the ones closest to extrastriate cortex, had optimal stimuli that were more elaborate than V4 neuron receptive fields. Actual objects such as toy animals were effective, although a tiger's face, for example, could be reduced to a simpler image of a rectangle with attached circles. More anterior regions of the IT cortex had more complex receptive fields, with patches of neurons that responded selectively to faces, colors, and scenes.

If a visual area like IT has neurons with selective responses to complicated images, a methodological problem arises. How do the experimenters know if they have found the optimal stimulus? It is feasible to show a test array of hundreds of photos of different images, flashing each photo briefly while detecting if an IT neuron fires action potentials, but the most effective stimulus may not be in the test set. The best that can be accomplished is to identify a general category that the neurons respond to, and then narrow down the important details in the stimulus. This strategy has been employed to characterize neurons that respond to objects and faces.

Another approach, especially for intermediate extrastriate areas like V4, has been to use computer-generated patterns that are systematically and randomly varied. Variations that lead to more vigorous firing are retained, while less effective variations are discarded. Repeating the cycle and continuing to choose more effective variations eventually generates apparently optimal stimuli, but they are often complicated and do not resemble simple geometric shapes that are easily described in words. This remains a puzzling aspect of visual processing.

Face-Selective Units

In the 1980s, exploratory recordings made by Charles Gross and his colleagues at Princeton University discovered neurons in monkey IT that responded vigorously to images of faces. The faces could be of monkeys, humans, or even cartoons, but if the eyes were omitted or the image was scrambled, the response was reduced or eliminated (Figure 6.33). Faces are an important element of communication for monkeys and humans. Faces support identification of familiar individuals, and they also reveal emotional expressions from unfamiliar strangers. In recording from randomly encountered neurons in electrode penetrations of

IT, the Princeton group found neurons that were selective for a variety of images, not just faces.

Figure 6.33 Face-selective units Recordings in inferotemporal cortex of monkeys shows neurons that respond selectively to faces. Image credit: Journal of Neurophysiology, Vol. 46, Issue 2. Visual properties of neurons in a polysensory area in superior temporal sulcus of the macaque. C Bruce, R Desimone, C G Gross. (1981). With permission from The American Psychological Association.

People Behind the Science: Dr. Doris Tsao and Current Approaches to Studying Face-Selective Units

Dr. Doris Tsao and her collaborators have introduced a more targeted approach to investigating face-selective units in primates. Dr. Tsao began her work on face patch neurons as a graduate student and postdoctoral scientist at Harvard Medical School, collaborating with Winrich Freiwald and Professor Margaret Livingstone. Tsao continued this work as a professor at Caltech, where she received a MacArthur “genius” award, and continues it now at the University of California at Berkeley. Dr. Tsao and her collaborators used fMRI to locate six face patches in IT cortex that contain neurons responsive to faces. They then recorded from individual neurons in each patch. Figure 6.34 (right side) shows the responses of 182 neurons in a face patch (vertical axis) to 96 standard images (horizontal axis) of faces, bodies, fruits, gadgets, hands, and scrambled photos. The images were flashed on a screen in random order. Each horizontal row represents the responses from one of the 182 recorded neurons, with red indicating a strong response. For analysis, the responses were lined up to place all the responses to one stimulus image in a vertical line, and to group the stimuli into six categories. For almost all the neurons in a face patch, it was clear that only the 16 images of faces consistently elicited strong responses, with little or no response to the other images.

Dr. Doris Tsao

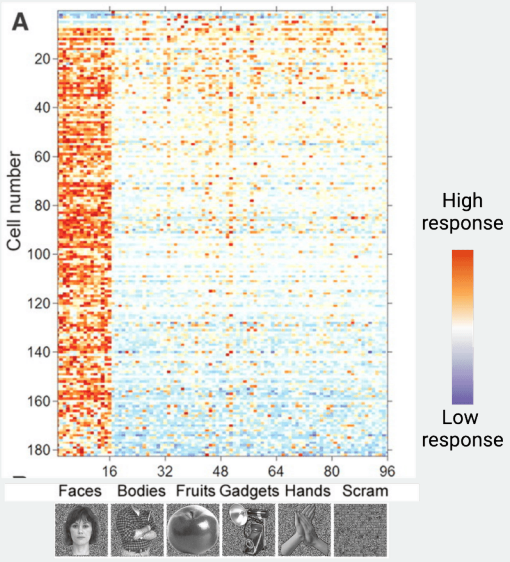

Figure 6.34 Doris Tsao and fMRI study of face-selective units Responses recorded from 182 individual neurons in one face patch show that only images of faces elicited strong responses from neurons in the face patch. Image credit: Doris Tsao by Giantnanoassembler, CC BY-SA 4.0, https://commons.wikimedia.org/w/inde...curid=71887161. Data and images of stimuli: Tsao DY, Freiwald WA, Tootell RB, Livingstone MS. A cortical region consisting entirely of face-selective cells. Science. 2006 Feb 3;311(5761):670-4. doi: 10.1126/science.1119983. PMID: 16456083; PMCID: PMC2678572. Reprinted with permission.

Other experiments used cartoon faces as stimuli, permitting systematic variation of features such as the proportions of the face, the size of the nose, the diameter of the eyes, and the height of the hair. Different neurons were tuned to extremes of some features but not affected by variations in other features. Later research found two additional face patches where the responses were affected by whether the face was familiar to the monkey being tested. One clear conclusion was that a given face would elicit responses from a large subset of neurons in multiple face patches, with different faces activating different subsets.

In online videos, Dr. Tsao explains characteristics of the first face-selective neurons she studied as well as her later work at Caltech.

Face patches have also been identified by fMRI in the human brain, a region called the fusiform face area (FFA). Research on IT face patches continues, with a goal of revealing how advanced visual processing occurs in sequential stages for a well-defined image category. These studies may help explain how a scene that activates millions of neurons in multiple cortical areas leads to our conscious perception of the components of the visual world around us.

2.2.7: Unsolved Questions In Visual Perception

Learning Objectives

By the end of this section, you should be able to

- 6.6.1 Describe several open questions about how visual perception is derived from visual sensory information
- 6.6.2 Define the major difference between top-down versus bottom-up processing in visual perception
- 6.6.3 Describe what a grandmother cell is

Starting with the discovery in the 1950s of the center-surround receptive fields of retinal ganglion cells, it became clear that visual processing in the eye and brain starts with the detection of edges. The edges can be between areas of different brightness (luminance differences) or spectral composition (color differences). V1 neurons extend the detection of edges by responding selectively to straight edges at particular angles. Subsequent extrastriate and IT areas respond to more complex optimal stimuli, such as images of specific objects or body parts or faces. Intermediate visual areas may extract features such as the direction and speed of movement, or stimulus color. These stages of visual processing are now well known, but there are still many unanswered questions about how they lead to conscious visual perception. This section will discuss a few aspects of vision and visual perception that remain poorly understood today.

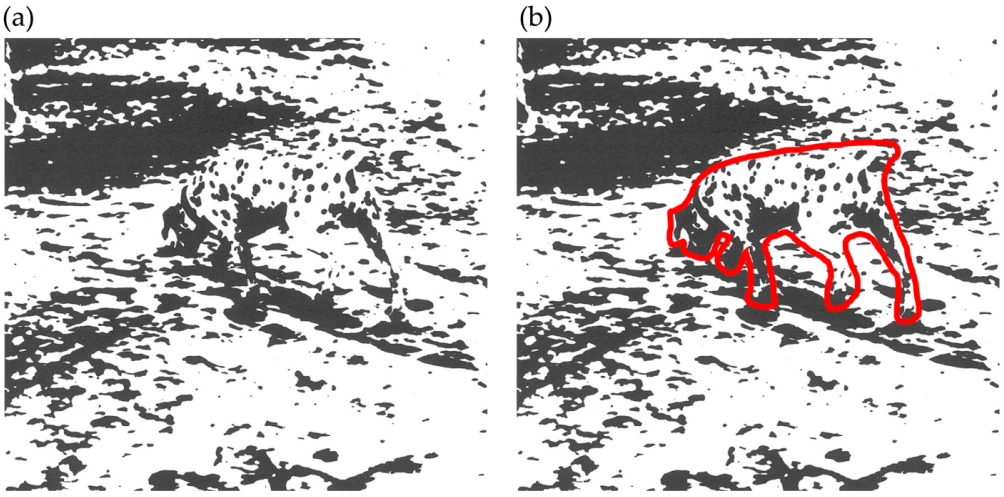
The Binding Problem

Any visual image elicits simultaneous responses from millions of neurons in V1 and the extrastriate areas that respond to aspects of the stimulus. For example, a bluebird flying across the sky will activate color-selective neurons in V1, V2, and V4 corresponding to the bird's color. The bird's motion will activate movement-selective neurons in MT. Other objects in the visual scene will activate other neurons in visual cortical areas. If many visual neurons are firing simultaneously to multiple components of the image, how are the ones activated by the bluebird identified as belonging together? This is the binding problem, the need to link activity in different neurons that are stimulated by the same stimulus object. We assume that the activity of these neurons is somehow combined to generate our perception of that object, but how?

One suggested mechanism for binding responses is rhythmic firing, where the timing of synchronous action potentials identifies neurons that are responding to a particular stimulus. Where and how that synchrony would be detected, and where conscious perception is ultimately localized, remain unanswered questions, and synchrony as the answer to the binding problem remains controversial.

Top-Down Processing

Figure 6.35 is a famous picture, a high-contrast assortment of shapes and splotches that leads most people to perceive a spotted dog in leafy shade.



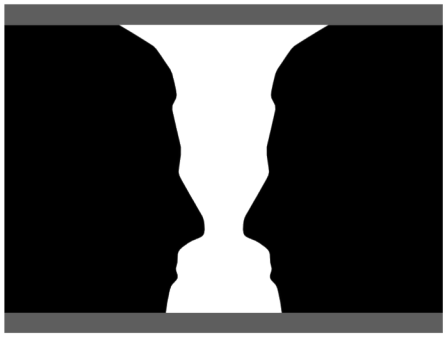


Figure 6.35 Top-down processing Image credit: Favela, L.H.; Amon, M.J. Enhancing Bayesian Approaches in the Cognitive and Neural Sciences via Complex Dynamical Systems Theory. Dynamics 2023, 3, 115-136. https://doi.org/10.3390/dynamics3010008. CC BY 4.0

It seems inconceivable that seeing the dog could be accomplished just from the activity of V1 neurons responding to the components of the image that fall within their receptive fields. That would be a “bottom-up” approach, where elements of the image are combined in successive stages of cortical processing to generate the perception of the object. Instead, some prior knowledge of the shape of a dog seems necessary for organizing the elements of the scene. That would be a “top-down” contribution to visual perception.

Computer scientists working on automatic image interpretation have described top-down processing as “hallucinating” the scene and then calculating how well the actual elements match the “hallucinated” image. After revising the imagined scene in areas where the match is poor, the calculation would repeat until a good match is found. Our visual system may work in a somewhat similar way. Bottom-up processing detects edges and activates neurons in V1 and extrastriate cortex, but top-down processing organizes the edges that are detected in the lower visual areas.

Visual illusions further support the existence of top-down organization of the elements of a scene. The image on the left of Figure 6.36 is either a white vase or profiles of two faces. We can instantly switch from one perception to the other, indicating that although the elements of the image falling on the retina that elicit bottom-up activity are unchanged, a top-down process determines how the components are grouped and perceived. Other visual illusions and ambiguous images support the same point.

One vase? Or two faces?

Young lady turning away? Or elderly lady in profile?

Figure 6.36 Visual perception Visual perception can change depending on your expectations even if the simulus does not change. Neuroscience in the lab: Top-Down Processing and Visual Attention

Another top-down process that affects perception is visual attention. Paying attention to one aspect of an image can enhance the activity of the neurons that respond to that aspect. A famous experiment measured the fMRI signals in people from temporal lobe brain regions that are known to respond selectively to faces or houses. As mentioned in the discussion of face-selective neurons in 6.5 Extrastriate Cortex, the fusiform face area (FFA) is active when a person views faces, but the FFA is not responsive to images of houses. Houses, in turn, enhance activity in the parahippocampal place area (PPA), but that area does not respond to faces.

In the experiment, subjects were placed in a scanner to record fMRI signals from the FFA and PPA while they viewed an image that superimposed a face and a house. In a series of trials, the subjects were instructed to pay attention to either the house or the face, and then after a short period of time, to switch their attention to the other component of the double image. As shown in Figure 6.37, when attention was directed to the face, the FFA was more active, while the PPA increased its activity when attending to the house. The important implication is that although the image on the retina was always the same and thus bottom-up processes would be the same, neurons in the visual processing pathway did change their activity. They were being modulated by a top-down process: in this case, attention (see Chapter 19 Attention and Executive Function)

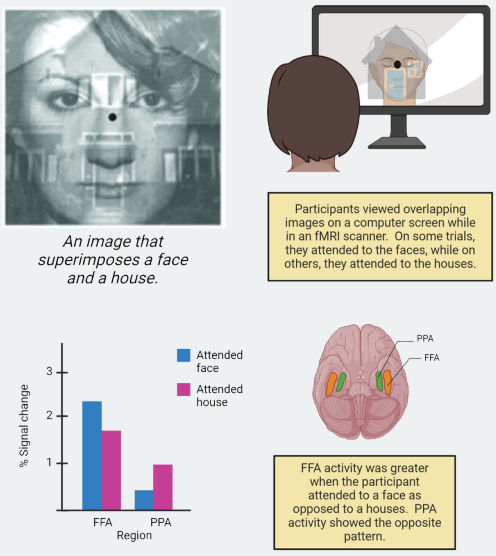

Figure 6.37 Attention provides top-down modulation of activity in visual areas Image credit: Face-house image from: Keizer, A.W., Nieuwenhuis, S., Colzato, L.S. et al. When moving faces activate the house area: an fMRI study of object-file retrieval. Behav Brain Funct 4, 50 (2008). https://doi.org/10.1186/1744-9081-4-50 CC BY 2.0

These examples make it clear that top-down processes influence the activity of neurons in visual areas, and thus that visual perception cannot be an exclusively bottom-up process. Other experiments recording from individual neurons in lower visual areas also show that their firing rates are modulated by activity in higher visual areas. Extensive axonal feedback connections from higher to lower areas offer an anatomical pathway for top-down modulation. However, how top-down processes modulate lower visual areas to contribute to visual perception is not generally known. Progress has been made, but this remains a largely unsolved puzzle in visual perception.

Grandmother Cells

The first stages of visual processing suggest that activity converges from one stage to the next. Axons from multiple LGN neurons converge to create the receptive fields of individual simple cells. Activity from multiple simple cells excites single complex cells, and so on. Very large receptive fields in extrastriate and IT cortex suggest the convergence of signals from earlier neurons that have small receptive fields. How high could this convergence reach? Could there be advanced neurons with extremely selective responses that combine visual and possibly other information? This idea was proposed, not seriously, as the existence of “grandmother cells”: cells that would respond to any view of your grandmother, and by extension, other neurons that would respond uniquely to other specific people or objects.

Although the term was presented mockingly, recordings of hippocampal neurons from a person undergoing brain surgery for epilepsy did reveal a neuron that seemed to respond to images and also the written name of a well-known actress, Jennifer Aniston (Quiroga et al., 2005). This opened two questions: first, could recognition depend on single neurons responsible for identifying a particular stimulus, and second, could neurons represent not just a visual image, but also other information about the subject?

The first possibility, that single neurons are responsible for recognizing an image, seems unlikely. Any visual stimulus evokes activity in an ensemble of hundreds or thousands of neurons, even at high levels. Similar visual stimuli would activate overlapping but distinct ensembles. There is no indication that potential loss of a single neuron suddenly eliminates recognition of a particular object. Loss of neurons does occur from strokes, for example, and the loss does eliminate function. Prosopagnosia is a neurological deficit where the patient no longer recognizes faces, but it involves the loss of whole regions of neurons and problems with many faces.

The second idea, that ensembles of neurons might encode information associated with a visual stimulus, seems more likely. “Gnostic neurons” have been proposed, and the neuron that responded to Jennifer Aniston’s image and written name seems to be an example of a gnostic neuron. It’s clear that our brains somehow generate our unified conscious experience, but like other aspects of consciousness, the later stages of visual perception remain an unsolved and challenging puzzle.

2.2.8: Section Summary

6.1 An Overview of the Visual System

Our visual sense allows us to reconstruct the world around us, which seems effortless and automatic, but in fact requires our eyes and brain to engage in extensive neural processing to allow us to perceive our surroundings. Light reflected from surfaces is imaged by the eye's optical system, the cornea and lens, onto the retina at the back of the eye, where photoreceptors detect photons of light energy. This begins a process that leads to the visual cortex and adjacent visual areas in the occipital and temporal lobes of the brain.

6.2 The Retina

In the first steps in vision, rods and cones capture photons to create an electrical signal that is proportional to the number of photons captured. This process, called "phototransduction," is unusual in that the receptors are depolarized in the dark but become less depolarized (hyperpolarized) in the light. When visual pigment molecules capture photons, it leads to a reduction in the concentration of a signaling molecule, cGMP, which when present activates Na+ channels to allow Na+ ions to enter the photoreceptors and depolarize them. Light reduces cGMP levels, closing Na+ channels and ending depolarization. Our color vision depends on having three different visual pigments in different classes of cones, since a single pigment cannot distinguish between a dim colored light that is absorbed well and a bright light of a different color that is absorbed poorly. Our color vision is trichromatic, but most mammals have only two cone visual pigments and see colors differently from people.

6.3 Visual Processing Begins in Bipolar, Horizontal, Amacrine and Ganglion Cells

Rods and cones respond to the brightness of the light hitting them, but neurons in the other layers of the retina discard brightness information and convert the information that leaves the eye into the location of edges between light and dark or borders between different colors. Edge-detection begins with bipolar cells, which have circular receptive fields that respond to dark or light spots in the center of the receptive field, with contrasting illumination in the receptive field surround. Uniform illumination that covers both center and surround does not excite bipolar cells. Ganglion cells receive synapses from bipolar cells and inherit their center-surround receptive fields. Ganglion cells are the first neurons in the processing chain that make action potentials, which travel to the brain in the optic nerve. Ganglion cells responsive to colors have opponent-color receptive fields, excited by one color and inhibited by its complement. The complementary, opponent-color pairs are red/green and blue/yellow.

6.4 The Thalamus and Primary Visual Cortex

The receptive fields of LGN neurons are circular, but neurons in primary visual cortex V1 have elongated receptive fields with a straight-line edge between the subdivisions. "Simple" cortical cells can be mapped with small spots, but "complex" cells require elongated stimuli such as light or dark bars. The elongated edge can be placed anywhere in a complex cell's receptive field as long as its orientation angle matches the cell's preferred orientation. Some cortical cells are responsive to stimuli moving in one direction but not the reverse. Some cells decrease their response if the stimulus bar extends beyond the receptive field ("endstopping"). Spatial frequency gratings at an appropriate angle are more effective stimuli than bars of equivalent width. The cortex's functional architecture reveals that neurons with the same orientation preference are grouped in vertical orientation columns that when viewed from the cortical surface appear like pinwheels. Neurons driven most strongly by one eye or the other are grouped in broad elongated ocular dominance columns. Examination of cortical layers shows that simple cells are found principally in middle layer 4 where LGN axons arrive, while complex cells are found in the upper and lower layers. Finally, some cortical neurons are selective for colors in addition to having a preferred location, angle and direction of movement.

6.5 Extrastriate Cortex

Neurons in V1 begin cortical visual processing by detecting edges in small regions of the image. The next steps occur in adjoining cortical areas, the extrastriate cortex, where two pathways have been identified: the dorsal stream detecting location

and movement, and the ventral stream leading to the inferotemporal cortex (IT), where images of objects elicit responses. Neurons in IT that respond selectively to faces are grouped in face patches, which provide an example of visual processing for a well-defined category of images.

6.6 Unsolved Questions In Visual Perception

Although the first stages of visual perception seem to be well understood, beginning in the retina and proceeding in steps though V1 and extrastriate cortex, and continuing into IT, the final stages of perception remain a mystery. One problem is how responses to a particular object, activating neurons in many different visual areas, are grouped to identify that object and not other objects in the scene. One theory involves the timing of action potentials, where rhythmic firing or synchrony may establish connections for each object, but this idea remains controversial. Another problem is how small components within a scene are organized into the perception of the full object, a process that seems to require prior knowledge of the object's shape. This suggests a role for top-down processing. One clear example of top-down modulation of earlier neural activity is visual attention, which organizes bottom-up components into a perceived scene. A bottom-up issue is converging activity, where many neurons with small receptive fields activate the next level of neurons with larger receptive fields, raising the question of how much convergence ultimately occurs. Could there be single neurons responsible for perceiving a particular object, so-called "grandmother cells" responsible for perceiving your grandmother? It seems much more likely that any particular object activates an ensemble of neurons, with different but possibly overlapping ensembles for other objects. These many open questions indicate that the final stages of visual processing are still an unsolved puzzle.

2.2.9: Key Terms

6.1 An Overview of the Visual System

Wavelength, electromagnetic spectrum, visible spectrum, cornea, crystalline lens, retina, aqueous humor, vitreous humor, photoreceptors, retinal ganglion cells, optic nerve, optic disk, fovea, choroid, sclera

6.2 The Retina

Phototransduction, receptors, bipolar cells, horizontal cells, amacrine cells, depolarized resting potential, visual pigment molecules, rhodopsin, opsin, 11-cis retinal, cGMP,, short/middle/long wavelength cones

6.3 Visual Processing Begins in Bipolar, Horizontal, Amacrine and Ganglion Cells

receptive field, center/surround, on-center and off-center bipolar cells, on-center and off-center ganglion cell, contrast, “magnocellular” cells, “parvocellular” ganglion cells, high-acuity vision, superior colliculus, intrinsically photosensitive ganglion cells (ipRGCs), circadian rhythms, three primary colors, complementary colors, opponent colors, achromatic ganglion cells, “off response”, red/green ganglion cells, opponent-color cells, blue/yellow ganglion cells

6.4 The Thalamus and Primary Visual Cortex

lateral geniculate nucleus of the thalamus (LGN), primary visual cortex, extrastriate visual areas, inferotemporal cortex, fixation point, visual field, magnocellular layers 1 and 2, parvocellular layers 3-6, koniocellular, retinotopic map, functional architecture, angle of orientation, simple cells, complex cells, directionally selective, sinusoidal luminance gratings, endstopping, narrowly tuned, binocular neurons, ocular dominance, functional anatomy, orientation columns, optical recording, cytochrome oxidase blobs, orientation pinwheels, cortical layers, layer 4

6.5 Extrastriate Cortex

dorsal pathway, ventral pathway, inferotemporal cortex, area MT, face patches, fusiform face area

6.6 Unsolved Questions In Visual Perception

binding problem, “bottom-up” vs “top down”, convergence, grandmother cells, ensemble, prosopagnosia, gnostic neurons

This page titled 2.2.9: Key Terms is shared under a CC BY-NC 4.0 license and was authored, remixed, and/or curated by Ivette Merced via source content that was edited to the style and standards of the LibreTexts platform.

2.2.11: Multiple Choice

6.1 An Overview of the Visual System

1.
Light is most frequently described by the:

a. amplitude of pressure waves in the air.
b. wavelength of electromagnetic waves.
c. size of photons.
d. speed of photons.

2 .
Where are the cells that respond to light in the eye located?

a. Lens
b. Cornea
c. Retina
d. Vitreous humor

3.
The defects that cause myopia are typically in the:

a. retina.
b. brain.
c. shape of the eye.
d. ear.

6.2 The Retina

4 .
Your sharpest (highest acuity) vision is mediated by:

a. rods.
b. cones.
c. outer segments.
d. inner segments.

5.
Imagine you are recording from a photoreceptor. You start recording in the dark then shine bright light on the photoreceptor. What will happen?

a. The photoreceptor will fire action potentials. The brighter the light, the more action potentials it will fire.
b. The photoreceptor will stop firing action potentials. The brighter the light, the fewer action potentials it will fire.
c. The photoreceptor will hyperpolarize. The brighter the light, the more it will hyperpolarize.
d. The photoreceptor will depolarize. The brighter the light, the more it will depolarize.

6 .
In the dark, Na+ channels in rods are:

a. open.
b. closed.
c. sensitized.
d. absent.

7.

Which of the following molecules changes shape directly in response to light exposure?

a. 11-cis-retinal
b. phosphodiesterase
c. cGMP
d. Na+ channels

8 .
Color vision relies on:

a. the sensitivities of different cone types to different wavelengths of light.
b. comparing activation of rods versus cones.
c. the location of the photoreceptors on the retina.
d. the 3 major types of retinal ganglion cells.

9.
Color blindness:

a. is caused by mutations that make one of the cone types less functional.
b. is more common in males than females.
c. does not make a person actually blind to a wavelength of light but just makes some colors look more similar than they do for non-color blind individuals.
d. All of these are true

10 .
What would the vision of someone who did not have red cones be like?

a. They would not see anything red; red objects would be mostly invisible
b. Red light would look similar to green light
c. Red light would look similar to blue light
d. They would have poor vision in the dark

6.3 Visual Processing Begins in Bipolar, Horizontal, Amacrine and Ganglion Cells

11.
Which of the following have receptive fields?

a. Photoreceptors
b. Bipolar cells
c. Retinal ganglion cells
d. All of these

12 .
Which of the following will cause an on-center bipolar cell to depolarize the most?

a. Light in the center of its receptive field
b. Light in the surround of its receptive field
c. Light in both the center and surround of its receptive field
d. Dark in the center of its receptive field

13.
High acuity vision relies on which cell type?

a. Magnocellular ganglion cells
b. Parvocellular ganglion cells
c. Ganglion cells that project to the superior colliculus
d. Melanopsin-containing ganglion cells

14 .
Regulating our circadian rhythm relies on which cell type?

a. Magnocellular ganglion cells
b. Parvocellular ganglion cells
c. Ganglion cells that project to the superior colliculus
d. Melanopsin-containing ganglion cells

6.4 The Thalamus and Primary Visual Cortex

15.
Visual information from the right visual field is transmitted to:

a. right LGN.
b. left LGN.
c. both right and left LGN.
d. right V1.

16 .
Imagine a brain injury that damaged the right optic nerve. Where would the visual deficits be?

a. Loss of right eye vision
b. Loss of left visual field
c. Loss of right visual field
d. Loss of left eye vision

17.
A cortical simple cell will respond well to a:

a. very bright spot of light.
b. straight-line edge of light contrasted with dark in a preferred spatial location.
c. straight-line edge of light contrasted with dark anywhere in the receptive field
d. dark spot on a bright background.

18 .
A cortical complex cell will respond best to a:

a. very bright spot of light.
b. straight-line edge of light contrasted with dark in a preferred spatial location.
c. straight-line edge of light contrasted with dark anywhere in the receptive field
d. dark spot on a bright background.

19.
The preferential responsiveness of a V1 neuron to input from one eye over the other is known as:

a. ocular dominance.
b. narrow tuning.
c. endstopping.
d. retinotopia.

20 .
Which statement best describes how visual information is processed in the cortex?

a. Information is processed by many cortical areas and divided up into separable features, such as object identification versus object location/speed.
b. Everything is processed in the primary visual cortex (V1).
c. Information from the 2 eyes is kept completely separate so you know which eye is providing a visualization of something.
d. Visual information is not processed by cortical areas. It stops at the thalamus.

21.
A recording electrode placed in the most posterior part of V1, at the very back of the occipital cortex, would be excited most by light from:

a. the periphery.
b. red wavelength.
c. the fovea.
d. the contralateral eye.

22 .
Simple cells in V1 are usually found in layer _____ while complex cells are found in layer _____.

a. Layer 4 and 6 / layer 2-3, 5 and 6
b. Layer 2-3, 5 and 6 / layer 4 and 6
c. Layer 5 / layer 1
d. Layer S / Layer C

6.5 Extrastriate Cortex

23.
The dorsal stream in visual processing:

a. mediates face recognition.
b. is composed primarily of area MT.
c. has information flow only in the forward direction, from V1 into dorsal cortical areas.
d. is composed of multiple brain regions with connections that send information forward and backwards (feedback).

24 .
The ventral stream in visual processing:

a. is composed of multiple brain regions with connections that send information forward and backwards (feedback).
b. is composed primarily of inferotemporal cortex.
c. has information flow only in the forward direction, from V1 into dorsal cortical areas.
d. mediates motion perception.

2.2.12: Fill in the Blank

6.1 An Overview of the Visual System

1.
Our visual system interprets the _____ of light as its color.

6.2 The Retina

2 .
_____ and _____ are two major cell types in the retina that modify the direct pathway for information about light and help create center-surround responses.
3.
Of the five major neuronal cell types in the retina, _____ are located closest to the incoming light.

6.3 Visual Processing Begins in Bipolar, Horizontal, Amacrine and Ganglion Cells

4 .
A retinal ganglion cell that is excited by light in its center and inhibited by light in its surround is called _____ -center.

6.4 The Thalamus and Primary Visual Cortex

5.
The _____ map is the map of receptive field positions in the visual system.

6.5 Extrastriate Cortex

6 .
The _____ pathway contains information about stimulus position and movement, while the _____ pathway contains information about object identity.

2.2.13: Vision

Vision

Learning Objectives

- Identify the key structures of the eye and the role they play in vision.
- Summarize how the eye and the visual cortex work together to sense and perceive the visual stimuli in the environment, including processing colors, shape, depth, and motion.
- Explain the benefit of having two eyes.
- Understand differences in color vision.
- Understand depth perception and vision.
- Understand motion detection.

Humans rely largely on vision and seeing the world around them through sight. Most non human organisms rely more on the other senses to interpret the world around them. Research indicates that a large part of the cerebral cortex in humans is dedicated to vision. As the information reaches the visual cortex in the brain, multiple neurons identify shapes, colors, and motions. When light falls on the eyes, sensory receptors begin the process of transduction. As this process occurs, individuals begin to perceive the environment around them.

Think about entering a dark theater or room if you have been outside on a sunny day; often times it takes time to adjust to the change of light intensity in the environment. The muscles in the iris of the eye adjust to allow more light to enter the pupil (**the round opening in the center of the iris**). The iris of the eye is the colored part of the eye that constricts and dilates the pupil to adjust for different light intensities that we may encounter throughout the day. Photoreceptors help distinguish the different characteristics of different objects. The types of photoreceptors in the human eye include rods and cones; rods are typically more prevalent than cones. Rods give us sensitivity under dim lighting conditions and allow us to see at night. Cones allow us to see fine details in bright light and give us the ability to distinguish color. Cones are tightly packed around the fovea (the small central region located at the back of the retina) and more sparsely elsewhere. Rods populate the periphery (the region surrounding the fovea) and are almost absent from the fovea. As organisms move about their environment throughout the day the information by light from objects both near and far is encoded by the brain and the identification of colors, shapes, and motion occurs (see Figure 2.2.13.1).

Anatomy of the Human Eye

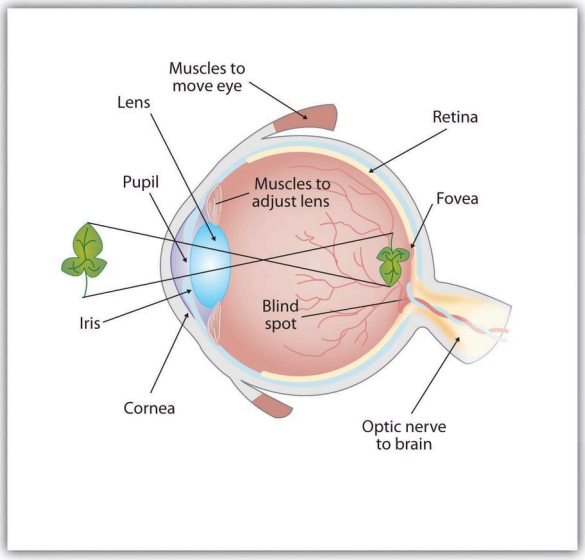

Figure 2.2.13.1: Light enters the eye through the transparent cornea, passing through the pupil at the center of the iris. The lens adjusts to focus the light on the retina, where it appears upside down and backward. Receptor cells on the retina send information via the optic nerve to the visual cortex. https://open.lib.umn.edu/intropsyc/c...04_s02_s01_f02

Normal, Nearsighted, and Farsighted Eyes Figure 2.2.13.2

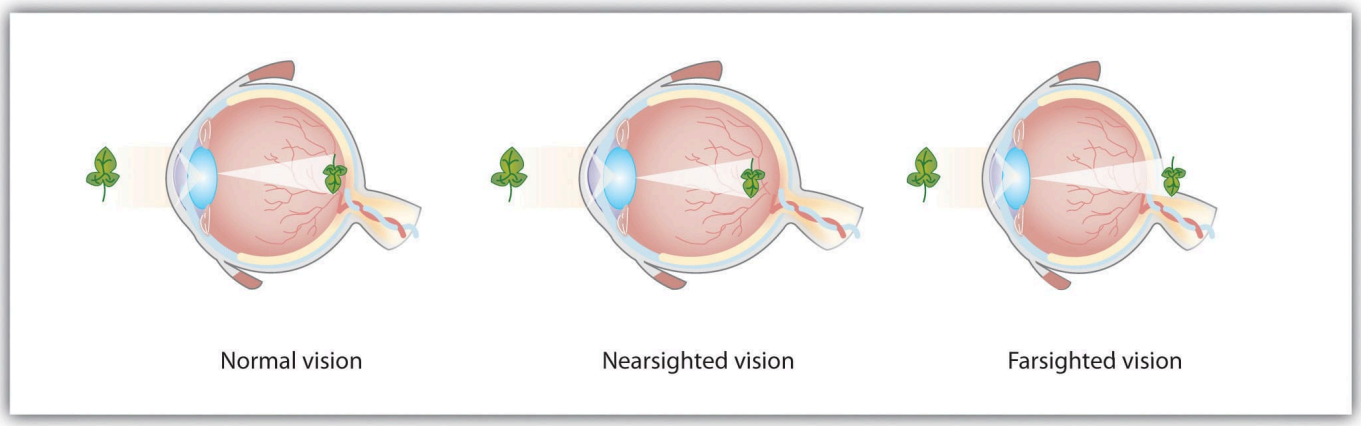

Figure 2.2.13.2 For people with normal vision (left), the lens properly focuses incoming light on the retina. For people who are nearsighted (center), images from far objects focus too far in front of the retina, whereas for people who are farsighted (right), images from near objects focus too far behind the retina. Eyeglasses solve the problem by adding a secondary, corrective, lens. https://open.lib.umn.edu/intropsyc/chapter/4-2-seeing/#stangor-ch04_s02_s01_f02

Research indicates that humans can distinguish between millions of different color variations (Gerald , 1972). Although humans can distinguish between a wide variety of variations there are three primary colors that form the base of these variations; red, green, and blue. The ability for these colors to form these variations is based on the hue or shade of the colors. The electromagnetic spectrum illustrated below shows that visible light for humans is just a small slice of the entire spectrum, which includes radiation that we cannot see as light because it is below the frequency of visible red light and above the frequency of visible violet light.

The Electromagnetic Spectrum Figure 2.2.13.3

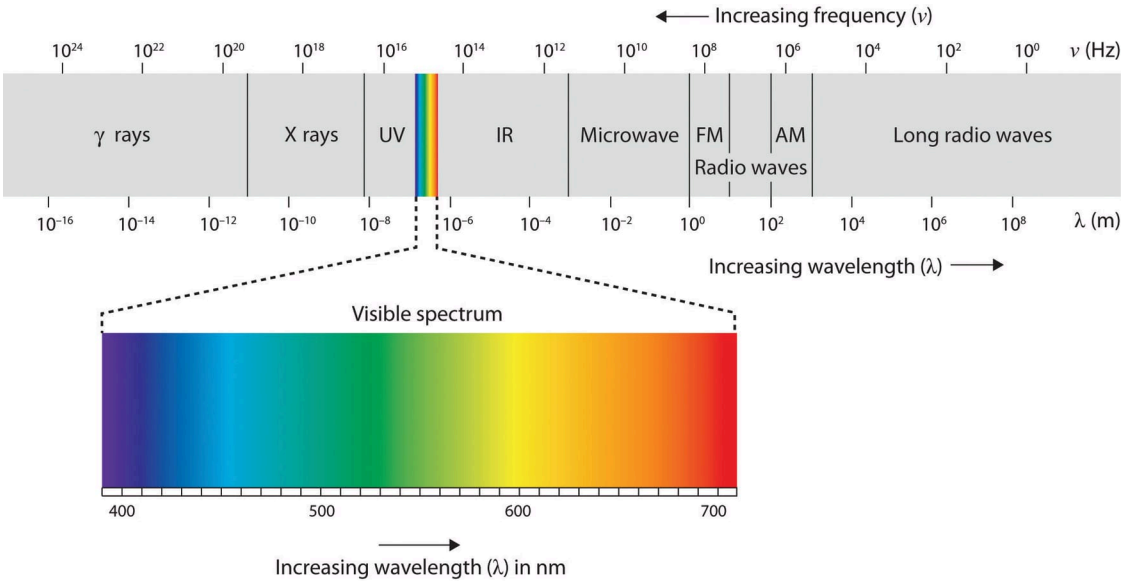

Figure 2.2.13.3: Only a small fraction of the electromagnetic energy that surrounds us (the visible spectrum) is detectable by the human eye.

In his important research on color vision, Hermann von Helmholtz theorized that color is perceived because the cones in the retina come in three types. One type of cone reacts primarily to blue light (short wavelengths), another reacts primarily to green light (medium wavelengths), and a third reacts primarily to red light (long wavelengths). The visual cortex then detects and compares the strength of the signals from each of the three types of cones, creating the experience of color. According to this Young-Helmholtz trichromatic color theory, *what color we see depends on the mix of the signals from the three types of cones*. If the brain is receiving primarily red and blue signals, for instance, it will perceive purple; if it is receiving primarily red and green signals it will perceive yellow; and if it is receiving messages from all three types of cones it will perceive white.

The different functions of the three types of cones are apparent in people who experience color blindness. Color blindness can be defined as having decreased capacity to see color or distinguish differences between colors. Red–green color blindness is the most common form, followed by blue–yellow color blindness and total color blindness. Red–green color blindness affects up to 8% of males and 0.5% of females of Northern European descent. Red-green color blindness is a result of an absence of long or medium wavelength cones or to the production of abnormal opsin pigments in these cones that affect red-green color vision (see Figure 2.2.13.4).

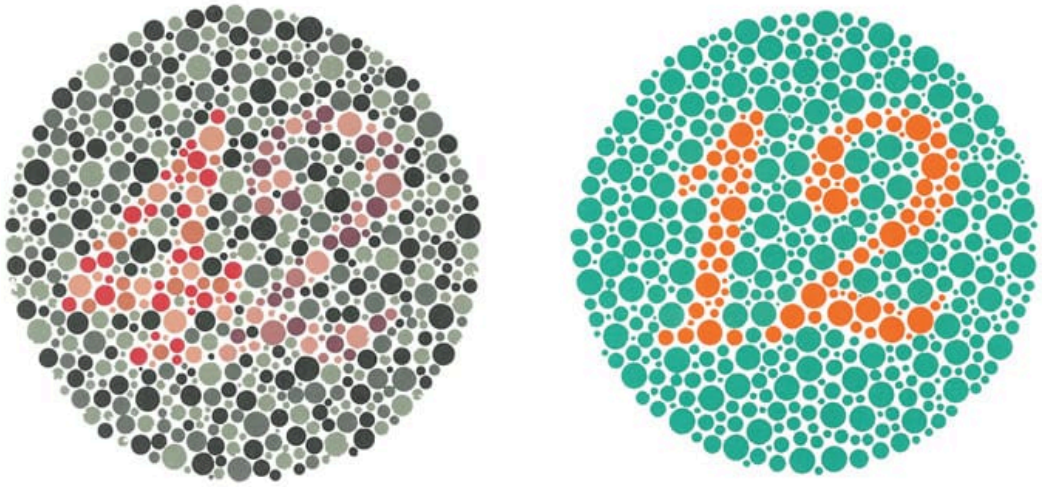

Figure 2.2.13.4: People with normal color vision can see the number 42 in the first image and the number 12 in the second (they are vague but apparent). However, people who are color blind cannot see the numbers at all. Wikimedia Commons.

An alternative approach to the Young-Helmholtz theory, known as the opponent-process color theory, *proposes that we analyze sensory information not in terms of three colors but rather in three sets of "opponent colors": red-green, yellow-blue, and white-black*. Evidence for the opponent-process theory comes from the fact that some neurons in the retina and in the visual cortex are excited by one color (e.g., red) but inhibited by another color (e.g., green).

One example of opponent processing occurs in the experience of an afterimage. If you stare at the flag on the left for about 30 seconds (the longer you look, the better the effect), and then move your eyes to the blank area to the right of it, you will see the afterimage. When we stare at the green stripes, our green receptors habituate and begin to process less strongly, whereas the red receptors remain at full strength. When we switch our gaze, we see primarily the red part of the opponent process. Similar processes create blue after yellow and white after black (see Figure 2.2.13.5).

Figure 2.2.13.5: U.S. Flag. The presence of an afterimage is best explained by the opponent-process theory of color perception. Stare at the flag for a few seconds, and then move your gaze to the blank space next to it. Do you see the afterimage? Mike Swanson – U.S. Flag (inverted) – public domain.

Depth Perception

Depth perception is *the ability to perceive three-dimensional space and to accurately judge distance*. Without depth perception, we would be unable to drive a car, thread a needle, or simply navigate our way around the supermarket (Howard & Rogers, 2001). Research has found that depth perception is in part based on innate capacities and in part learned through experience (Witherington, 2005).

Psychologists Eleanor Gibson and Richard Walk (1960) tested the ability to perceive depth in 6- to 14-month-old infants by placing them on a **visual cliff**, *a mechanism that gives the perception of a dangerous drop-off, in which infants can be safely tested for their perception of depth* (see Figure 2.2.13.6). The infants were placed on one side of the "cliff," while their mothers called to them from the other side. Gibson and Walk found that most infants either crawled away from the cliff or remained on the board and cried because they wanted to go to their mothers, but the infants perceived a chasm that they instinctively could not cross. Further research has found that even very young children who cannot yet crawl are fearful of heights (Campos, Langer, & Krowitz, 1970). On the other hand, studies have also found that infants improve their hand-eye coordination as they learn to better grasp objects and as they gain more experience in crawling, indicating that depth perception is also learned (Adolph, 2000).

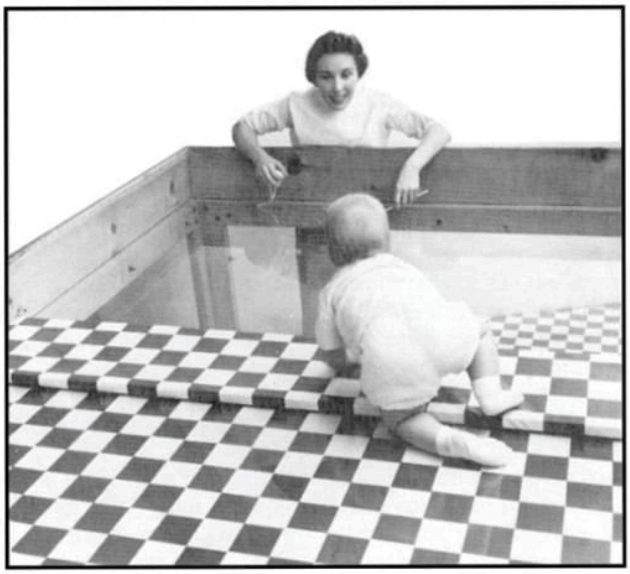

Figure 2.2.13.6: Visual Cliff- A mother urging her child from across the deep side of the visual cliff. Despite a transparent surface covering the cliff, the child hesitates to move forward. (From Gibson and Walk (1960). Copyright 1960 Nature Publishing Group., CC BY 4.0 <https://creativecommons.org/licenses/by/4.0>, via Wikimedia Commons)

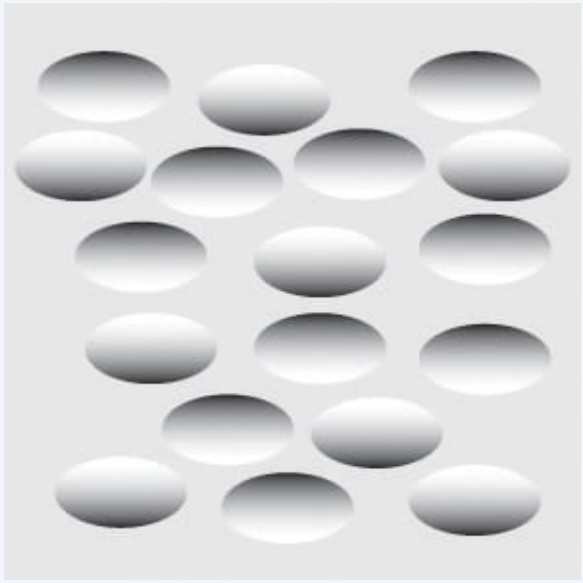
Depth perception is the result of our use of **depth cues**, *messages from our bodies and the external environment that supply us with information about space and distance*. **Binocular depth cues** are *depth cues that are created by retinal image disparity—that*

is, the space between our eyes, and thus which require the coordination of both eyes. One outcome of retinal disparity is that the images projected on each eye are slightly different from each other. The visual cortex automatically merges the two images into one, enabling us to perceive depth. Three-dimensional movies make use of retinal disparity by using 3-D glasses that the viewer wears to create a different image on each eye. The perceptual system quickly, easily, and unconsciously turns the disparity into 3-D.



An important binocular depth cue is **convergence**, *the inward turning of our eyes that is required to focus on objects that are less than about 50 feet away from us*. The visual cortex uses the size of the convergence angle between the eyes to judge the object's distance. You will be able to feel your eyes converging if you slowly bring a finger closer to your nose while continuing to focus on it. When you close one eye, you no longer feel the tension—convergence is a binocular depth cue that requires both eyes to work.

The visual system also uses *accommodation* to help determine depth. As the lens changes its curvature to focus on distant or close objects, information relayed from the muscles attached to the lens helps us determine an object's distance. Accommodation is only effective at short viewing distances, however, so while it comes in handy when threading a needle or tying shoelaces, it is far less effective when driving or playing sports.

Although the best cues to depth occur when both eyes work together, we are able to see depth even with one eye closed. **Monocular depth cues** are *depth cues that help us perceive depth using only one eye* (Sekuler & Blake, 2006). Some of the most important are summarized in Table 2.2.13.1 "Monocular Depth Cues That Help Us Judge Depth at a Distance".

Table 2.2.13.1 Monocular Depth Cues That Help Us Judge Depth at a Distance

Name	Description	Example	Image
Position	We tend to see objects higher up in our field of vision as farther away.	The fence posts at right appear farther away not only because they become smaller but also because they appear higher up in the picture.	Figure  Andrew Huff – Rotted Fence – CC BY 2.0.
Relative size	Assuming that the objects in a scene are the same size, smaller objects are perceived as farther away.	At right, the cars in the distance appear smaller than those nearer to us.	Figure  Allan Ferguson – Trolley Crosses Freeway – CC BY 2.0.

Name	Description	Example	Image
Linear perspective	Parallel lines appear to converge at a distance.	We know that the tracks at right are parallel. When they appear closer together, we determine they are farther away.	Figure  Bo Insogna, TheLightningMan.com – Lightning Striking By The Train Tracks – CC BY-NC-ND 2.0.
Light and shadow	The eye receives more reflected light from objects that are closer to us. Normally, light comes from above, so darker images are in shadow.	We see the images at right as extending and indented according to their shadowing. If we invert the picture, the images will reverse.	Figure 

Name	Description	Example	Image
Interposition	When one object overlaps another object, we view it as closer.	At right, because the blue star covers the pink bar, it is seen as closer than the yellow moon.	Figure 
Aerial perspective	Objects that appear hazy, or that are covered with smog or dust, appear farther away.	The artist who painted the picture on the right used aerial perspective to make the distant hills more hazy and thus appear farther away.	Figure  Frans Koppelaar – Landscape near Bologna – CC BY-SA 2.5.

Motion

Many animals, including human beings, have very sophisticated perceptual skills that allow them to coordinate their own motion with the motion of moving objects in order to create a collision with that object. Bats and birds use this mechanism to catch up with prey, dogs use it to catch a Frisbee, and humans use it to catch a moving football. The brain detects motion partly from the changing size of an image on the retina (objects that look bigger are usually closer to us) and in part from the relative brightness of objects.

We also experience motion when objects near each other change their appearance. The **beta effect** refers to *the perception of motion that occurs when different images are presented next to each other in succession* (see Note “Beta Effect and Phi Phenomenon”). The visual cortex fills in the missing part of the motion and we see the object moving. The beta effect is used in movies to create the experience of motion. A related effect is the **phi phenomenon**, in which *we perceive a sensation of motion caused by the appearance and disappearance of objects that are near each other*. The phi phenomenon looks like a moving zone or cloud of background color surrounding the flashing objects. The beta effect and the phi phenomenon are other examples of the importance of the gestalt—our tendency to “see more than the sum of the parts.”

Beta Effect and Phi Phenomenon

In the beta effect, our eyes detect motion from a series of still images, each with the object in a different place. This is the fundamental mechanism of motion pictures (movies). In the phi phenomenon, the perception of motion is based on the momentary hiding of an image.

Imagine yourself lying in a field on a warm summer day. With your eyes closed, you can hear the wind moving through the grass, and off to your left, through the branches of an oak tree. In the tree, a Scrub Jay is giving a loud, screeching call, while a Western Meadowlark is singing its long, warbled improvisations. Over to your right, a stream is lazily flowing through the meadow except where it spills around some rocks. At intervals, you hear splashes from the water. Your friend is throwing in rocks. Just as you are starting to doze off, she calls your name, waking you up. You can sense a note of impatience in her voice. Later, in a crowded room, you are straining to listen to an acquaintance tell a rather boring story over the sounds of a dozen other conversations when you hear your friend say your name again, and you turn your head to look at her.

How is it possible to gain so much information from sound? How are you able to distinguish one type of bird from another, or tell the difference between the texture of wind in grass from wind in a tree, or between a lazy brook and one that is moving rapidly? How do you know where sounds originate, even in a complex landscape of other sounds? How can you follow a conversation against a background of similar, almost identical voices, and how can the sound of your name arouse you from unconsciousness or instantly claim your attention?

Some of these questions can be answered now, while others remain mostly unsolved. This chapter will introduce you to the auditory system, which consists of the ear, a highly specialized sensory organ that can detect miniscule movements in the air, along with the assembly of nerves and brain areas that filter and process this information into a rich perceptual world.

This chapter also covers the vestibular system, which detects movement of the head and is responsible for the sense of balance. The vestibular sensory organ is also located in the inner ear, and there are close similarities in how both systems convert physical movement into neural signals.

2.3.2: Acoustic Cues and Signals

Learning Objectives

By the end of this section, you should be able to

- 7.1.1 Identify auditory cues and signals and explain their behavioral relevance.
- 7.1.2 Describe what an acoustic wave is and how it propagates through air and interacts with solid objects.

The world is full of sound, and almost every species of animal possesses the ability to sense and respond to sounds. Indeed, hearing is so important that several components of the auditory system have evolved not once but many times. In this section, we will explore what causes sound, first from the standpoint of function and then from the standpoint of physics. This will prepare you for the next section, which covers how sound is detected by the ear and transmitted to the brain.

Why is the sense of hearing important?

Like every other sensory system, the auditory system has evolved because it provides useful information about the objects and events in an animal's environment. Animals that can accurately sense what is happening around them can respond in a way that increases their chances of survival and of successfully passing on their genes. Hearing is especially valuable to survival because sound can travel over long distances and around obstacles, allowing animals to make timely responses, for example by fleeing from a predator before it gets too close.

To further illustrate why hearing is such an important sense, consider the female bird pictured perching in the center of Figure 7.2. Sounds are coming from every direction. Some are not especially relevant, like the splash of a turtle falling into the water or the rippling of water flowing in the stream. Other sounds carry important information, like the rustle in the nearby bushes that could be coming from a predator, or the song of a nearby male advertising himself as a potential mate. Sounds that are produced *unintentionally* are called cues, whereas sounds produced *intentionally*, with the goal of communicating something, are called signals.

Some of the most common and important cues are the sounds animals make as they move. Predators and prey alike have evolved to move as quietly as possible to minimize the cues they give about their presence and location. It is almost impossible to avoid making any sounds, however. Sticks break, grasses rustle, and even simply moving through the air can create turbulence. As we will see, all of these events can generate acoustic waves that travel for tens of meters or even further. Just as there is selective pressure for animals to move quietly, many species have evolved extremely sophisticated and sensitive auditory systems. For example, the common house cat (*Felis domesticus*) can hear a mosquito flying in a quiet room from as far as 30 m away — no wonder my cat seems to appear from nowhere the moment I open a can of food!

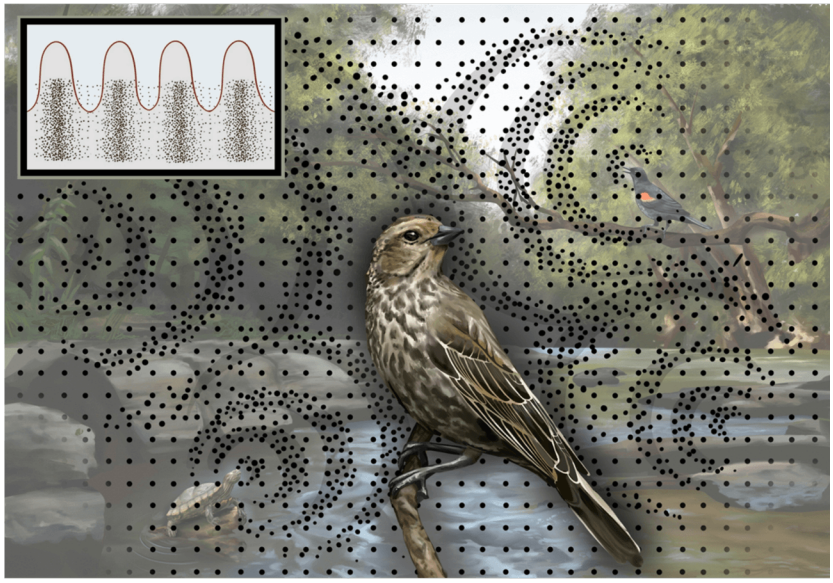

Figure 7.2 Acoustic signals Perceiving the acoustic scene: the acoustic signals converge, resulting in perception. Brush rustles: potential predator? Turtle leaves water: Interference, not a threat. Potential mate singing: Stimulus to prioritize. Water flowing: Noise, background stimulus, not important. Image credit: Created by Natalie M. Lucas. CC BY-NC-SA 4.0.

In contrast with cues, acoustic signals have evolved to allow one individual, called a sender, to influence the behavior of another individual, the receiver. Birdsong, for example, is a signal that communicates to female songbirds that a potential mate is nearby. The male sings with the intent of influencing females to approach and mate. In many species, the song also informs the female of how desirable the male is, because only healthy males can produce songs with a certain level of complexity (Nowicki and Searcy 2004). Acoustic mating displays are common throughout the animal kingdom, including many insects, fishes, amphibians, birds, and mammals.

Acoustic signals can also be used to broadcast the identity of the individual producing the signal, as long as receivers can distinguish the unique features of each individual's signal. Individual recognition is particularly important to animals that live in large social groups where visual cues are not easily distinguished, as in a flock of nesting seagulls or a herd of elephants (McComb et al., 2000) or where individuals need to find each other over long distances, as in dolphins and other marine mammals (Sayigh et al., 1999).

Animals use acoustic signals to communicate to each other about more than just themselves. When social animals are foraging in large groups, a few individuals may keep watch and signal to the group about sources of danger. Acoustic signals have a particular advantage here because they can travel long distances and around obstacles that would block sight. For example, vervet monkeys have different kinds of alarm calls that indicate the presence of specific kinds of predators (Seyfarth and Cheney 1990). When one monkey sees a leopard, it makes the "leopard" call, and the other members of its troupe will climb into trees, even without themselves seeing the leopard. In contrast, when a monkey makes the "eagle" call, the troupe will hide in nearby bushes that are too thick for an aerial predator to enter. The monkeys' auditory system must be able to discriminate between these signals for them to respond appropriately.

Humans have evolved a much more elaborate system of acoustic communication called speech, in which words are formed from combinations of distinct vocal elements called phonemes. For example, the vowels in the English words "bat" and "pat" are the same phoneme (/a/), whereas the initial consonants (/b/ and /p/) are different. One of the most important tasks of the human auditory system is to identify and discriminate between similar-sounding phonemes, and as we will see in 7.3 How Does the Brain Process Acoustic Information?, this ability is shaped by the sounds an infant hears in the first year of life.

Some species produce acoustic signals for themselves to hear, with the purpose of detecting obstacles and prey in their environment. Because sound waves reflect from solids and liquids, they can be used for echolocation. The ability to echolocate has evolved separately in bats and in some aquatic mammals. Echolocating animals produce short vocalizations that reflect off nearby objects. Specialized neural circuits use the delay between the signal and its echo to determine distances to those objects, while other circuits compute the direction of the object (see 7.3 How Does the Brain Process Acoustic Information?) and even some of its physical characteristics (Moss and Sinha 2003). A bat hunting by echolocation can easily discriminate between a solid obstacle and a delicious insect, and it can rapidly alter its course of flight to intercept the insect while avoiding the obstacles (Surlykke et al., 2009).

In summary, the sense of hearing serves many important functions for humans and other animals. Acoustic cues and signals are a critical source of information about predators, prey, obstacles, and dangers in the nearby environment, as well as the presence and intentions of conspecifics (other animals of the same species). In the next section, we will see how the physical nature of sound allows it to transmit this information in a way that complements the other senses.

How is sound produced?

What is sound? From the perspective of physics, sound consists of pressure waves moving through air or some other physical material. Waves are found throughout nature and share a common mathematical description. At the same time, acoustic waves have special properties that make them distinct from other kinds of waves.

To illustrate what a wave is, imagine throwing a rock into a still pool of water. When it hits the surface, the rock will displace some of the water, causing it to rise in a circle around the point of impact. Gravity pulls the displaced water back down, which in turn pushes up the water a little further out. This process repeats again and again to produce what we observe: a ripple *traveling* outward from the point of impact. An acoustic wave moves in much the same way, except that instead of a two-dimensional surface moving up and down, the molecules of the air move closer together and further apart, and the wave spreads in three dimensions.

Now instead of throwing a rock into a pool, imagine clapping your hands together. As your hands meet, they push air out of the space between them. Where does this air go? There is air all around your hands, but air is mostly empty space, so there is plenty of room for the displaced molecules of air to crowd in with the molecules that are already there. Now there is a region around your hands where the air is at a higher pressure, with an increased density of air molecules. The compressed molecules in the region of higher pressure push out into the surrounding space, which is less dense, or rarefied. This creates a new region of higher pressure, which in turn spreads further out from your hands. Just as the water ripple radiates out in a circle from a central point, the pressure wave created by your hands clapping radiates out in a sphere. If a microphone or some other pressure sensor is placed along the path of the wave, it will measure successive increases and decreases in the pressure at that location as the wave travels through space (Figure 7.3).

It is important to notice that the individual air molecules do not move nearly as fast or as far as the acoustic wave. The air itself is not flowing, as in a wind. Instead, neighboring molecules are bumping into each other, and an individual molecule pushed out from a region of higher pressure may only travel a few nanometers before it collides with another molecule. Sound waves move through air at around 343 m/s, but this varies depending on temperature and elevation.

Acoustic waves can be described in terms of three principal quantities: amplitude, frequency, and phase. Amplitude (also called intensity or level) is a measure of how much the air pressure changes between compression and rarefaction. Clapping your hands more forcefully causes a larger increase in pressure and a wave with a higher amplitude. Amplitude is measured in units of pressure (in the metric system, Pascals); however, because the perception of acoustic amplitude follows a logarithmic scale, it is more often reported in units of decibels of sound pressure level (dB SPL). As shown in Table 7.1, each step of 20 on the decibel scale corresponds to a proportional, ten-fold increase in the pressure.

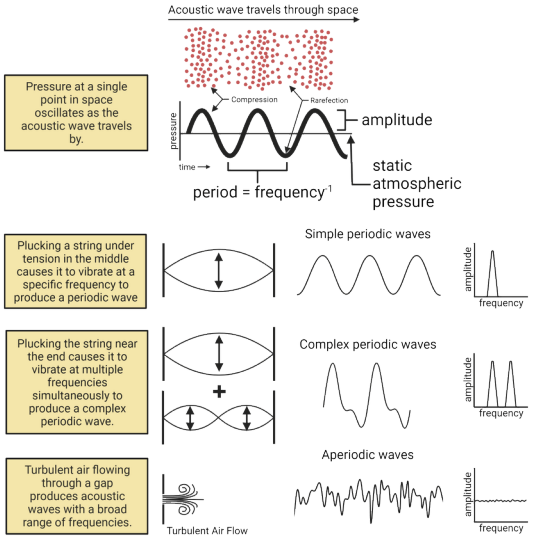

Figure 7.3 Physical properties of acoustic waves

The frequency of a wave is a measure of how rapidly the air at one location changes from compressed to rarefied and back (Figure 7.3). Frequency is measured in Hertz (Hz), the number of cycles that occur each second. The frequency of a sound wave is perceived as pitch. Low-frequency waves sound deep and rich, whereas high-frequency waves are perceived as sharp and thin.

The phase of a wave is a measure of time relative to the cycles of compression and rarefaction. Phase is not perceived directly, but it affects how different waves interact with each other.

Almost any process that displaces air molecules will result in an acoustic wave. One of the most common sources of sound is periodic vibration. You can generate periodic motion by plucking or striking a string that is under tension (for example, on a guitar, piano, or harp). Pluck it right in the middle, and listen to the sound while watching the string. The vibration will probably be too fast for your eyes to track, so the string will appear wide in the middle and narrow at the ends, as illustrated in Figure 7.3. As it vibrates, the string compresses the air while moving in one direction and rarefies it while moving in the other. The vibrations tend to occur at a specific frequency that depends on the mass of the string, its length, and how tightly it is tensioned. The motion of the string and the sound wave it produces are described by a simple mathematical function called a sinusoid (or sine wave) with a single frequency and amplitude. The form of this function and its relationship to the physical properties of the string will be covered in most elementary physics texts.

Amplitude		
dB SPL	Pa	Example
0	0.00002	Mosquito 3 m away in silent room (human hearing threshold)
10	0.000063	Calm breathing
30	0.00063	A quiet office with computer off
50	0.0063	Normal conversation 1 m away
70	0.063	Comfortable music listening level
90	0.63	Traffic on a busy roadway
100	2	Jackhammer 1 m away
120	20	Jet engine 100 m away (risk of instantaneous noise-induced hearing loss)
170	6300	Firecracker 0.5 m away

Table 7.1 Properties of sound

Now press the string down or pinch it at its midpoint before plucking it. The half that you pluck will vibrate twice as fast as the

whole string did, producing a sound wave with twice the frequency. You might notice that the higher note sounds similar even though the frequency is higher. If you pinch the string three-quarters of the way and pluck the short part, the frequency will be four times as high, but the note will still sound similar. This is an illustration of how the perception of frequency is logarithmic, as we'll discuss more later.

What happens if you pluck the whole string, but nearer to one end? You might notice that the note sounds richer and more complex, and that the movement of the string looks more complicated, without one clear wide part in the middle. Just as white light is composed of electromagnetic waves with frequencies spanning from red to violet, sounds can be composed of multiple waves with different frequencies. When the guitar string is plucked nearer the end, it will vibrate at the frequency corresponding to the full length of the string but also at twice that frequency (corresponding to half the length), three times that frequency (corresponding to one third of the length), and so on. A series of integer multiples like this is called a harmonic series. The lower-frequency and higher-frequency sound waves add together to produce complex harmonic motion. The specific combination of frequencies in a complex sound is called its spectrum. Most simple and complex periodic sounds are perceived as tones with a defined pitch that corresponds to the lowest frequency in the harmonic series.

Take a moment to think about this: you hear the string on the guitar as a single note, yet it is composed of several waves with different frequencies. As we will see later, each of these waves activates a different set of receptors in the inner ear and a different set of neurons that transmit information into the brain. In order for us to understand how audition works, we will need to understand how these different channels of information are combined by the brain to produce a single unified percept or split apart to distinguish between different sources, as when a person is singing along to the guitar.

Many species of animals generate sounds through periodic motion. The chirp of a cricket is produced by rubbing two textured surfaces on their wings together. The vocal folds in the mammalian larynx and the avian syrinx vibrate periodically as air is exhaled, and the frequency of the vibrations can be controlled by muscles that increase or relax the tension. In human speech (and even more so in singing), the vowels are produced by periodic movement of the vocal folds.

Sounds that do not have a regularly repeating pattern are not perceived as having pitch and are called aperiodic. The main sources of aperiodic sounds are transient collisions between surfaces and continuous, turbulent air flow. In turbulent air flow, the molecules are not all moving at the same speed and direction. This causes eddies and ripples to form as faster-moving air collides with slower-moving air, and the pressure variations in the ripples propagate outward as acoustic waves. Turbulent flow tends to occur whenever air is forced through narrow openings or disorderly obstacles like trees. You can make turbulent air flow by lightly pursing your lips and exhaling forcefully (but not forcefully enough to make a whistle). Aperiodic sounds do not contain a single frequency or even a regular combination of frequencies as in complex harmonic sounds. Instead, the pressure fluctuates at random across a broad range of frequencies. This is perceived as noise. A continuous sound that has equal amplitude across all frequencies is called white noise. Aperiodic sounds are also commonly used in acoustic communication. In human speech, many of the consonants are produced by aperiodic sounds.

How does sound travel and interact with objects?

Sound's ability to travel through the air is what allows the auditory system to sense cues and signals coming from a distance. In this respect, the sense of hearing shares certain similarities with vision, but acoustic waves are much slower and have longer wavelengths than visible light. Humans can hear sounds with frequencies between approximately 20 and 20,000 Hz. In air, these frequencies correspond to wavelengths between 17 m and 17 mm. In contrast, visible light has wavelengths between 400 and 780 nm. In other words, whereas light waves are much, much smaller than most behaviorally relevant objects, sound waves are around the same size. As a consequence, acoustic waves exhibit a number of phenomena that are important to understanding how sound works.

First, sound waves can diffract around common objects. You can illustrate diffraction by placing a stone about 1 cm in diameter in the center of a shallow bowl of water. Tap the water near the edge of the bowl and watch how the ripples seem to pass right through the stone. This is diffraction. Waves can diffract around objects that are around the same size or smaller than the wavelength, which means that lower frequencies (longer wavelengths) are less likely to be blocked. Thus, a predator may be impossible to see when it hides behind a rock or a tree, but most of the noises it makes will simply pass around the object.

Second, solid objects are more likely to transmit sound waves than visible light waves. Low-frequency sounds in particular are more easily transmitted through solids, which is why you can hear construction noises through solid walls and the bass line from your downstairs neighbor's music. At higher frequencies, solids tend to reflect sound. Reflections cause an acoustical phenomenon called reverberation, in which echoes of a sound reach the same point at slightly different times. For example, if you are in a large room with a concrete floor and metal walls, and someone a few meters away from you claps, you will hear not only

the wave coming directly from the source to your ears, but all the other waves that reflect off the floor and the walls. The reflected waves have longer to travel, and because the speed of sound is around 343 m/s, there can be a perceptible delay between the time when the direct wave and its reflections arrive. Reverberations with long delays are heard as distinct echoes. Reverberations with short delays tend to fuse with the main sound, making it sound more “alive”. Surfaces that are soft or uneven are better able to absorb sound, reducing the intensity of the reverberation, and rooms that have little reverberation sound muffled or “dead”. With practice, people can learn to use the acoustical characteristics of different materials as cues to their location within a room, an ability akin to the specialized echolocation of bats and dolphins.

The long wavelengths and reflectiveness of sound cause another phenomenon called resonance. If sound waves enter a space where they can reflect back and forth between two surfaces, they will interact with each other through interference. If the sound has a wavelength the same as the distance between the two surfaces (or an integral fraction of the distance), the peaks and valleys of the wave going in one direction will overlap with the wave going in the other direction, leading to constructive interference. Wavelengths that are not an integral fraction of the difference will not overlap, leading to destructive interference. For complex sounds comprising waves of multiple frequencies, resonance boosts certain frequencies (wavelengths) while attenuating others. This effect is also known as filtering. When you blow across the mouth of a bottle, the aperiodic noise produced by turbulence resonates in the bottle, boosting a single frequency (and its harmonics) to produce a tone.

Filtering is important to the production of speech. Recall that vowels are produced by periodic motion of the vocal folds. But how do we make different vowels? You can illustrate this by singing “aah” and then changing to “ooh” while holding the same pitch. If you pay close attention to your tongue and lips, you’ll notice that the shape of your mouth changes as you transition between different vowels. What’s happening as you move those muscles is that the sizes of the oral and pharyngeal cavities in your airway are changing to create different resonances that boost and suppress specific frequencies in the sound coming from your larynx.

A consequence of these phenomena is that it is common for a listener to hear many different sound sources simultaneously. This is an advantage in that it is possible to hear sounds without having to look at them, to take in an entire auditory scene in full 360-degree surround, and to hear multiple instruments or singers making music together. It also makes a difficult task for the auditory system, which has to separate out multiple sound sources and determine their locations. As we shall see, the structure of the ear performs a part of this task, separating complex sounds into their component frequencies, but the central nervous system still has an enormous amount of work to do to transform auditory scenes into coherent perception.

2.3.3: How Does Acoustic Information Enter the Brain?

Learning Objectives

By the end of this section, you should be able to

- 7.2.1 Identify the major anatomical parts of the ear and describe their function.
- 7.2.2 Explain how the cochlea separates complex sounds into their component frequencies and transduces acoustic energy into neural signals.
- 7.2.3 Describe how neural information ascends to the cerebral cortex through the major nuclei and fiber tracts of the classical ascending auditory pathway.

In the previous topic, we've seen how the air is full of acoustic waves carrying cues and signals vital to survival. These waves consist of minute variations in air pressure that can be up to 10 billion times smaller than the overall pressure exerted by the atmosphere. In this topic, we will examine how the incredibly sensitive organ known as the ear is able to detect these tiny fluctuations and convert them to neural signals that the brain can process.

The ear consists of three main parts, shown in Figure 7.4: the external ear, the middle ear, and the inner ear. Auditory stimuli enter through the external ear as acoustic waves and exit the inner ear as neural impulses.

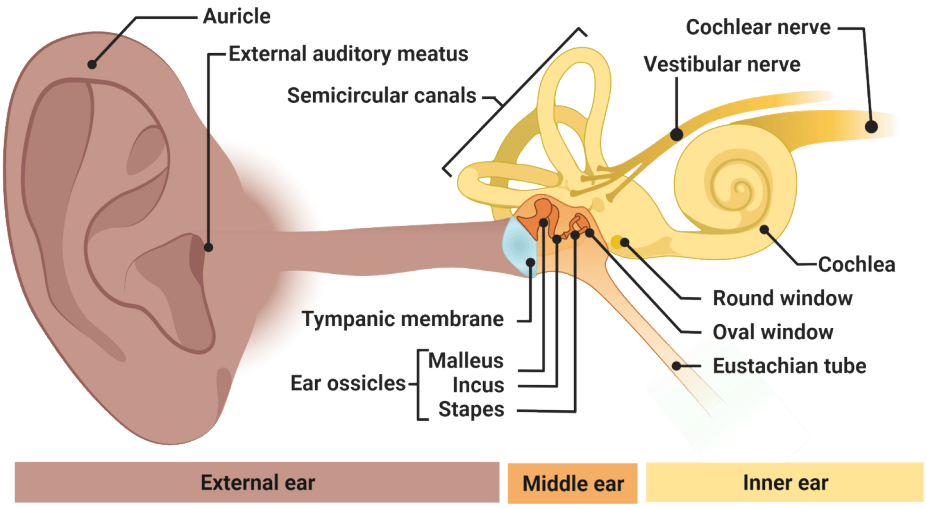

Figure 7.4 Ear anatomy Ear anatomy

External ear

When someone is asked to point to their ears, they will usually indicate their auricles, structures of skin and cartilage on either side of their head. The shape of the auricles (also called pinna), differs greatly among species. Some species, like cats, can manipulate the shape of their pinna using muscles on the skull, while many other species, including most birds, amphibians, and reptiles, have no pinna at all.

The auricle serves two functions. The first is to funnel acoustic waves into the external auditory meatus (ear canal). This amplifies the waves by compressing them into a smaller opening, increasing the sensitivity of hearing by up to 10 dB. The second function is to aid in localizing sound sources. The ridges and folds in the auricle create resonant cavities that filter out specific frequencies that depend on the direction from which the sound is coming. As a simple experiment, filling the cavities of the auricles with modeling clay makes it considerably more difficult to tell where a sound is coming from with your eyes closed (Oldfield and Parker 1984).

Middle ear

Separating the external auditory meatus from the middle ear cavity is the tympanic membrane, a thin sheet of tissue. Like the tightly stretched surface of a drum, the tympanic membrane vibrates in response to acoustic waves in the ear canal. As compressed air reaches the membrane, it pushes it inward, because the pressure in the ear canal is slightly higher than the pressure in the middle ear. Similarly, when the air in the ear canal is at a lower pressure (rarefied), the tympanic membrane is pushed outward by the air in the middle ear.

In order for the tympanic membrane to vibrate effectively, the static pressure in the ear canal and the middle ear cavity need to be equal. The external atmospheric pressure depends on altitude, and a rapid change of altitude, as in a descending or ascending airplane, creates an imbalance that reduces hearing sensitivity, particularly for high frequencies. The Eustachian tube, which connects the middle ear to the oral cavity, allows the balance to be restored. Sometimes it is necessary to encourage the Eustachian tube to open by "popping your ears". A bad cold or sinus infection can cause the Eustachian tube to close. This results in a persistent imbalance that can be acutely painful and even cause damage to the tympanic membrane. Infections of the middle ear, called otitis media, can cause the middle ear cavity to fill with fluid, causing a pressure imbalance if the fluid is unable to drain through the Eustachian tube.

In mammals, the middle ear cavity contains three bones: the malleus (hammer), the incus (anvil) and the stapes (stirrup). These bones are the smallest in the human body. Their function is to transmit the vibrations of the tympanic membrane to the inner ear, specifically the oval window of the cochlea. The middle ear bones form a mechanical lever that compensates for the large difference in the impedance of the air in the ear canal and the fluid inside the cochlea. As illustrated in Figure 7.5, when air is on both sides of a barrier like the tympanic membrane, acoustic energy is efficiently transferred from one side to another because the molecules have the same size and density. They collide like billiard balls: one ball comes to a stop while the other absorbs its momentum and moves on with the same speed. However, when an acoustic wave in air collides with a fluid, the water molecules are densely packed, and much of the energy is reflected, like ping-pong balls bouncing off a bowling ball. The ear compensates for this impedance mismatch through mechanical advantage. The tympanic membrane has a surface area around ten times the size of the oval window. Its vibrations are captured by the stiff middle ear bones, which add further mechanical advantage by acting as levers. Without the middle ear, only a thousandth of the energy in airborne acoustic waves would make its way into the fluid filling the cochlea (Wever and Lawrence 1948).

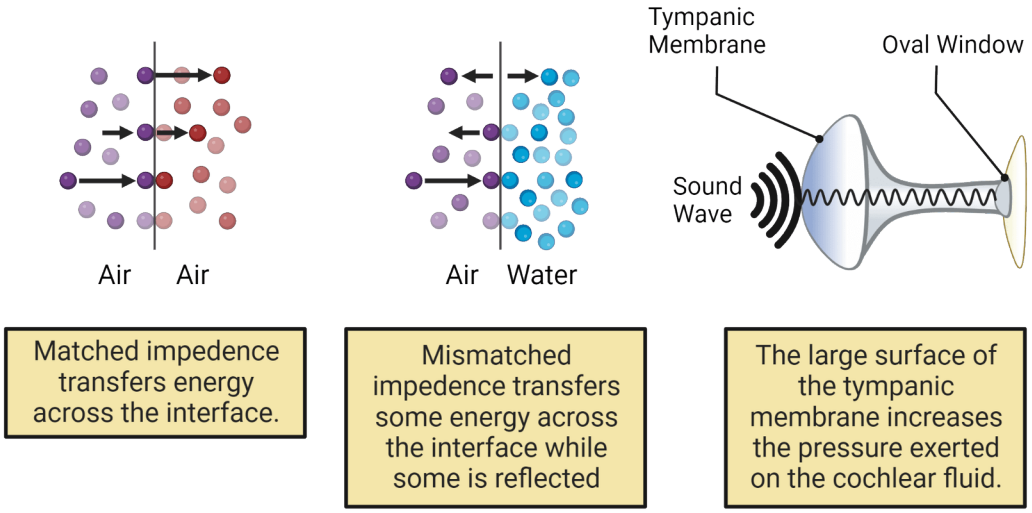

Figure 7.5 Acoustic impedance

The impedance-matching of the middle ear can be compromised by buildup of scar tissue from repeated middle ear infections or by immobilization of the ligaments supporting the middle ear bones. This condition can result in a severe loss of hearing.

The middle ear also contains two muscles that attach to the middle ear bones, the tensor tympani and the stapedius (Figure 7.6). These muscles adjust the tension of the tympanic membrane and the stiffness of the connection between the incus and stapes, respectively. These muscles allow the brain to control the gain of the middle ear. The stapedius reflexively contracts in response to high-intensity sounds and during self-vocalizations, causing a reduction in transmission through the inner ear by up to 25 dB

(Pang and Peake 1986; Rosowski 1991). This reflex is an important protection against the damage that intense sounds can do to the inner ear, but like every reflex, there is some delay. Very sudden sounds like gunshots can therefore do significant harm.

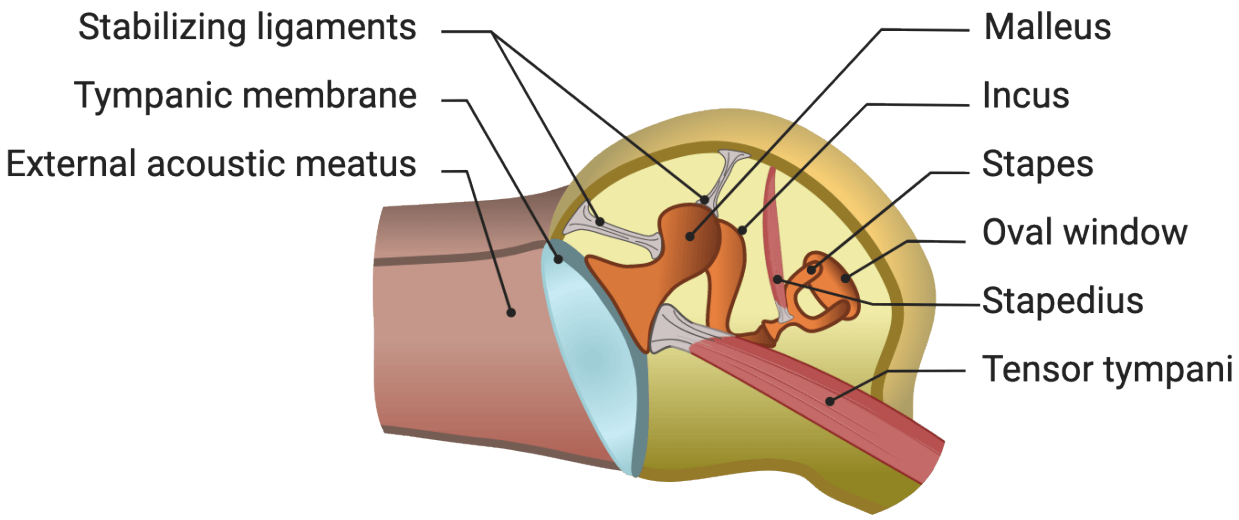

Figure 7.6 Acoustic reflex The stapedius muscle contracts in response to loud noises, attenuating sound transmission through the middle ear.

Inner ear

The inner ear is a hollow bony structure that contains epithelial tissue and fluid. It comprises the cochlea, which is involved in hearing, along with the semicircular canals, the utricle, and the saccule, which are part of the vestibular system. The cochlea gets its name from the Greek for “snail” because it is shaped like a spiral (in mammals).

Cochlea

The interior of the cochlea (Figure 7.7) has a circular cross-section, divided into three fluid-filled compartments that run the length of the cochlear duct: the scala vestibuli, the scala media, and the scala tympani. The scala vestibuli begins at the base of the cochlea at the oval window, a membrane-covered opening that contacts the foot of the stapes. It connects to the scala tympani at the apex, the tip of the innermost spiral of the cochlea. The scala tympani terminates at the base of the cochlea in the round window, another membrane-covered opening. The fluid found in the scala vestibuli and scala tympani is called the perilymph. The scala media is a separate compartment filled with a different fluid called endolymph.

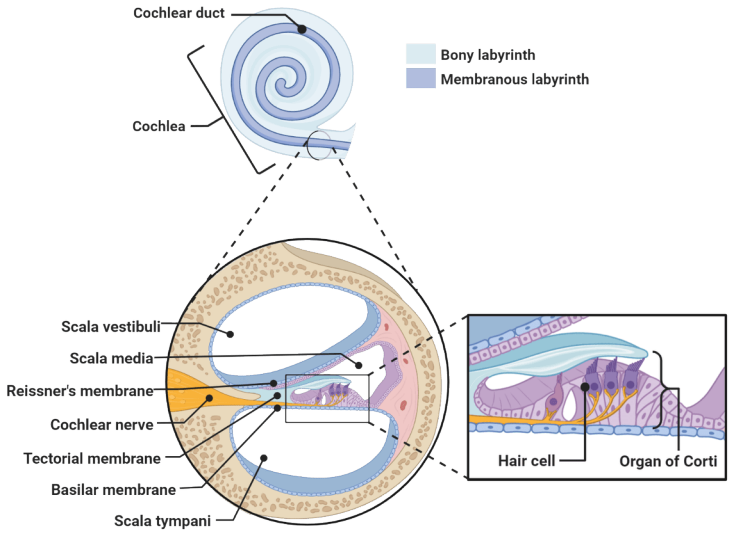

Figure 7.7 Inner ear and cochlea

Basilar membrane

Acoustic waves enter the cochlea through the oval window via the stapes. As the stapes vibrates in and out, it pushes and pulls on the perilymph in the scala vestibuli and scala tympani, which in turn displaces the membrane covering the round window. Some of the energy of this wave, however, is absorbed by the basilar membrane, which stretches between the two walls of the cochlear duct and is able to move up and down. The basilar membrane varies systematically in thickness and width over its length. It is thickest and narrowest at the base and thinnest and widest at the apex (Figure 7.8). These physical properties translate into tuning for different frequencies, a phenomenon called resonance. Near the base, the basilar membrane resonates at high frequencies, around 20,000 Hz. Vibrations in the acoustic wave at these frequencies are absorbed into vertical displacements of the basilar membrane, while the lower-frequency components continue to travel down the scala vestibuli. The resonance of the basilar membrane becomes progressively lower, to about 20 Hz at the apex, so as the acoustic wave travels toward the apex, each segment of the basilar membrane absorbs energy at its resonant frequency (von Békésy G 1960; Rhode 1971).

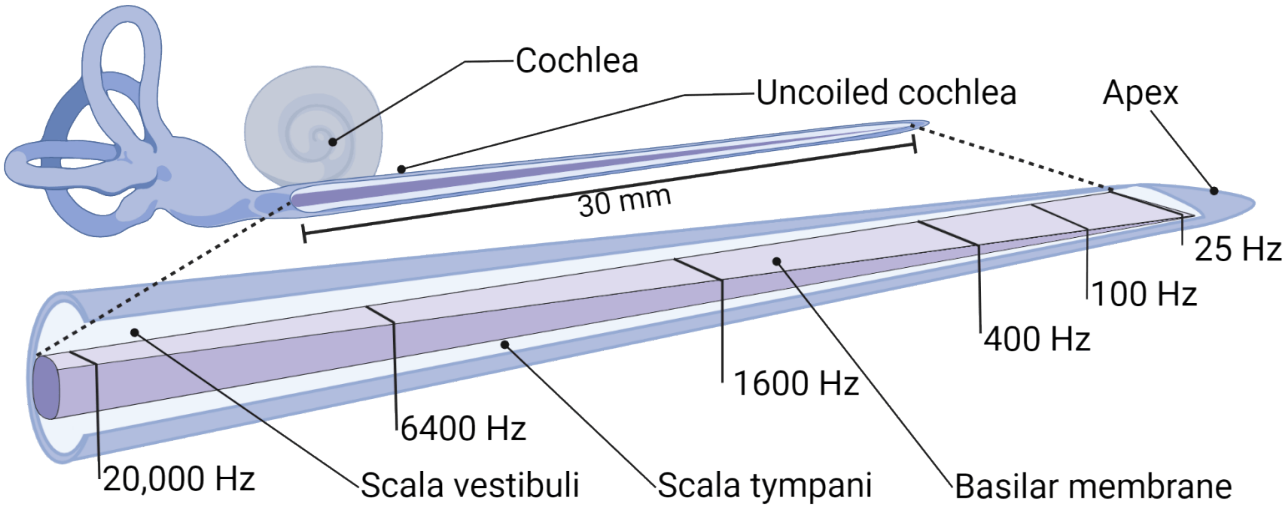

Figure 7.8 Unrolled cochlea

Take a moment to notice in Figure 7.8 how the frequencies are spaced along the basilar membrane. About half of the length is dedicated to the frequencies between 25 and 1600 Hz; the other half goes from 1600 to 20,000 Hz, a much larger range. In other words, the relationship between frequency and position is not linear but (approximately) logarithmic. This organization may be

related to how frequencies in a harmonic series are spaced logarithmically (i.e., integer multiples of the fundamental frequency). In humans, it may also reflect the fact that most of the information in speech is carried by relatively low frequencies (see 7.3 How Does the Brain Process Acoustic Information?).

Although the physical principles are different, the way the basilar membrane separates complex sounds into waves of different frequencies is analogous to the way a prism can separate white light into its component frequencies (or colors). It is an essential first step in how the brain analyzes complex sounds. The organization of frequency (a non-spatial property of the sound) along the axis of the basilar membrane (a spatial dimension) is an example of topography. Because the ear contains a map of frequency, this topography is also known as tonotopy.

On top of the basilar membrane sits the organ of Corti, the epithelial membrane that transduces mechanical movements of the basilar membrane into neural impulses. The organ of Corti comprises four rows of hair cells along with a large number of various kinds of support cells. Hair cells are characterized by stereocilia arranged in a stairstep bundle that protrudes into the endolymph filling the scala media (Figure 7.9; . The organ of Corti is attached at one side to the tectorial membrane, forming a hinge. The tectorial membrane is a gelatinous structure that floats just above the tips of the hair cells' stereocilia.

There are two types of hair cells in the organ of Corti. The inner hair cells form a single row nearest the hinge with the tectorial membrane. They are responsible for sensing the movement of the basilar membrane and transducing those movements into neural impulses. The other three rows are the outer hair cells. Their function is not to sense movement, but to help amplify low-intensity sounds.

Inner hair cells

The inner hair cells are in many ways the most important cells in the auditory system, because they are the sole point at which the physical energy of acoustic waves is converted into the electrochemical signals used by the nervous system. On one end, called the apical end, are the stereocilia, whereas the basal end makes a synapse with an afferent terminal from a single bipolar neuron in the spiral ganglion. There are about 3500 inner hair cells in the human cochlea.

As the basilar membrane vibrates up and down, the tectorial membrane slides back and forth in the transverse direction. The fluid between the organ of Corti and the tectorial membrane tends to remain stationary because of inertia, causing the stereocilia of the inner hair cells to deflect toward and away from the hinge. The tips of the inner hair cell stereocilia contain ion channels that are physically attached to the next-tallest cilium by a tip link. As illustrated in Figure 7.10, deflection of the stereocilia toward the taller edge of the bundle puts tension on the tip links, opening the ion channels and permitting potassium and calcium ions to enter the cell from the endolymph. This depolarizes the cell, causing voltage-gated calcium channels at the basal end of the hair cell to open, which in turn causes synaptic vesicles to fuse with the plasma membrane and release neurotransmitter into the synapse. Deflection of the stereocilia in the other direction relieves tension on the tip link, closing the ion channels, hyperpolarizing the cell, and stopping neurotransmitter release (Hudspeth 1985; Fettiplace 2017).

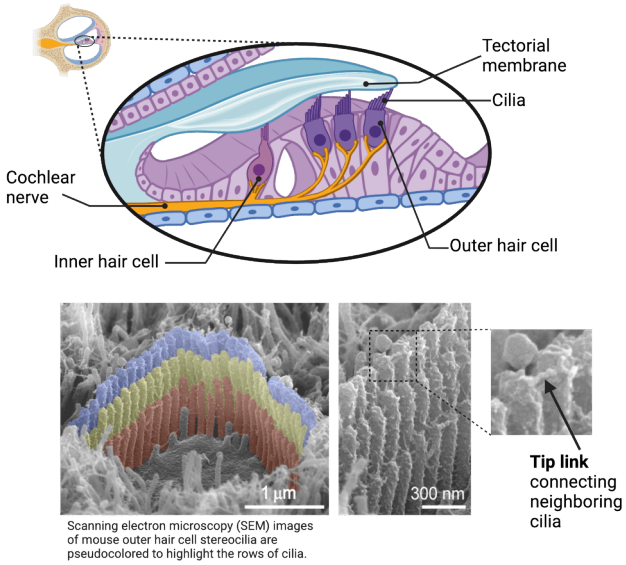

Figure 7.9 SEM of cilia Image credit: SEM cilia images from: Velez-Ortega et al., 2017, eLife https://elifesciences.org/articles/24661. CC BY 4.0.)

The transduction process in inner hair cells is exceptionally sensitive and fast. Sounds at the threshold of hearing produce basilar membrane movements of about 0.1 nm, about the diameter of a hydrogen atom, and movements of the stereocilia may be even smaller. The membrane potential of the hair cell responds to stereocilia deflection in as little as 10 µs, and a specialized ribbon synapse (Figure 7.10) allows neurotransmitter to be rapidly released onto the afferent fiber. The speed and fidelity of neurotransmission allows auditory nerve fibers to track frequencies as high as 1000 Hz or more, firing only at a specific phase of a periodic sound (Dynes and Delgutte 1992). Phase-locking is critical to one of the mechanisms the brain uses to determine the direction of a sound.

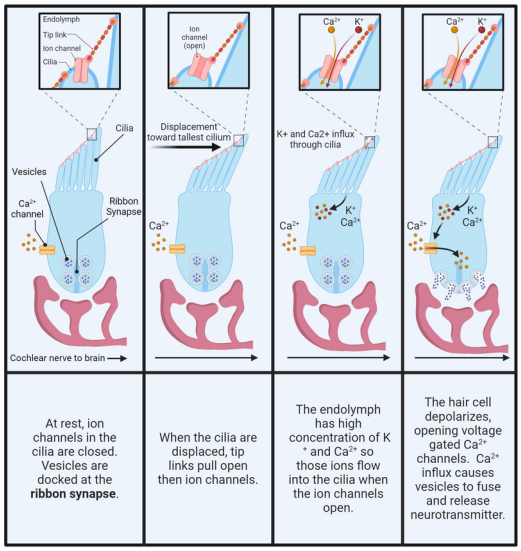

Figure 7.10 Tip link channel transduction

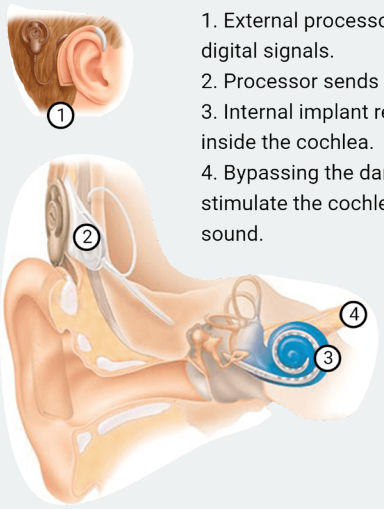
Outer hair cells

The other three rows of hair cells in the organ of Corti comprise the outer hair cells. Outer hair cells have a similar appearance to inner hair cells, but serve a different function. Whereas the inner hair cells primarily receive afferent connections that carry neural signals into the brain, the outer hair cells primarily receive efferent connections carrying signals out from the brain. When an outer hair cell is stimulated, either by deflection of its stereocilia or by synaptic transmission from efferent fibers, it changes its shape. This electromotive response, which is generated by the molecular motor prestin, can occur at frequencies up to 50 kHz,

among the fastest cellular movements known (Zheng et al., 2000). Because the stereocilia of outer hair cells are embedded in the tectorial membrane, these movements are translated into the basilar membrane. This allows the brain to selectively amplify very weak sounds at specific frequencies (Dallos 1992). This is one of the major reasons why we are able to detect extremely low-intensity sounds. However, as anyone who has heard what happens when a microphone is placed directly in front of a loudspeaker can attest, amplifiers are sensitive to overstimulation. This means that the outer hair cells are easily damaged, leading to hearing loss.

Developmental Perspective: Noise, hearing loss, and tinnitus

Hearing loss affects one in eight people aged 12 and older in the US (Lin et al., 2011). Many of these cases are termed conductive hearing loss, because they are related to deficits in how acoustic energy is transmitted from the air to the cochlea. Common causes of conductive hearing loss include occlusion of the ear canal, damage to the eardrum, otitis media, and damage or congenital defects in the middle ear bones. Other cases may involve damage to a component of the nervous system, such as hair cells in the inner ear, the auditory nerve, or an auditory area of the brain. These are termed sensorineural hearing loss. In humans and other mammals, hair cells cannot regenerate, so sensorineural hearing loss is almost always progressive and irreversible (Wagner and Shin 2019). Exposure to excessive noise is one of the most common causes of damage to hair cells. This damage can be easily prevented with appropriate hearing protection. High-intensity acoustic waves cause large displacements of the basilar and tectorial membranes, generating shearing forces strong enough to break tip links, which can be repaired, even in mammals, or loss of stereocilia, which cannot. Blows to the head, aging, genetic defects, and certain ototoxic drugs (including some antibiotics), can also damage hair cells. Outer hair cells are particularly sensitive to noise-induced hearing loss, perhaps because of electromotive feedback or because their tips are directly embedded in the tectorial membrane. Loss of outer hair cells not only makes it more difficult to hear low-intensity sounds, but also impacts the ability to understand speech in noisy conditions, because the brain is no longer able to selectively amplify specific frequencies of interest. Thus, although hearing aids can correct for some of the loss of sensitivity, they are less effective at restoring intelligibility.



Exposure to intense noise can also produce a hearing disorder called tinnitus, a perception of a tone or buzzing sound in the absence of an external stimulus. Although the mechanisms of hearing-loss-related tinnitus remain unclear, one hypothesis is that the illusory tones are the result of overcompensation by central brain areas for regions of the organ of Corti where hearing loss has occurred (Knipper et al., 2021).

Neuroscience in the Lab

Cochlear implants

Most cases of deafness are caused by conductive hearing loss, by sensorineural damage to hair cells, or by a combination of the two. What if it were possible to bypass these parts of the ear and directly stimulate the afferent auditory nerve fibers? In recent decades, the technology to do just that has restored hearing for hundreds of thousands of individuals, including some who were unable to hear from birth.

A cochlear implant consists of two main parts (Figure 7.11). A thin array of electrodes is surgically implanted in the cochlear partition, close to the afferent terminals of the auditory nerve. When an electrical pulse is delivered to one of these electrodes, it depolarizes the axons directly, causing them to generate action potentials that travel into the brain. Electrodes near the base of the cochlea activate the axons associated with high frequencies, while electrodes near the apex activate the axons associated with low frequencies.

1. External processor captures sound and converts it into digital signals.
2. Processor sends digital signals to internal implant.
3. Internal implant relays the signal to an electrode array inside the cochlea.
4. Bypassing the damaged hair cells, the electrodes stimulate the cochlear nerve and the brain perceives the sound.

A child wearing a cochlear implant

Figure 7.11 Cochlear implant Image credit: Cochlear implant image modified from by BC Family Hearing www.bcfamilyhearing.com/%20my...lear-implants/, CCBY-SA 4.0,commons.wikimedia.org/w/inde...curid=48252363; Child image from Image by Matt Ralph - Flickr, CC BY 2.0

The second part of the implant is a controller placed outside the skull. It has a microphone to sense acoustic waves, and a digital processor that separates the acoustic signal into its component frequencies and converts the signal in each frequency band into a sequence of electrical pulses that are sent to the appropriate electrode.

Cochlear implants are an almost miraculous technology. They enable many individuals to more fully participate in societies that place great emphasis on verbal, acoustic communication. Deaf children who are fitted with implants early in life, before the onset of sensitive periods for learning the acoustic structure of speech, can achieve close to normal language development (Kral and Sharma 2011). Cochlear implants are not without their limitations, however, and research continues to improve their sensitivity and fidelity. As of this writing, typical cochlear implants have around 12–24 electrodes (Dhanasingh and Jolly 2017). This is much less than the approximately 3500 inner hair cells, so each electrode stimulates a large number of fibers and the spectral resolution is low. Fortunately, much of the information in speech is contained not only in which fibers are activated, but also in their rate and relative timing. Because of this, the sophisticated signal processing in cochlear implants is generally able to produce an intelligible percept of speech. Other kinds of signals for which the ability to resolve distinct frequencies is critical, like music, remain difficult for cochlear implants to transmit to the brain with fidelity (Fowler et al., 2021). Another limitation of cochlear implants is the absence of the dynamic amplification provided by outer hair cells, which impairs intelligibility of speech in noisy conditions or when there are multiple speakers.

Ascending auditory pathways

After the inner hair cells of the organ of Corti have transduced the mechanical deflection of their hair bundles into the release of neurotransmitter, the auditory stimulus propagates as neural impulses through a number of brain regions and fiber tracts on its way to the cerebral cortex. This ascending pathway is more complex than the pathways for other sensory systems, so there are more names and connections to learn. One reason for this complexity may be that information about the location of sound sources, arguably one of the most important tasks for the auditory system's function in predator avoidance, needs to be extracted from the stimulus early on.

This section will focus on the anatomy of the classical ascending auditory pathway, the most prominent and best studied route by which auditory information enters the brain (Figure 7.12). Although we may briefly note the function of some brain regions and pathways, a full discussion of the physiology and neural computations will be deferred to 7.3 How Does the Brain Process Acoustic Information?.

Auditory nerve

The inner hair cells form synapses with the dendrites of auditory nerve cells, which are bipolar neurons with their cell bodies in

the spiral ganglion, a thin strip of gray matter within the spiraling interior wall of the cochlea. The axons of these cells course together in the center of the cochlea to form the auditory branch of cranial nerve VIII. The auditory nerve also contains many efferent axons descending from the brain to the cochlea; these primarily make synapses with the outer hair cells.

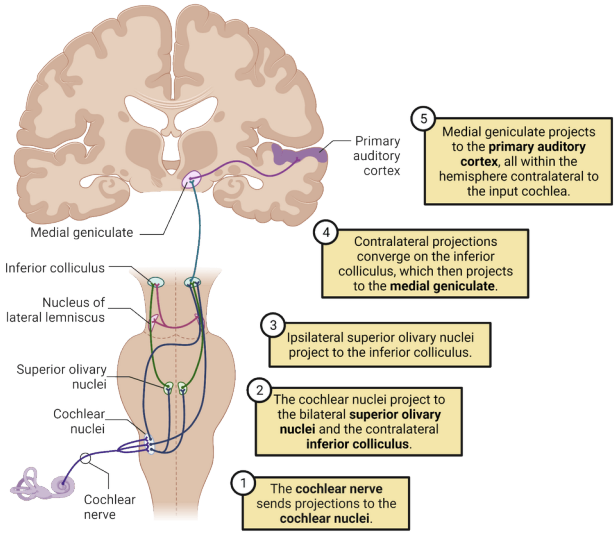


Figure 7.12 Central auditory pathways

Cochlear nucleus

All of the afferent axons in the auditory nerve terminate in the cochlear nucleus, located right at the junction between the medulla and the pons. The cochlear nucleus has three subdivisions: dorsal, posterior ventral, and anterior ventral. Each auditory axon branches twice to make synapses in all three subdivisions. The tonotopic organization of the cochlea is preserved in these projections, resulting in three complete maps of frequency within the cochlear nucleus, one per subdivision (Figure 7.13). Almost all of the stations in the classical auditory pathway have a complete tonotopic map.

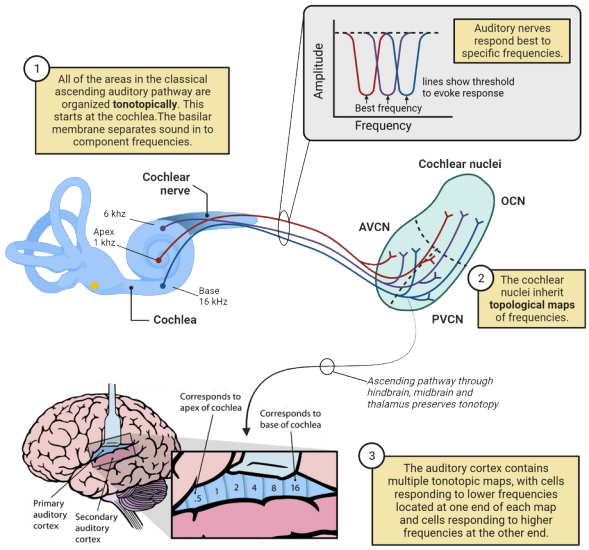

Figure 7.13 Tonotopic oragnization auditory cortex Image credit: Primary auditory cortex image from: Chittka L. and Brockmann A. - Perception Space—The Final Frontier, A PLoS Biology Vol. 3, No. 4, e137 doi:10.1371/journal.pbio.0030137 ([1]/[2]), CC BY 2.5, https://commons.wikimedia.org/w/inde...?curid=5929021

The neurons within the cochlear nucleus give rise to three major output pathways that cross the midline and then ascend up the brainstem through a bundle of axons called the lateral lemniscus.

Superior olivary complex

The superior olivary complex is the first station in the auditory pathway that receives input from both ears. It is located in the pons and comprises three main nuclei: the medial superior olive (MSO), the lateral superior olive (LSO), and the nucleus of the trapezoid body (NTB). These areas primarily receive input from the cochlear nucleus, and all three are involved in determining the location of sound sources using differences in the timing and level of stimuli arriving at the two ears.

Lateral lemniscus and nuclei

The lateral lemniscus is a tract that includes axons from ipsilateral and contralateral cochlear and superior olivary complex nuclei. Some of these axons form synapses in the nucleus of the lateral lemniscus (NLL), while others continue to ascend to the inferior colliculus.

Inferior colliculus

All the axons in the lateral lemniscus terminate in the inferior colliculus, the first midbrain auditory area and a major relay station. There are three major auditory areas within the inferior colliculus: the central nucleus, the external nucleus, and the cortex. Only the central nucleus is considered to be part of the classical pathway. Its main output is via the brachium of the inferior colliculus to the medial geniculate body, a nucleus in the thalamus. The central nucleus of the inferior colliculus also projects to the superior colliculus, an important midbrain area that integrates auditory, visual, and somatosensory input to create a unified map of space relative to head location. This map facilitates rapid orientation of the eyes and head to startling sounds.

Medial geniculate body

The medial geniculate body is a nucleus in the dorsal thalamus, and is the primary gateway for auditory information to reach the cerebral cortex. As such, it plays an important role in suppressing these inputs during sleep and boosting them during arousal. Like the inferior colliculus, the medial geniculate body has three main subdivisions: dorsal, ventral, and medial. Only the ventral medial geniculate body is considered to be part of the classical pathway. It receives input from the ipsilateral central inferior colliculus and sends its output to the ipsilateral auditory cortex, the primary auditory cortex.

Auditory cortex

Ascending auditory information in the classical pathway reaches the cerebral cortex in a region called primary auditory cortex, or A1. In humans, this area is located in the temporal lobe. As in other primary sensory areas, thalamic afferents primarily form synapses in layer 4. There are also inputs from the medial geniculate body onto two neighboring areas, secondary auditory cortex, and auditory association cortex.

The primary auditory cortex and its neighboring areas (sometimes called the core) together make up the first stage in a hierarchy of cortical areas. They each have a tonotopic map representing the full range of audible frequencies, and receive input from both ears. The core is surrounded by secondary cortical areas that receive auditory input via the core and also show tonotopic organization (shown in the bottom portion of Figure 7.13). The secondary areas are heavily interconnected with each other, and appear to be involved in processing more complex acoustic features and in storing auditory memories. The secondary areas project to higher-order sensory association areas that receive input from more than one sensory modality (e.g., visual and auditory) and, in humans, to areas that are specialized for perception and production of speech. These higher-order areas project back to primary and secondary auditory areas. These top-down connections feed back information about context that can help parse complicated scenes by suppressing specific frequency bands and boosting others.

Bilateral processing and descending pathways

Auditory perception is inherently binaural, because one of its most essential and probably primitive functions is to localize acoustic cues. As we will see, this requires input from both ears. It is therefore unsurprising to find many connections between the hemispheres at multiple levels of the auditory pathway. For example, the cochlear nucleus not only makes connections to the superior olivary complex on the same side of the brain (ipsilateral), it also projects to structures on the opposite (contralateral) side of the brain, including the contralateral cochlear nucleus, superior olivary complex, nucleus of the lateral lemniscus, and inferior colliculus. There are also cross-hemisphere connections (called commissures) in the midbrain and in the cortex. One

consequence of this extensive interconnection between hemispheres is that damage to one hemisphere of the auditory system, such as lesions caused by strokes, typically do not result in deafness on either side, though there may be deficits in localization.

Many of the ascending connections discussed in this section are paralleled by descending connections, axons traveling in the opposite direction from cortex to periphery. Indeed, descending connections from cortex to thalamus and other lower stations can far outnumber the ascending ones (Winer et al., 1998; Winer et al., 2001). These connections can modulate processing at almost every level down to the cochlea, where dynamic control of outer hair cells is thought to support dynamic amplification and filtering of signals of interest (de Boer et al., 2012).

2.3.4: How Does the Brain Process Acoustic Information?

Learning Objectives

By the end of this section, you should be able to

- 7.3.1 Describe how circuits in the auditory system determine the location of sound sources by comparing the inputs arriving at each ear.
- 7.3.2 Relate the physical characteristics of sounds to auditory perception.
- 7.3.3 Describe how speech perception changes in early childhood and the role of experience-dependent neural plasticity in this process.

It is remarkable to consider how the flapping of a mosquito's wings can set in motion a process that involves thousands if not millions of neurons. We have traced the pathway this process takes from the outer ear to the cerebral cortex, exploring the exquisitely sensitive mechanisms for amplifying acoustic waves, breaking them down into component frequencies, and converting them to neural impulses. We have followed these impulses as they jump from neuron to neuron along the auditory pathway, crossing the midline one or more times. This process is not just the passive transmission of information, however: at each station in the pathway, signals are filtered, refined, and compared between ears. This section will explore the complicated relationship between acoustic properties and perception.

Location

One of the most important functions of the auditory system is to locate nearby animals. If the other animal is a predator, knowing its location may enable it to be escaped. If the other animal is prey, knowing its location may allow it to be captured. In behavioral tests, humans can reliably pinpoint the location of sound sources to within several degrees (Oldfield and Parker 1984). The acuity of sound localization is highest in front of the head along the horizontal axis. In our own experience, the reflexive turning of the head to look at an unexpected sound is so natural and automatic, it may be difficult to appreciate how difficult the underlying calculations are. Yet evolution has solved this problem with incredible precision.

Interaural timing and level differences

The fact that animals have two ears is not simply a consequence of bilateral symmetry. Depending on the location of a sound source, the two ears will receive slightly different inputs. By comparing the inputs between the ears, the brain is able to determine the location of the source.

When we discuss auditory spatial cues, we are referring to location relative to the head (Figure 7.14). More specifically, what the brain needs to determine is the angle of the source relative to some reference direction, which by convention is usually taken to be the front of the head. The angle of the source has two components: the azimuth, which is the angle to the left or right on a horizontal plane, and the elevation, which is the angle up or down from that plane. Because the ears are separated from each other by the head along the plane of the azimuth, the azimuth of a sound source will affect the relative level and timing at which the sound reaches each ear.

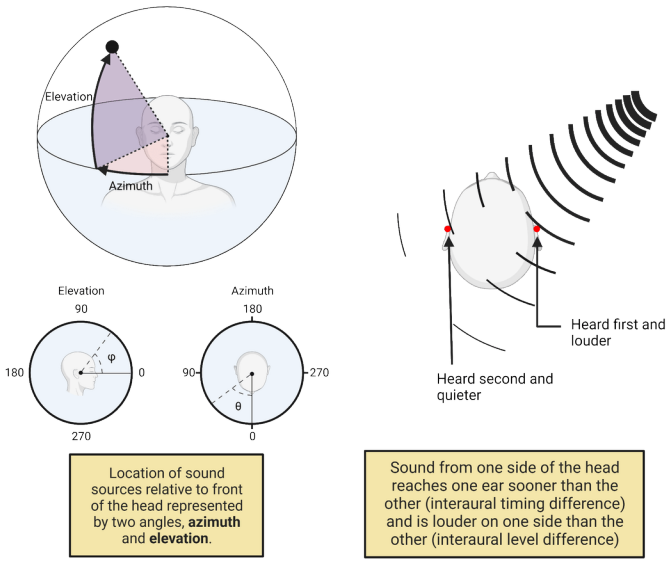

Figure 7.14 Locating sources of sound

Level differences between the ears arise because the head casts an acoustic shadow. Incoming sound waves tend to reflect off the head or to be absorbed by it, so the ear that is closer to the sound source will receive pressure waves with a higher amplitude. This effect is more pronounced for higher frequencies, because low-frequency sounds can more easily transmit through the head and diffract around it. The interaural level difference is greatest when the sound source is 90 degrees to the left or the right, and zero when it is directly in front of (0 degrees) or behind (180 degrees) the head.

Timing differences between the ears arise because the speed of sound is finite (343 m/s at sea level). At 90 degrees azimuth, the distance between the ears in humans is around 0.2 m, corresponding to a delay of about 600 µs. By comparing the timing at which sound arrives at the two ears, it is possible to determine its azimuth. For transient sounds, this comparison involves the difference between the times when the pressure wave's onset arrives at either ear. This difference is called the interaural time delay. Interaural time differences are more relevant cues for the location of low-frequency sounds, whereas interaural level differences are more important at high frequencies.

The elevation of a sound source does not produce interaural differences in level or timing. Nevertheless, humans and many other species can determine the elevation of sound sources thanks to the irregular shape of the auricles. The cavities and ridges of the auricle create resonances that selectively amplify some frequencies while dampening others, creating "notches" in the sound spectrum. These resonances depend on both the elevation and azimuth of the sound source (Oldfield and Parker 1984). Thus, by determining where there are notches in the sound spectrum, it is possible for the brain to determine elevation.

The cues for distance are subtle, and much less is known about how this percept is formed (Kolarik et al., 2016). Without any obstacles, sound attenuates with the square of the distance, so there is no difference in intensity between a source two meters away from one that is twice the distance but four times the amplitude. However, sounds coming from greater distances have the opportunity to interact with more objects, resulting in greater reverberance. It is likely that the perception of distance relies on such cues.

Neural circuits involved in decoding location

The superior olivary complex is the primary brain structure involved in determining azimuthal location. The medial superior olive compares timing between the two ears, whereas the lateral superior olive compares levels between the ears (Figure 7.15).

Top: Left: Line graph od Response v ITD in micro-seconds, showing an oscilating wave. Right: a diagram of a section of brainstem with pathways from the right and left cochlea to the AVCN, which then project to the MSO. Bottom: Left: Line graph od #spikes v ILD in decibels with I

Figure 7.15 Neural circuits for decoding sound location

One of the earliest models for how the brain might calculate timing differences is the coincidence detector. As proposed by Jeffress (1948), if a neuron receives input from both ears, neither of which alone is enough to make it spike, then it will only

fire when the two inputs are active coincidently (i.e., at the same time) (see Chapter 2 Neurophysiology). If the pathways from the ipsilateral and contralateral ear are the same length, then coincidence will only occur when the sound arrives at both ears simultaneously, from directly in front (0 degrees) or behind (180 degrees). If the ipsilateral pathway is slightly shorter, then the neuron will respond best when the input arrives at the contralateral ear slightly before the ipsilateral one. By systematically varying the relative lengths of the axons, an array of such coincidence detectors would be able to represent timing differences as a place code, much as different frequencies are represented in a tonotopic map. In birds, the medial superior olive appears to implement just such a detector (Figure 7.16). It receives inputs from the contralateral and ipsilateral cochlear nucleus, and the incoming axons, in many species, branch to form an orderly array, with the shortest paths from the ipsilateral side at one end and the longest paths at the other. In further support of this model, electrophysiological recordings from the medial superior olive reveal that neurons in this area respond preferentially to specific interaural time differences (Joris et al., 1998). The calculation of interaural time differences in mammals uses a similar principle, but is implemented differently (Lesica et al., 2010).

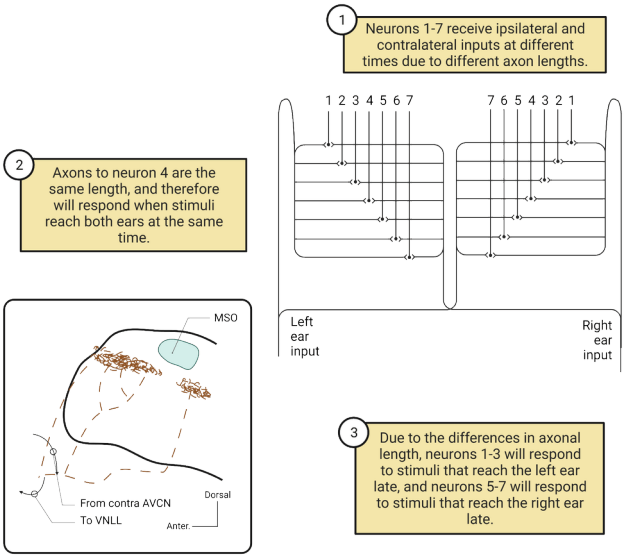

Figure 7.16 A model of coincidence detection for sound localization

Differences in level between the two ears are computed by the lateral superior olive, which receives excitatory input from the ipsilateral ear and inhibitory input from the contralateral ear (via the nucleus of the trapezoidal body). The firing rates of these inputs are proportional to the sound level in each ear. Neurons in the lateral superior olive add together the excitatory (positive) and inhibitory (negative) inputs, so their firing rate represents the difference in the sound level between the ears.

Spatial information from the superior olivary complex propagates forward through the auditory pathway, and as it does, inputs from the medial and lateral superior olive combine to integrate information about timing and level differences. This results in a coherent, unitary perception of sound location.

Perceptual contents

In addition to determining the locations where sounds originate, the auditory system also has to determine what is making the sounds. These complex identifications are based on patterns of simpler spectral and temporal features of the sounds. In other words, we can describe complex sounds like “bird singing” or “lion roaring” in terms of simpler perceptual features. In this section, we will examine some of these perceptual features and how they relate to the physical properties of the sound, then describe some of the neural circuits involved in decoding these features.

Loudness, pitch, and timbre

In 7.1 Acoustic Cues and Signals, we learned that acoustic waves can be described in terms of three quantities: amplitude, frequency, and phase. Simple, sinusoidal sounds have a single value for each of these quantities. Complex sounds are combinations of simple sinusoids, which means that they can be described as a spectrum of frequencies, each with its own amplitude and phase. The basilar membrane decomposes complex sounds into their constituent frequencies, but how are these complex patterns of activation perceived?

Acoustic amplitude (or intensity) is perceived as loudness. Sounds with higher amplitudes sound louder. The relationship between physical amplitude and perceived loudness is geometric (also called logarithmic), which means that proportional increases in amplitude are perceived as linear increments in loudness. Because intensity is usually reported using the logarithmic decibel (dB) scale (see Table 7.1), a linear step in decibels of intensity corresponds to a linear step in perceived loudness. In other words, the perceived difference in loudness between a 65 dB tone and a 75 dB tone is the same as the perceived difference between a 70 dB tone and an 80 dB tone. This relationship only holds if the cochlea is healthy and undamaged, and if the intensity is within the range of human hearing. Below 0 dB, sounds are inaudible, and above 120 dB, the perception of loudness is distorted by saturation (i.e., overstimulation) of the physical and neural processes of transduction.

Frequency is perceived as pitch. Similarly to loudness, this is a geometric relationship. A doubling of frequency corresponds to a perceived pitch interval of one octave, regardless of where you are on the musical scale.

Periodic sounds usually contain multiple frequencies. It is very rare to hear pure sinusoidal tones. When physical objects vibrate, they often produce a harmonic series. consisting of frequencies that are integer multiples of the lowest frequency. Such sounds are perceived as having a pitch corresponding to the lowest frequency in the series, the fundamental frequency. The numerical relationship between harmonics influences the perception of tonality, or how different pitches sound in relation to each other. For example, tones that are an octave apart sound “the same” because the harmonics of the higher note overlap completely with the harmonics of the lower note.

The higher harmonics (also called overtones) are not heard as distinct tones, but instead influence perception of timbre. Timbre is a qualitative rather than a quantitative percept (McAdams 2019). It may be difficult to describe how a clarinet sounds in words, but it is easy to distinguish it from a violin or a French horn, even when they are playing notes of the same pitch. This is because, as illustrated in Figure 7.18, the relative distribution of amplitude in the harmonics a clarinet produces is different from the distribution of amplitude in the same harmonics produced by a violin.

Surprisingly, the perception of pitch does not require hearing the fundamental frequency. Even when the fundamental frequency is filtered out from a note, listeners perceive the sound as having the same pitch (Plack and Oxenham 2005). This observation clearly shows that the perception of pitch is constructed by the auditory system and that it requires neural circuits to integrate information across multiple frequencies.

Neuroscience in the Lab

Psychoacoustic experiments

The study of how physical properties of acoustic stimuli relate to perception is called psychoacoustics. It is a branch of a broader field called psychophysics. Although psychoacoustics does not directly examine the brain, it has yielded many important insights into how the brain processes sound purely by examining behavior.

Psychoacoustic experiments require precise control over how stimuli are presented. They usually take place in specially constructed acoustic isolation chambers that strongly attenuate extraneous sounds. Stimuli are generated by computer programs that can synthesize sounds or manipulate digital recordings. Computers are also used to control presentation of different stimuli and to record the subject’s responses, which usually involve pressing keys rather than making qualitative descriptions. Human subjects can be instructed about how to respond, but nonhuman animals can also be used in psychophysics using operant conditioning or other forms of behavioral training (see Chapter 18 Learning and Memory).

Figure 7.17 illustrates two common psychoacoustic paradigms.

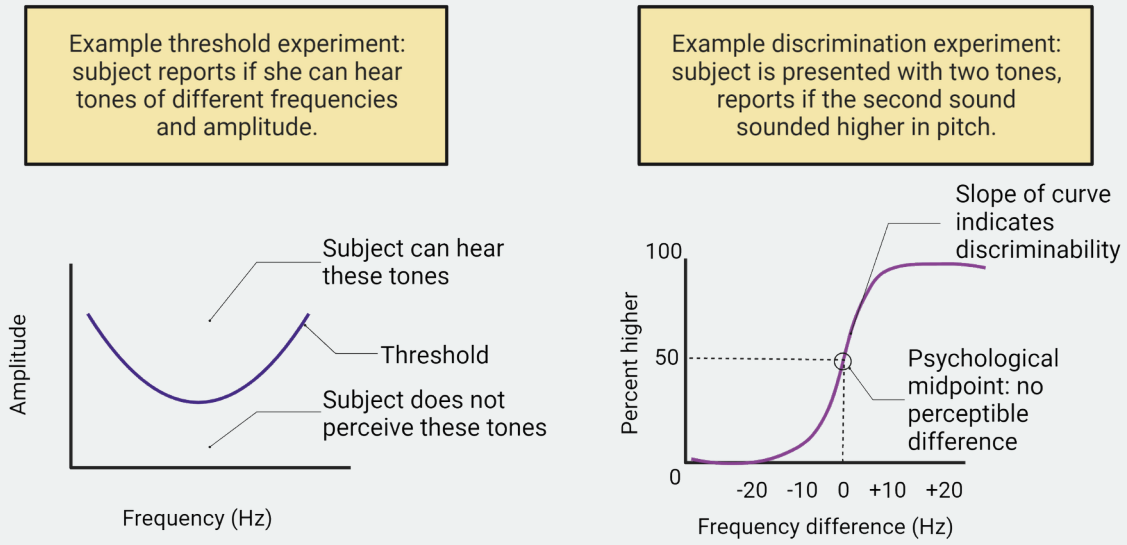

Figure 7.17 Psychoacoustic experiments

In a threshold experiment, subjects report whether they can hear a stimulus or hear the difference between two stimuli. A threshold plot is used to show the minimum value or difference required to elicit a response. In a discrimination experiment, subjects report whether stimuli belong to a group. For example, a subject might be required to indicate whether the second tone in a series is higher than the first. This type of experiment produces a psychometric curve showing the proportion of times the subject or subjects gave a specific response. Psychometric curves typically have a sigmoidal shape. The midpoint of this curve indicates the "psychological midpoint" at which the subject cannot discriminate which category the stimulus belongs to, and the slope of the curve indicates how sharply the subject discriminates between the categories.

Neural circuits decoding contents

Much less is known about how the brain decodes the perceptual contents of auditory stimuli. Natural sounds often comprise multiple frequencies and extend over time, so the neural circuits that decode contents and identify sources need to integrate over multiple frequencies and over time. Even the perception of loudness, though it primarily depends on amplitude, is not entirely straightforward. Amplitude is encoded at the earliest stages of audition. Amplitude affects the displacement of the basilar membrane and hair cell stereocilia, and the firing rate of auditory nerve fibers is proportional to amplitude. This representation of amplitude is maintained throughout the auditory pathway, with most neurons firing more rapidly to more intense stimuli. However, the perception of loudness also depends on duration. Shorter bursts of white noise sound quieter than longer bursts even when they are the same amplitude (Scharf 1978). This implies that the auditory system is keeping a memory of intensity over short intervals of time through temporal summation (or integration).

Conversely, the perception of pitch and timbre requires integration across multiple frequencies. Auditory nerve fibers are tuned to single frequencies corresponding to the region of the basilar membrane they innervate. Many neurons throughout the ascending auditory pathway share this selectivity, but increasingly larger proportions of neurons respond strongly to more than one frequency. These "multi-peak" neurons are prevalent in the auditory cortex (Winter 2005); interestingly, many of these neurons are tuned to frequencies that are integer multiples of a fundamental frequency, just like the harmonics in a complex periodic sound (see Figure 7.18). This suggests that these neurons may be involved in the perception of pitch (Wang 2013).

The auditory cortex is also likely to be the site where short-term and long-term memories of specific sounds and acoustic patterns are stored. Electroencephalography and neuroimaging studies in humans consistently show that responses to complex sounds or to deviations from expectations (a form of memory) are centered in the auditory cortex (Demany and Semal 2008) (see Methods: Electroencepahology). In nonhuman animals, training to recognize or discriminate complex sounds results in neural plasticity within the auditory cortex, implying that the memories associated with the animals' newly acquired perceptual abilities are formed within the cortex (Bao et al., 2013).

Speech and other communication signals

Acoustic communication signals are often complex, consisting of periodic and aperiodic sounds. The frequency and amplitude of these components are often dynamic, changing over time. To illustrate, Figure 7.21 shows a spectrogram of a song sparrow singing (top) and the author speaking a phrase (middle). Spectrograms are two-dimensional plots of how the spectrum of a complex sound changes over time. Frequency is shown on the y-axis, time on the x-axis, and the relative amplitude by the intensity or color of the plot. The sparrow song consists of a series of different kinds of tonal (periodic) sounds in rapid succession. Some of the tonal sounds have clear harmonics, indicated by parallel lines at integer multiples of the lowest frequency. In other sounds, there is only a single frequency, but it is rapidly modulated up or down to produce chirps and trills. The human speech consists of long tonal components, corresponding to vowels, transients spanning the whole range of frequencies, corresponding to consonants like “t”, “b”, and “k” where the flow of air is stopped by the tongue or lips, and broadband aperiodic noises, corresponding to consonants like “s” where turbulent air is passing through the teeth.

In this section, we will focus on human speech, one of the most important stimuli our auditory system has to process.

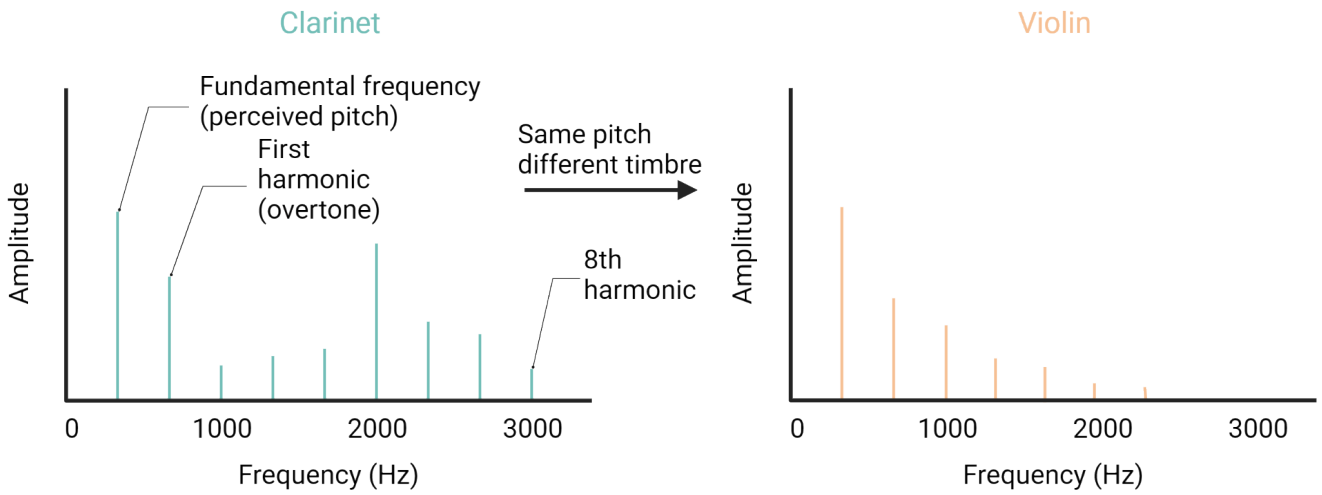

Figure 7.18 Perception of auditory features

The acoustic and phonetic structure of speech

Human speech consists of a series of periodic and aperiodic sounds. Speech sounds are produced by the movement of air through the vocal tract. The parts of the vocal tract that are moved to shape the air stream and produce speech sounds are called articulators.

The main articulator for speech is the larynx, and more specifically, the vocal folds, bands of muscle tissue in the center of the airway. In normal breathing, the vocal folds are relaxed, and air is able to pass through freely. In speaking or singing, the folds are tightened and the air pressure from the lungs increases, causing them to vibrate open and closed. This vibration, also called phonation, produces a periodic wave that forms the basis for vowels.

In most languages, vowels are distinguished not by the fundamental frequency of the vocal fold vibrations, but by how this sound, which is rich in harmonics, is filtered in the upper vocal tract. Positioning the tongue and lips creates cavities of different sizes and shapes. The resonances of these cavities act as filters, producing peaks in the vocal spectrum called formants.

Consonants are phonemes that occur at the beginnings and ends of vowels. They can be produced by starting and stopping air flow through the vocal tract, or by restricting its flow through a narrow opening, producing turbulence.

As you might imagine, the human vocal system can produce a great variety of different vowels and consonants. Not every speech sound, or phone, is used in every language, however, and different phones may be used interchangeably. A group of phones that can be used interchangeably is called a phoneme. In English, the phones [r] and [l] are distinguished from each other: switching [r] for [l] causes the meaning of a word to change (for example “right” and “light”). The same is not true in Japanese: there is only

a single phoneme that includes the whole range of sounds between [r] and [l].

Phonetic perception is categorical: acoustically dissimilar stimuli can be perceived as identical. This phenomenon was demonstrated by Alvin Liberman and Ignatius Mattingly, two pioneers of speech perception, using synthetically generated speech (Liberman et al., 1957; Liberman and Mattingly 1985). As illustrated in Figure 7.19, when the shape of the onset of a consonant-vowel syllable is systematically shifted, English-speaking listeners report hearing either “ba”, “da”, or “ga”. Even though the acoustic difference in each step is the same, this linear acoustic relationship is not reflected in what listeners perceive. Rather, listeners hear sudden transitions from one phoneme to another (there is no percept midway between “ba” and “da”), and they are unable to distinguish sounds within the same category from each other.

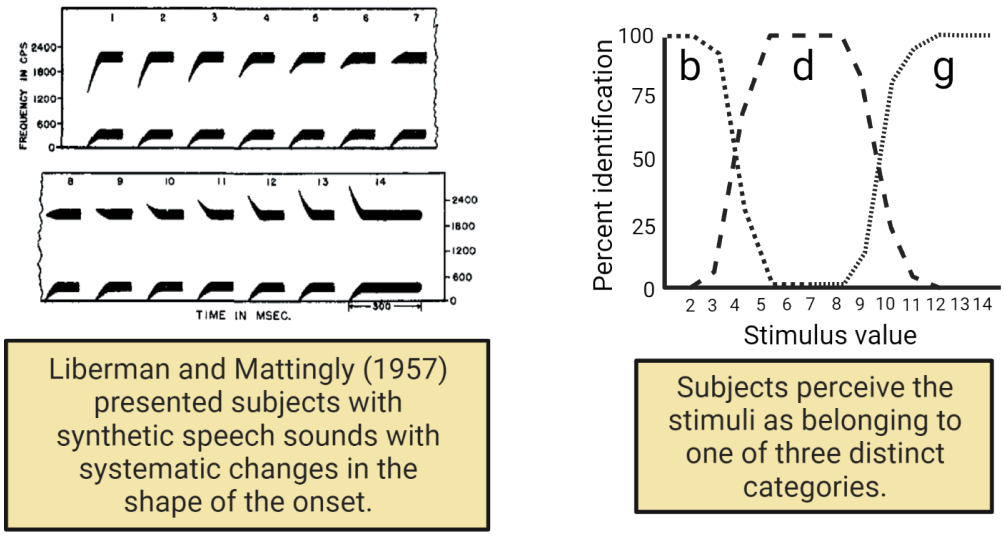

Figure 7.19 Categorical perception of phonemes Image credit: Data re-traced and image reused from Liberman, A. M., Harris, K. S., Hoffman, H. S., & Griffith, B. C. (1957). The discrimination of speech sounds within and across phoneme boundaries. Journal of Experimental Psychology, 54(5), 358–368. doi.org/10.1037/h0044417. Article in the public domain (CC0).

Categorical perception results in a many-to-one mapping between the acoustic structure of speech and phonetic perception. At some level of the auditory pathway, the brain must be responding the same way to different stimuli (Holt and Lotto 2010). This is a critical feature of vocal communication, because it allows us to understand the same words and phonemes produced by different individuals despite wide variations in pronunciation. It also allows us to understand the same phoneme produced by the same individual in different contexts, at different frequencies, and with different emphases.

Developmental Perspective: Normal development of phonetic perception

Different languages have different sets of phonemes, and categorical perception tends to follow the phonetic structure of the listener’s native language. In other words, individuals who grow up hearing English may not be able to hear the difference between sounds that form two distinct phonemes in another language. This observation suggests that phonetic perception is shaped by experience. Moreover, the older people get, the more difficult it is for them to learn to perceive the phonemes of a new language. They hear the new language through the lens, so to speak, of their native language, which makes it more difficult to rapidly process speech or correct an accent. These observations imply that the effect of experience on perception is limited to a narrow window during development, i.e. a critical period (see Chapter 5 Neurodevelopment).

Work by Patricia Kuhl and Janet Werker has revealed how phonetic perception is established early in life (Werker and Tees 1984; Kuhl et al., 2006). Prior to about 6 months of age, infants from all over the world, raised in environments where different languages are spoken, can discriminate between all of the phonemes found in all languages. However, by 9–12 months of age, infants become better at discriminating phonemes in the language of their parents or caregivers and worse at discriminating phonetic contrasts not found in that language (Figure 7.20). Children raised hearing Japanese lose the ability to distinguish [r] from [l]. In contrast, children raised in English-speaking environments stop being able to tell apart “dental” [t], made by placing the tongue against the teeth, from “retroflex” [T], formed by placing the tongue against the roof of the mouth; these sounds are distinct phonemes in Hindi but not in English. This shift, which commits the infant to a certain way of hearing speech, is echoed by changes in how the brain responds to native and nonnative phonemes (Bosseler et al., 2013). This commitment is necessary for normal language

development (Tsao et al., 2004), but it makes it increasingly difficult for children to hear other languages as native speakers do. This could explain why children who begin learning a language later in life are more likely to speak with an accent (Piske et al., 2001), because they would have a harder time hearing their own mispronunciations and correcting their errors.

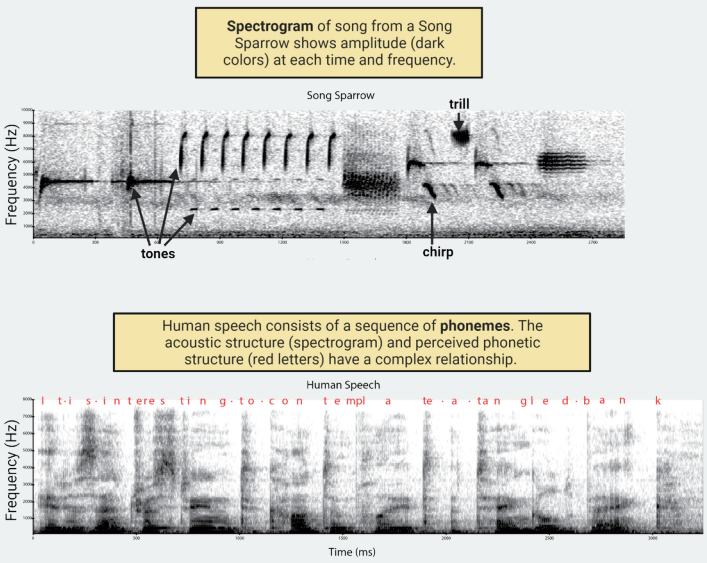
Neuroscience in the Lab

Measuring perception in infants and nonverbal animals

How is it possible to measure what an infant is hearing before it can speak or even understand questions? Kuhl, Werker, and their colleagues devised a clever technique that takes advantage of basic mechanisms of perception and learning (Werker and Tees 1984; Kuhl et al., 2006). As illustrated in Figure 7.20, infants sit on their mother's lap while viewing a toy. As the infant watches the toy, experimenters play a series of consonant-vowel pairs like "ka". At random intervals, the "ka" sound is replaced by a different sound like "ba", and a few seconds later, a more exciting toy is revealed in a different direction. The infant's gaze is drawn to the new visual stimulus, a natural *orienting response* that can be observed almost immediately after birth. Within several such trials, the infant learns that the change in sound predicts the exciting toy, and will turn its head to look at the toy even before it appears. The proportion of trials when the infant shifts its gaze is therefore a measure of how perceptually dissimilar the "oddball" is from the standard. Using this approach, Werker and Kuhl were able to show that native phonemes become more easily discriminated at 9–12 months of age, while nonnative phonemes become harder to tell apart.



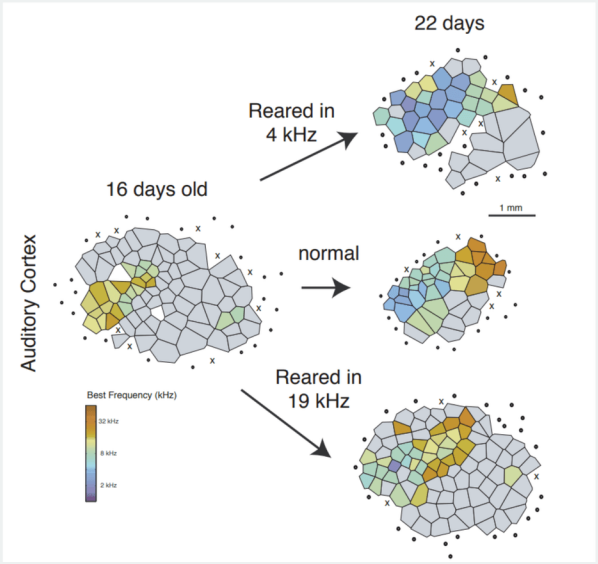


Figure 7.21 Spectrograms of birdsong and human speech

Neuroscience Across Species: Experience-dependent plasticity in animal models

What happens as a child's brain commits itself to a particular set of phonemes? Although it is not possible to study this at a cellular or molecular level in humans, work in nonhuman animal models has shed light on how experience could be reshaping how the auditory system processes sounds.

The auditory cortex in rats, as in other species, is organized by frequency in a tonotopic map (Figure 7.22). This organization is seen throughout the classical auditory pathway, so a reasonable hypothesis would be that the cortical organization is inherited via topological connections from earlier stations. This does not mean that the map is not able to change: work from Michael Merzenich and his colleagues has shown that the map is plastic early in life, subject to alteration by experience (Zhang et al., 2001). When a rat is raised in an environment dominated by tones of a single frequency, the map that results is dominated by that frequency. In other words, repeated exposure to 4 kHz tones results in more neurons over a larger area of cortex responding preferentially to that frequency. Similar effects are seen with other features like rhythm (Zhou et al., 2008). However, the map is only plastic for a limited period during development. The same treatment has little effect on older animals. This closely resembles what is seen in humans: once a child's brain has committed to a specific language's phonetic map, it becomes much more difficult to change (Kuhl et al., 2006; Bosseler et al., 2013).

In rats exposed to constant 4 kHz tones, a large portion of the tonotopic map is dedicated to that frequency.

In normally reared rats, all the frequencies from 2-32 kHz are represented about equally.

In rats exposed to 19 kHz tones, it is the higher frequencies that are overrepresented.

2.3.5: Balance- A Sense of Where You Are

Learning Objectives

By the end of this section, you should be able to

- 7.4.1 Identify the anatomical structures of the vestibular system.
- 7.4.2 Describe how linear and angular acceleration are transduced into neural signals.
- 7.4.3 Identify vestibular reflexes and the associated neural circuits.

The auditory system, responsible for the sense of hearing, is closely associated with the vestibular system, which is responsible for the sense of balance and for helping the brain to track the body's movements in space. Both systems use mechanosensitive hair cells to transduce physical forces into neural signals, and the vestibular hair cells are located within the same organ as the cochlear hair cells. Both systems also send their input to the brain via cranial nerve VIII. However, central processing of vestibular inputs involves different pathways and brain areas, and the behavioral consequences are different as well.

Sensing angular and linear movements

As animals move around in the world, they undergo many changes in position and orientation. These movements occur within the earth's gravitational field, which exerts a force that must be resisted to avoid falling over. To understand how the vestibular system tracks these movements and forces, it is necessary to consider some elementary physics.

Movements in space can be linear or angular (see Figure 7.23). Linear movements are changes in the position of the animal's center of mass. These can occur along any of the three dimensions of space, or some combination of directions. From the animal's frame of reference, these are up and down, left and right, and forward and backwards. Angular movements are changes in the orientation of the animal around the center of mass. These can also occur along three dimensions: pitch, roll, and yaw. Pitch corresponds to nodding the head, yaw to shaking it from side to side (like indicating "no"), and roll to tipping it sideways (like getting water out of your ear). If the animal is at rest, any change in linear or angular position requires a change in linear or angular velocity. A change in velocity is called acceleration. According to Newton's first law, acceleration is proportional to net force. The forces produced by acceleration are dynamic. Bodies are also subject to the static force produced by gravity. Much as the cochlea has evolved to sense the forces produced by acoustic pressure, the vestibular labyrinth has evolved to sense the forces produced by acceleration of the head and by the earth's gravitational field.

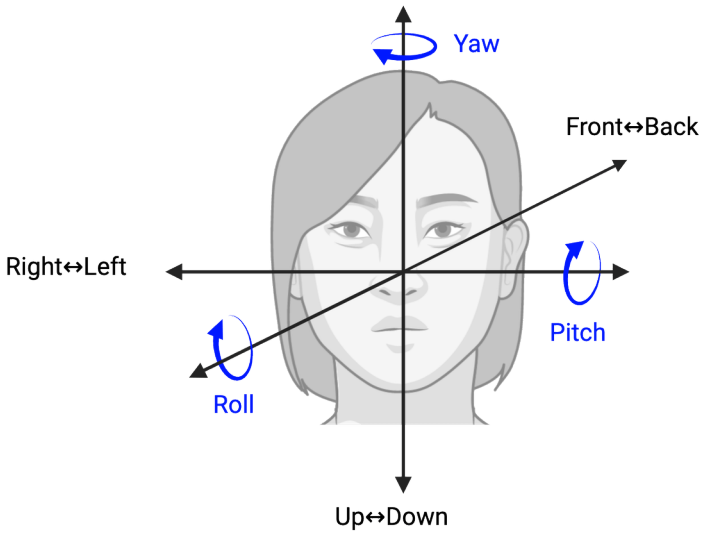

Figure 7.23 Angular and linear movement The vestibular system can sense movement in three linear directions (black lines) and three angular directions (blue circular arrows).

The vestibular labyrinth is a fluid-filled structure connected to the cochlea and sharing the same endolymph (Figure 7.24). In humans, the labyrinth consists of the anterior, posterior, and lateral semicircular canals, three swellings at the base of the canals called ampullae, and two larger swellings called the utricle and the saccule, which together are called the otolith organs.

The semicircular canals and ampullae are responsible for sensing the dynamic forces created by angular movements. They are arranged at right angles to each other. The anterior and posterior canals sense a combination of pitch and roll, and the lateral canal senses yaw. When the head is rotated along a plane parallel to the canal, the inertia of the endolymph causes it to stay still while the surrounding bony and membranous structure moves. This relative motion between the fluid and surrounding tissue exerts a force on the cupula, a gelatinous mass found in each of the three ampullae, atop the ampullary crest (Figure 7.25). The ampullary crest contains hair cells with stereocilia embedded in the cupula. Deflection of the cupula by the force of fluid motion produces depolarization of the hair cells by a similar mechanism to the one seen in the inner hair cells of the organ of Corti. The hair bundles within each ampulla are aligned, so that rotation of the head in one direction causes excitation while movement in the other direction causes inhibition.

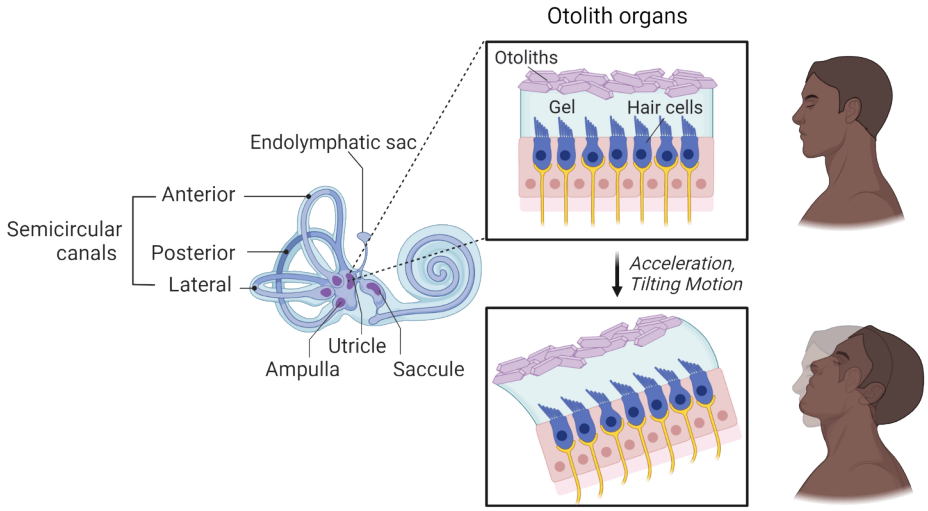

Figure 7.24 Otolith organs

The otolith organs are responsible for sensing linear movements and the direction of gravity. They consist of swellings similar to the ampullae. The floor of each swelling, called the macula, contains hair cells covered in a gelatinous mass. Unlike the cupula, this mass is embedded with crystals of calcium carbonate called otoconia (“ear dust”). The utricular macula is parallel to the horizontal plane of the head. When the head is tilted or linearly accelerated along the horizontal plane, a force is exerted on the otoliths, which in turn causes the hair cells to bend (Figure 7.24). The saccular macula is oriented along the vertical plane of the head and senses linear movement up and down or to the left and right. Whereas the stereocilia in the ampullae are all aligned in the same direction, the macular hair cells have stereocilia that point in all directions. Tilting or linear movement of the head therefore depolarizes some hair cells while hyperpolarizing others.

Vestibular hair cells are innervated by afferent nerve fibers from bipolar neurons with their cell bodies in the vestibular ganglion. As in the cochlea, they also receive efferent connections from neurons in the brainstem, but the function of this system remains poorly understood. The ascending axons from vestibular ganglion neurons course through cranial nerve VIII and synapse in the vestibular nuclear complex, a group of nuclei located in the medulla and the pons. The main outputs of the vestibular nuclei are to the cerebellum, the spinal cord, and the reticular formation, involved in postural control, and to the abducens nucleus and the oculomotor nucleus, which are responsible for maintaining gaze direction while the head is rotated (Figure 7.27). The vestibular nuclei also project to the cortex via the thalamus, and this pathway is responsible for the conscious perception of tilt and acceleration. The cerebellum contributes a major descending connection to the vestibular nuclei that is responsible for modulating the gain of postural and gaze reflexes.

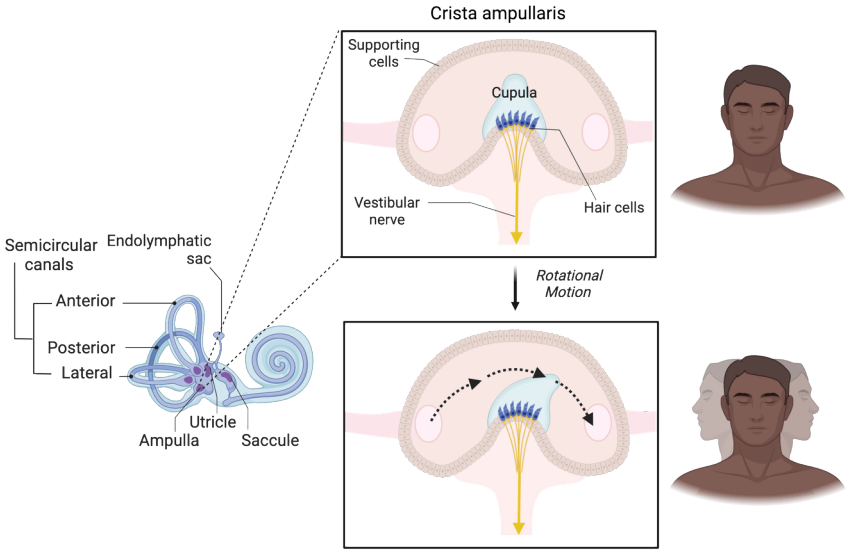

Figure 7.25 Crista ampullaris Fluid flow through canals and ampulla displaces cupula.

Vestibular control of gaze and balance

Maintaining balance, especially in bipedal species like humans, requires rapid, reflexive muscular movements to keep the body's center of mass in alignment with gravity. Furthermore, locomotory activities like running, walking, and flying cause displacements of the head, and animals need to correct for these movements to maintain a clear visual image. The vestibular system plays a critical role in both of these processes.

The central concept in understanding how gaze and balance are maintained is feedback: movements that displace the body or the eyes from the desired position produce signals in the vestibular system that output to the specific muscles that generate a corrective or compensatory movement. The vestibular reflexes are some of the fastest in the body, and to achieve that speed, the underlying circuitry is relatively simple.

The vestibulo-ocular reflex (VOR) is the simplest and most easily demonstrated vestibular reflex. Hold a finger up at arm's length directly in front of your eyes, and then rotate your head from side to side while maintaining your gaze on the finger. Notice how the image of the finger remains sharp and stable. Now try moving your finger back and forth while holding your head still and notice how the image starts to blur. The blurring occurs because the brain is not fast enough to adjust the position of the eyes in response to a rapidly changing visual stimulus: there are many synapses between the retina and the muscles of the eyes, and computing the position of a moving object from a visual image is not trivial.

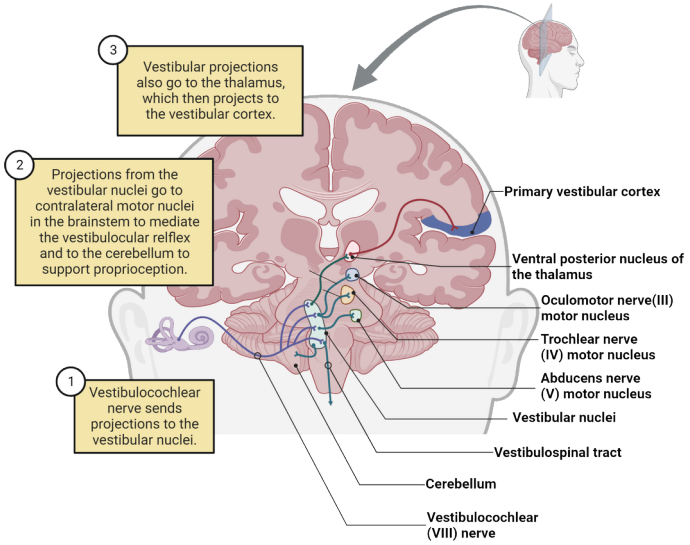

Figure 7.26 Central vestibular pathways

The VOR is fast because the hair cells in the semicircular canals provide direct information about the movement of the head, and they are connected to the ocular muscles by only 2–3 synapses. Figure 7.27 illustrates how the VOR works for rotations along the horizontal plane (yaw). As the head moves counterclockwise, the fluid in the lateral semicircular canals remains stationary due to inertia. This deflects the hair cells in the lateral ampullae, producing excitation on the left side and inhibition on the right. Excitation of neurons in the left vestibular ganglion in turn excites neurons in the left vestibular nucleus and then the left abducens nucleus. The abducens excites the contralateral rectus via cranial nerve VI, which adducts the right eye, pulling it away from the midline. The abducens also excites the contralateral oculomotor nucleus, which activates the medial rectus muscle of the left eye, abducting it towards the midline. The output from the left lateral ampulla is inhibited, which in turn causes the opposing muscles (the left lateral rectus and the right medial rectus) to relax. The net effect is for the eyes to move in the opposite direction from the head, directly compensating for its motion without the need for any visual processing. There are similar circuits that mediate ocular reflexes in response to angular and linear movements along the other directions, thereby allowing animals to maintain steady gaze during all kinds of tasks.

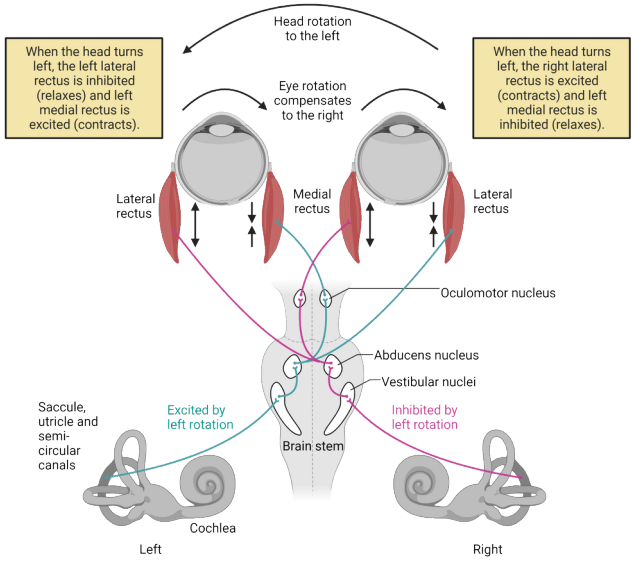

Figure 7.27 Vestibuloocular reflex Image credit: Modification of "Vestibulo-ocular Reflex" in OpenStax Anatomy and Physiology, CC BY 4.0.

For the VOR to maintain gaze, the angular distance of the eye movement needs to be matched to the angular displacement of the head. The scaling between the sensory input (head movement) and the motor output (eye movement) is called the gain of the reflex, and it depends on the distance of the object from the eyes. To illustrate, repeat the experiment in the previous paragraph, holding your finger still while rotating your head from side to side. Keep your focus on your finger, but notice how objects in

the background do not remain steady. Now focus on the background, and notice how your finger now appears to move. This modulation in gain depends on descending input from the cerebellum to the vestibular nucleus. Purkinje neurons in the flocculus of the cerebellum integrate information from many sources, including optic flow from the superior colliculus, neck movements from proprioceptors, and motor commands from the cortex to predict how eye movements will affect the visual image. The output of these neurons can increase or decrease the gain of the vestibular nucleus neurons to appropriately scale eye movements. The cerebellum can learn to adjust its predictions when visual or vestibular inputs are perturbed, for example if the vestibular hair cells on one side of the head are damaged or if glasses are worn with prisms that distort or reverse the visual image (Blazquez et al., 2004; Day and Fitzpatrick 2005).

The other two major vestibular reflexes are the vestibulocollic reflex and the vestibulospinal reflex. The vestibulocollic reflex generates neck muscle contractions to stabilize the head's position relative to the body, whereas the vestibulospinal reflex generates limb and core muscle movements to maintain balance. When the head and trunk tilt to one side, signals from the vestibular nucleus to motor neurons in the spinal cord cause the ipsilateral limbs to extend while the contralateral limbs contract, which has the net effect of pushing the body back towards the vertical. As with the VOR, the cerebellum is responsible for modulating the gain of the vestibulocollic and vestibulospinal reflexes during volitional movements.

Hearing is a critical sense that allows animals to detect objects and events in their environments. It is based on the perception of sound, acoustic pressure waves that travel through the air. Understanding the different ways sounds are generated and how sound waves interact with the physical environment lays the groundwork for examining how the ear senses sound and how the brain processes acoustic information.

7.2 How Does Acoustic Information Enter the Brain?

In terrestrial vertebrates, acoustic signals are sensed by the ear. The external ear funnels sound waves into the ear canal and contributes to localizing sounds. The middle ear transforms oscillations in pressure into mechanical displacements of the fluid in the cochlea. The cochlea contains the basilar membrane, which separates complex sounds into their component frequencies, and the organ of Corti, which contains mechanosensitive hair cells that transduce movements of the cochlear endolymph into neural impulses. These neural impulses are processed in a series of interconnected nuclei called the ascending auditory pathway, eventually reaching the cerebral cortex.

7.3 How Does the Brain Process Acoustic Information?

The neural circuits of the auditory system process incoming stimuli to determine where sounds are coming from and what is making them. The locations of sound sources are determined early in the auditory pathway, primarily by comparing the relative timing and level of sounds arriving at the two ears. Neural circuits later in the auditory pathway are responsible for decoding information about what is being heard. Many complex sounds are perceived in terms of basic features of pitch, loudness, and amplitude, while other sounds like speech are perceived as discrete categories. In humans, the perception of phonetic speech categories emerges early in life as a consequence of experience.

7.4 Balance: A Sense of Where You Are

The vestibular system senses linear and angular movements of the head and its tilt relative to gravity. These forces are transduced to neural signals by hair cells within the semicircular canals and the otolith organs of the vestibular labyrinth. The vestibular nuclei are responsible for generating reflexes in the eye muscles that maintain gaze and for reflexes in the neck and body muscles that maintain head position and balance.

2.3.7: Key Terms

7.1 Acoustic Cues and Signals

amplitude, complex harmonic motion, cue, decibels, diffraction, echolocation, filtering, frequency, interference, periodic/aperiodic, pressure, rarefaction, receiver, reflection, resonance, reverberation, sender, signal, sinusoid, spectrum, speech

7.2 How Does Acoustic Information Enter the Brain?

auditory cortex, auricles, basilar membrane, cochlea, cochlear nucleus, commissural connection, conductive hearing loss, endolymph, Eustachian tube, external ear, hair cell, impedance, incus, inferior colliculus, inner ear, inner hair cell, lateral lemniscus, lateral superior olive, malleus, medial superior olive, middle ear, organ of Corti, ototoxic, oval window, perilymph, positive feedback, round window, sensorineural hearing loss, stapedius, stapes, stereocilia, tectorial membrane, tensor tympani, thalamus, tonotopic organization, top-down, tympanic membrane

7.3 How Does the Brain Process Acoustic Information?

articulator, azimuth, categorical perception, elevation, formant, fundamental frequency, harmonic series, intensity, interaural level difference, interaural time delay, larynx, loudness, operant conditioning, phase, phonation, phone, phoneme, place code, psychometric curve, spectrum, threshold plot, vowel, Weber-Fechner scaling

7.4 Balance: A Sense of Where You Are

abduct, acceleration, adduct, ampulla, ampullary crest, cupula, dynamic force, endolymph, feedback, gain, macula, otoconia, otolith organs, saccule, semicircular canals, static force, vestibular ganglion, vestibular nuclear complex, vestibulo-ocular reflex, vestibulocollic reflex, vestibulospinal reflex, utricle

This page titled 2.3.7: Key Terms is shared under a CC BY-NC 4.0 license and was authored, remixed, and/or curated by Ivette Merced via source content that was edited to the style and standards of the LibreTexts platform.

- 7.7: Key Terms by OpenStax is licensed CC BY 4.0. Original source: https://openstax.org/books/introduction-behavioral-neuroscience.

2.3.9: Multiple Choice

7.1 Acoustic Cues and Signals

1.
Which of the following is an example of an auditory signal?

a. A bird's song.
b. Water splashing in a creek.
c. Wind blowing through the leaves of a tree.
d. The buzz of a mosquito's wings.

2 .
Why is the sense of hearing especially valuable for communication?

a. Because sound is only detected at short distances.
b. Because sound can travel long distances and around obstacles.
c. Because hearing is more reliable than other senses.
d. Because only sound can carry information about the identity of individuals.

3.
What does the frequency of an acoustic wave measure?

a. How fast air molecules are displaced.
b. How much the air pressure changes between compression and rarefaction.
c. How rapidly the air pressure changes between compression and rarefaction.
d. How often an animal produces a sound over the course of a day.

4 .
The perception of pitch is primarily related to:

a. the amplitude of a sound.
b. the frequency of a sound.
c. whether the sound is periodic or aperiodic.
d. the phase of the sound.

5.
The ability of sound waves to travel around solid objects is known as:

a. reverberation.
b. diffraction.
c. resonance.
d. interference.

7.2 How Does Acoustic Information Enter the Brain?

6 .
Which middle ear bone is connected to the tympanic membrane?

a. The malleus
b. The incus
c. The stapes
d. The tensor tympani

7.
Which part of the ear separates complex sounds into component frequencies?

a. The Organ of Corti
b. The basilar membrane
c. The scala vestibuli
d. The tectorial membrane

8 .
What is the function of the inner hair cells in the cochlea?

a. To convert the physical energy of acoustic waves into neural signals.
b. To protect the cochlea from overstimulation.
c. To amplify low-intensity sounds.
d. To regulate the pressure within the cochlea.

9.
Which of the following is a common cause of conductive hearing loss?

a. Damage to stereocilia by high-intensity sounds
b. Damage to the auditory nerve
c. Death of hair cells from ototoxic antibiotics
d. Infection of the middle ear

10 .
All of the axons in the auditory nerve form synapses in the:

a. medial superior olive.
b. cochlear nucleus.
c. inferior colliculus.
d. spiral ganglion.

11.
Which region in the auditory pathway only receives input from the contralateral ear?

a. The cochlear nucleus
b. The lateral superior olive
c. The medial geniculate body
d. None of the above

12 .
Which brain region is involved in comparing the relative timing of sounds between the two ears?

a. The lateral superior olive
b. The nucleus of the trapezoid body
c. The medial superior olive
d. The inferior colliculus

13.
What is the role of the medial geniculate body in the ascending auditory pathway?

a. It is the primary gateway for auditory information to reach the cortex.
b. It forms synapses with the outer hair cells of the cochlea.
c. It determines the location of sound sources using differences in timing and level of stimuli.
d. It integrates auditory, visual, and somatosensory input to create a unified map of space relative to head location.

14 .
A tonotopic organization of auditory information is found in:

a. the cochlea.
b. the cochlear nucleus.
c. the primary auditory cortex.
d. All of the above

7.3 How Does the Brain Process Acoustic Information?

15.
The azimuth of a sound source refers to:

a. the elevation of a sound source.
b. the angle left or right on a horizontal plane.
c. the distance of a sound source.
d. the perceptual contents of a sound source.

16 .
What are interaural timing and level differences used to determine?

a. The elevation of a sound source
b. The azimuth of a sound source
c. The distance of a sound source
d. The perceptual contents of a sound source

17.
What is the function of a coincidence detector in the auditory system?

a. To determine the distance of a sound source.
b. To compare the timing difference between inputs from the two ears.
c. To compare the difference in level of inputs from the two ears.
d. To identify whether a sound source is periodic or aperiodic.

18 .
Memories of complex sounds are thought to be stored in:

a. the inferior colliculus.
b. the medial geniculate body.
c. the hippocampus.
d. the auditory cortex.

19.
A group of speech sounds that can be used interchangeably is called a:

a. phoneme.
b. lexeme.
c. phone.
d. syllable.

20 .
What change occurs in phonetic perception between the ages of 6 months and 9-12 months in human infants?

a. Infants learn to discriminate between all phonemes regardless of their native language.
b. Infants become better at discriminating phonemes in the language of their parents or caregivers and worse at discriminating phonemes not found in that language.
c. They lose the ability to distinguish phonemes.
d. They start speaking in their native language.

7.4 Balance: A Sense of Where You Are

21.
Which structure within the vestibular system is responsible for sensing the dynamic forces created by angular movements?

a. The cochlea
b. The semicircular canals and ampullae
c. The utricle and saccule
d. The otoliths

22 .
The utricle and saccule are primarily responsible for sensing:

a. linear movements and the direction of gravity.
b. pitch and roll.
c. the low frequencies in sound waves.
d. static pressure differences in the middle ear.

23.
Ascending axons from the vestibular ganglion form synapses in the:

a. cerebellum.
b. oculomotor nucleus.
c. medial superior olive.
d. vestibular nuclear complex.

24 .
Which of the following is a characteristic of vestibular reflexes?

a. They are among the slowest in the body.
b. They are among the fastest in the body.
c. They are complex and involve a large number of synapses.
d. They are only found in primitive mammals.

2.3.10: Fill in the Blank

7.2 How Does Acoustic Information Enter the Brain?

1.
The balance of air pressure on the two sides of the tympanic membrane is maintained by the _____.
2 .
Many brain regions in the auditory pathway are spatially organized by frequency. This is called a _____ map.
3.
The axons from vestibular ganglion neurons enter the brain through cranial nerve _____.

7.3 How Does the Brain Process Acoustic Information?

4 .
The perceived difference in loudness between a 65 dB tone and a 75 dB tone is the same as the perceived difference between a 70 dB tone and a(n) _____ dB tone.
5.
The ability of the brain to change and adapt in response to experiences is called _____.

7.4 Balance: A Sense of Where You Are

6 .
The _____ reflex is responsible for generating neck muscle contractions to stabilize the head's position relative to the body.

Your neuroscience study group is getting together to work on its end-of-course presentation and one of your group members has kindly brought some of their “famous” homemade chips and salsa for the group to enjoy. After a few hours of work, the group decides to break for a tasty snack. As each of the members bites into a chip loaded with salsa you hear in quick succession:

“Yuck, this tastes like soap!”

“Ouch, this burns!”
“Yum, this is the best salsa ever!”

How could the same food produce such different responses among people? Why would the nervous systems of members of the same species produce such diametrically opposed responses?

Chemicals are the building blocks of our world. From the sweet taste of an apple to the fresh smell of a newly cut lawn and even the burn of onion in our eyes, every substance we encounter requires us to interact with chemicals. The chemical senses allow us to build internal representations of the rich chemical environment that comprises our external world. Our repertoire of chemical senses directs us toward energy-providing food, alerts us to danger, and helps many animals find mates. While the anatomical, cellular, and molecular features of the chemical senses vary between systems and comparatively between organisms, each system serves a unique purpose in allowing animals to both interact and engage with the chemical environment surrounding them.

2.3.12: The Chemical Senses are Several Distinct Sensory Systems

Learning Objectives

By the end of this section, you should be able to

- 8.1.1 List the basic taste modalities, and for each, provide examples of the type of molecules they represent; for these examples describe why it might be important for an organism to detect those types of molecules.
- 8.1.2 Describe behaviors that rely on olfactory cues in their environment and how these behaviors promote survival.

Signal integration is arguably the most fundamental function of the nervous system. While our brain can integrate information from any of our senses, our perception of taste and smell is likely the most profound sensory integration a human commonly experiences. One often-used example of this phenomenon is how a head cold alters the perception of food. Who among us has not sought the comfort in a favorite food while unwell only to be shocked at the incredible blandness? We might have even thought or said: "I cannot 'taste' anything today." However, this perception is typically not the result of dysfunction in any signaling proteins, receptor cells, or sensory neurons of the "taste" neural system. Instead, in this example, our perception of altered taste is caused by the absence of the olfactory signals that typically occur while feeding. Our brains so tightly interweave the signals produced by the chemical senses during feeding that the common definitions of taste and smell lack the precision needed for describing the underlying neurobiology.

The complex connections between taste and smell can also make communicating about these systems challenging. While the common definitions of taste and smell are imprecise, they are helpful in accurately describing human perceptions that motivate fundamental animal behaviors. Thus, in this chapter, we use the term smell when referring to the chemosensory perception of inhaled air but use olfaction when describing the chemosensory system housed primarily in the nasal cavity. Similarly, the term taste commonly refers to the chemosensory perception of the oral cavity, but gustation specifically refers to the chemosensory system housed primarily in the oral cavity. To make this distinction even more explicit, flavor is the preferred term neuroscientists use to refer to the perception of oral chemosensation, which is produced when the brain integrates signals from the gustatory, olfactory and somatosensory systems. Comprehending these distinctions is the first step in understanding the neuroscience of the chemical senses and the vital behaviors they mediate. In this section, we will use the above vocabulary to explain the basic functioning of chemosensory systems before we explore how each system produces specific sensations in subsequent sections.

Taste-mediated behaviors

The primary role of the sense of gustation is to determine the chemical composition of substances we are about to ingest. The gustatory system is capable of detecting only a few specific types of molecules when in high concentration at close proximity with receptor cells, and it triggers only a handful of sensations or modalities (Sweet, Umami, Salty, Sour, Bitter, etc.). While this is relatively few modalities compared to olfaction, gustation is essential for survival. It is the final mechanism by which animals decide if materials are full of life-giving nutrients or life-threatening poisons.

Acquiring molecules essential for life

All animals consume food for energy and to obtain the chemical building blocks used to construct and repair their bodies. In humans and most other species, there are several broad classes of molecules that must be identified by the organism and ingested. Specifically, the detection of carbohydrates and/or protein (strings of amino acids) in food are critically important for most animals. Many animals also require a source of essential fatty acids that they cannot synthesize *de novo*, as well as external sources of salts to help maintain healthy fluid balance. The ability of animals to perceive carbohydrates, amino acids, fatty acids, and salts in food is largely mediated by the gustatory system. Each of these molecules plays an indispensable role in the fundamental physiological and metabolic processes of animals and must be acquired through ingesting food. Thus, one of the most important roles the gustatory system plays in animal behavior is to allow an animal to determine the nutritive value of a particular food before it is ingested and mediate decisions about which food sources to pursue. For humans, the positive hedonic experience provided by consuming sweet, umami, fatty, and salty foods drives food choices that exacerbate some of the most

prevalent diseases in the developed world (see Chapter 16 Homeostasis). Therefore, understanding how the gustatory system and brain work in concert to decide which foods an animal seeks out is of primary importance to understanding animal behaviors and managing human diseases.

Rejection of potentially toxic or poisonous chemicals

Of equal importance to the gustatory system's role in the selecting of nutritious foods is its capacity to detect dangerous chemicals. Consuming essential molecules is a constant necessity for animal life, but mistakenly ingesting toxic, poisonous, or infectious materials only once can be a fatal error! Accordingly, the detection of compounds that indicate contamination with microorganisms or potential poisons can trigger the rejection or avoidance of those foods. For example, many vertebrate animals, including human infants, find sour foods aversive. Humans describe the taste of acids as being sour. Weakly acidic compounds are often produced in high concentrations by microorganisms metabolizing biomolecules—a process called fermentation. A possible explanation for the tendency of most animals to avoid sour substances is that foods with a high concentration of weak acids were likely decaying and were possibly dangerous to consume. Nevertheless, most adult humans readily consume foods that are fermented, like alcoholic beverages, yogurt, miso, kimchi, sauerkraut, garum, and certain types of sausages and cheeses. However, almost all these foods are thought of as "acquired tastes" that are avoided by inexperienced eaters. This phenomenon highlights the plasticity of the gustatory system and is an indication of how experience can shape the hedonic valence of the foods we consume.

Another example of a taste that potentially signals danger is bitterness. Humans perceive several classes of molecules as being bitter. These molecules are usually found in plants and are likely to have physiological or psychoactive effects on animals. Analogous to "acquiring a taste" for fermented foods, many humans also acquire a taste for bitter compounds that alter their physiology; alcohol, caffeine, nicotine, and cocaine are all perceived as being intensely bitter, but humans commonly will learn to tolerate the bitter taste of these drugs in pursuit of the psychoactive effects. Conversely, the bitter taste of many pharmaceuticals can cause individuals to avoid ingesting therapeutic drugs, and some green vegetables that have health benefits are also avoided because of their bitter taste. Despite these last two examples, perceiving compounds as bitter likely warns of a substance that could detrimentally alter an animal's health.

The primary behavior mediated by the gustatory system is the acceptance or rejection of particular foods. However, it is the integration of these signals with olfactory signals and even the somatosensory system (see 8.2 The Gustatory System) by the brain that creates the sensation we refer to as "taste" or more precisely flavor.

Olfactory-mediated behaviors

The function of the olfactory system stands in contrast to the gustatory system. While the gustatory system detects only a handful of molecules, the olfactory system can detect almost any type of volatile (e.g. air-borne) organic molecule, producing a seemingly inexhaustible collection of different types of smells by detecting specific motifs in those molecules. The olfactory system is also sensitive to incredibly small concentrations of molecules and can therefore detect sources of volatile molecules at great distances. Our sense of smell does more than just add sensory complexity to the flavor profile of a meal or allow us to enjoy the scent of a spring flower. Across the animal kingdom, the olfactory system is an important sensory modality for numerous sensory-guided behaviors. Below, we describe three olfaction-dependent behaviors: navigation, nutrient finding, and mate selection/communication.

Navigation

Navigation occurs on many scales. Bacteria climb chemical gradients to traverse mere fractions of an inch. Insects, like ants and honeybees, travel dozens of meters to find food and nectar. And salmon return hundreds of kilometers to spawn in the very same river from which they hatched. While these examples occur on vastly different spatial scales, they each rely on interactions with chemical cues in the environment. It has long been a mystery how salmon know to return to the exact location they hatched from an egg. We now know that the local olfactory or chemical composition of a river plays an important role in their migration. Fish can smell underwater by detecting waterborne chemicals, much like we do for airborne odors.

Nutrient finding

Nutrients are found in food sources that provide animals with energy and essential compounds for their growth. We discussed above the critical role of gustation in helping animals to assess the nutrients in food they might ingest, but olfaction is essential

to locating these nutrients. A crying baby searching for its mother's milk is a familiar example of nutrient sensing that relies on olfaction. Milk is especially rich in lipids (fats) and all mammals rely on it for their caloric intake early in life. Because of this, it is critical that animals can locate and obtain this important food source. Many mammals, like rodents, begin life without the ability to see or hear and must find their way to milk in order to thrive. These animals rely on their sense of smell to find their mother and her milk. Similarly, not all fats and sugars carry the same nutritional content; olfaction helps babies and adults are able to distinguish between them.

Mate selection and communication

The selection and identification of mates is a universal need for all animals that reproduce sexually. When selecting a mate, animals must gauge both the receptiveness and fitness of potential reproductive partners. These cues can be delivered through numerous behavioral displays; however, olfactory cues often play an important role in bringing mates together. Many signals related to reproductive behaviors are conveyed by chemicals called pheromones, which are sensed using their own specialized olfactory system, separate from smells associated with things like nutrients. Pheromones are powerful substances that can signal sexual receptivity between animals, influence physiological responses like the estrus cycle, and be used to coordinate other behaviors among animals. Behavioral responses to pheromones are innate rather than learned. Later in this chapter we will discuss how pheromones may even play an important role in human partner selection.

Chemesthesis-related behaviors

Many of the culinary ingredients we call spices contain chemicals that stimulate the somatosensory system to produce warming and cooling sensations. The technical term for the chemical stimulation of the somatosensory system is chemesthesis. Many plants produce chemicals that simulate thermal stimuli to alter the behavior of predatory animals. However, because our brains integrate chemesthetic with olfactory and gustatory signals to produce the perception of flavor, human beings cultivate these plants to use as flavor enhancers. The sense of chemesthesis is essential to describing the distinct culinary traditions around the world, but increasingly research indicates that the sense of chemesthesis is important for monitoring parts the body for growing bacteria (see 8.4 Chemethesis, Spices, and Solitary Chemosensory Cells).

The Jelly Bean Experiment: How can you tell the difference between Taste and Smell?

Without training, it can be difficult to distinguish between gustatory, olfactory and chemesthetic sensations. This simple experiment highlights the differences between the senses of olfaction, gustation and chemesthesis discussed in this chapter, and the role the olfaction plays in our perception of flavor. It requires only paper, a writing utensil, jellybeans, mints, and a way to pinch your nose closed.

Materials

- Paper and writing utensil to record your results. You will likely have to record your observation with one hand if you are using the other to pinch your nose, so phones and keyboards are not ideal equipment.
- A couple fruit-flavored jellybeans. The experiment will not work if you use jellybeans flavored with licorice, mint or flavors you might describe as being "spicy."
- A few mints. The more intense the spicy flavor, the better the experiment will work. Cinnamon flavored mints work particularly well.
- A way to pinch your nose. The easiest way will likely be to use your non-dominant hand to squeeze your nose shut just hard enough that it makes your voice increase in pitch. Other options include having a friend pinch your nose closed for you or purchasing specialized padded clips (like the sort made for swimmers) for comfortably holding your nose closed for an extended time.

Methods:

- Step 1: Draw two lines on your paper (one down the center, the other across), dividing the paper into four quadrants. Label the four quadrants "Jellybean/Pinched," "Jellybean/Open," "Mint/Pinched," and "Mint/Open."

Part 1: Gustation and Olfaction:

- Step 2: Tightly pinch your nose. While your nose is pinched you will breathe through your mouth.
- Step 3: Place a jellybean in your mouth on your tongue for at least 5 seconds and chew it a few times.
- Step 4: Write down words to describe the sensations caused by the jellybean in the “Jellybean/Pinched” section of your paper. Don’t swallow the jellybean yet!
- Step 5: Start chewing the jellybean, release your nose and exhale through it. Try to chew the jellybean for at least 5 seconds while breathing through your nose. During this time write down words to describe the sensations caused by the jellybean in the “Jellybean/Open” section.
- Step 6: You can finish chewing the jellybean and swallow it now if you want. If it is convenient, the quality of the experiment is improved by taking a few sips of water here to cleanse your palate.

Part 2: Chemethesis:

- Step 7: Tightly pinch your nose again. While your nose is pinched you will breathe through your mouth.
- Step 8: Place a mint in your mouth on your tongue for at least 5 seconds and chew it a few times.
- Step 9: Write down words to describe the sensations caused by the mint in the “Mint/Pinched” section of your paper. Don’t swallow the mint yet!
- Step 10: Start chewing the mint, release your nose and exhale through it. Try to chew the mint for at least 5 seconds while breathing through your nose. During this time write down words in the “Mint/Open” section to describe the sensations caused by the mint.
- Step 11: You can finish chewing the mint and swallow it now if you want. If it is convenient, the quality of the experiment is improved by taking a few drinks sips of water here to cleanse your palate.

Part 3: “Smell” or Orthonasal Olfaction:

- Step 12: Find a jellybean of the same flavor you used in Part 1. Hold the jellybean in front of your nose and sniff its odor (if you cannot smell the jellybean, try mashing it between two fingers). Write down words to describe this sensation on the back of your paper.
- Step 13: If you did this experiment with a group of people, combine the data you all have collected and discuss how the types of sensations and the words you used to describe them are similar and different for each experience. What patterns do you see?

What you will likely notice when you do this experiment is that the descriptive words used to describe the “Jellybean/Pinched” experience tend to be synonymous with the five basic taste qualities (e.g. Sweet, Sour, Salty, Bitter, Savory). However, once your nose is released, the “Jellybean/Open” descriptors become much more diverse, perhaps even identifying exactly the flavor of the jean bean. While your nose is pinched, very little air is moving from your oral cavity to your nasal cavity through your pharynx, so the chemicals from food cannot reach the olfactory system in the nasal cavity. However, when you exhale out of your nose while chewing, chemicals from your oral cavity can easily travel from your oral cavity into your nasal cavity to stimulate the olfactory system; a process called retronasal olfaction.

These differences highlight that stimulation of the gustatory system is only capable of producing a few very specific sensations that correspond to a few specific classes of molecules; conversely the olfactory system can detect the presence of an almost limitless number of different compounds and the language we use to describe those sensations is similarly diverse. Additionally, you can begin to determine the different sensations mediated by the gustatory and olfactory systems by comparing how similar your description of sniffing the jellybean was to the other experiences. Likely, the sniffing description was very similar to what was recorded for the “Jellybean/Open” experience. There are some foods, however, that may produce different sensations from orthonasal olfaction (e.g. sniffing) and retronasal olfaction. For example, some cheeses (e.g. parmesan cheese or blue cheeses) are famously stinky when perceived by orthonasal olfaction but produce a different sensation when perceived retronasally.

When you compare the description of the mint to the jellybean, you will likely notice the addition of words like burning, cool, pungent, or painful in the description of the mint. These sensations are due to chemicals in the mint stimulating the free nerve endings of the trigeminal nerve—part of the somatosensory system, your sense of chemesthesis.

The jellybean experiment is easy to do with most foods, and, by practicing it, you can become better at perceiving the difference between gustation, olfaction, and chemethesis. Eventually you may even be able to tell the difference without pinching your nose closed!

2.3.13: The Gustatory System

Learning Objectives

By the end of this section, you should be able to

- 8.2.1 Describe the functional anatomy of the gustatory system from cellular receptors to neural pathways in vertebrates.
- 8.2.2 Describe the molecular pathways required for the detection of a taste modality
- 8.2.3 List some of the ways gustation can be parallel and different across species

Imagine it is a cool fall evening at a street festival, and you are hungrily wandering through the food trucks trying to find the perfect snack. You have been looking forward to this moment all week; even planning lighter meals today to facilitate your guiltless indulgence of the calorically rich food. Suddenly you see just what you have been looking for: at least a cubic foot of pink, blue, and mauve spun sugar on a stick. Salivating, you purchase the snack and are filled with joy as handfuls of the cotton candy instantaneously liquefies into sweetness as it hits your tongue. In this section, we will explore how the gustatory system is able to distinguish between different classes of molecules to produce different sensations (e.g. Sweet, Umami, Salty, Sour, Bitter) and current theories about how these signals are processed in the CNS.

Gustation and peripheral anatomy to receptors

The primary role of the gustatory system is to assess the quality and concentration of chemicals before they are allowed entrance into the digestive tract. This process begins with bringing chemicals into the mouth where they can interact with specialized receptors on sensory cells.

The tongue and oral cavity

The sensory cells of the gustatory system are typically concentrated in the oral cavity. These sensory cells are found in clusters called taste buds. The exact distribution of taste buds will vary among species. In most mammals, taste buds are concentrated on the tongue (Figure 8.2), but are also found on the soft palate, epiglottis, larynx, upper esophagus, and associated with salivary glands behind the molars.

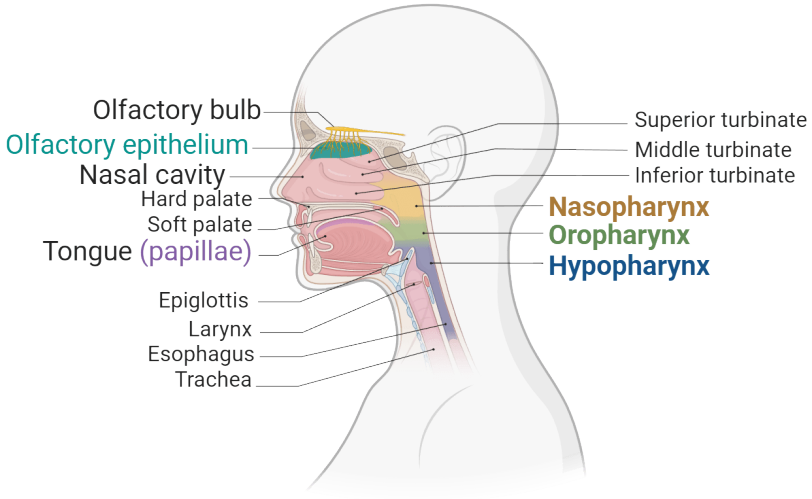

Figure 8.2 Gross anatomy of gustatory and olfactory systems

Many species of fish, in contrast, possess taste buds in the oral cavity but also on their lips and on the skin of their bodies—indeed,

taste buds are so prevalent on the bodies of catfish that they are sometimes described as being “swimming tongues.” Conversely, marine mammals (e.g. dolphins, seals) that feed by swallowing prey whole typically have a reduced number of taste buds throughout the oral cavity and tongue. These anatomical adaptations all facilitate the specific feeding behaviors of each species. Despite the observed anatomical variation, chemicals in food are detected by sensory cells in taste buds, and this information is subsequently passed on to homologous regions of the central nervous system.

While there is great variation in the anatomy of the oral cavity between species, the tongue of most vertebrates is a sensory organ specialized for both chemosensation and somatosensation. If you have ever looked at your tongue closely in the mirror, you might have noticed that its anterior surface appears rough, except for scattered bumps which have a smooth texture (Figure 8.3).

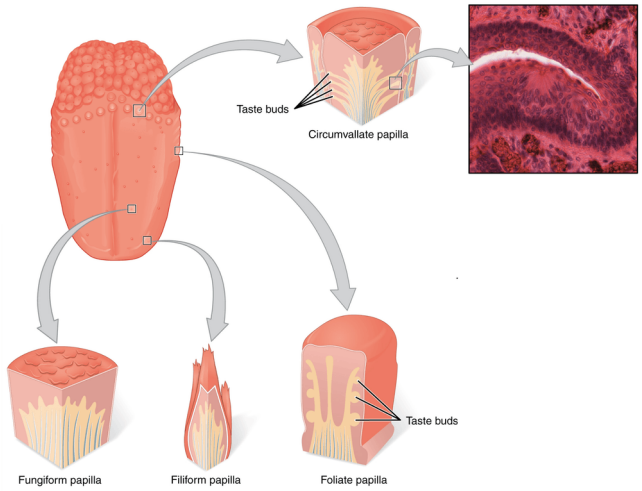

Figure 8.3 Tongue and papillae anatomy Image from: By OpenStax - https://openstax.org/books/anatomy-and-physiology-2e

Both the rough areas and smooth bumps are made up of structures called papillae, which enhance somatosensation on the tongue. The rough areas of the tongue are covered in filiform papillae, which are cone-shaped, come to a point, and do not contain taste buds. The three other types of papillae contain taste buds: the smooth round bumps on the tongue are called fungiform papillae and often have 1 to 5 taste buds at their apex. On either side of your tongue there are 4 to 6 groves lined with hundreds of taste buds called foliate papillae. And at the very back of your tongue are 4 to 8 circular troughs containing taste buds called circumvallate papillae. The exact number of papillae varies across vertebrate animals, but most have each type of papillae to facilitate exploring the textures of food and channeling the biomolecules towards taste buds.

Behind the tongue is a space called the pharynx. Figure 8.2 shows the three major divisions of the pharynx. In most terrestrial animals, this space connects to the oral cavity, esophagus, trachea, nasal cavity, and even the inner ear (see Chapter 7 Hearing and Balance. This anatomical arrangement allows for the chemicals in food to be sampled with both the gustatory and olfactory systems simultaneously. The co-simulation of these systems when eating strengthens and facilitates our perceived integration of these senses.

Taste buds and taste receptor cells

Papillae are visible with the naked eye, while taste buds are so small they require a microscope to see. People without formal anatomical training sometimes mistakenly equate fungiform papillae (0.5 to 0.8 millimeters or 500 to 800 micrometers across) with taste buds (30 to 100 micrometers across). Taste buds resemble an onion or bulb of garlic in cross-section (Figure 8.4).

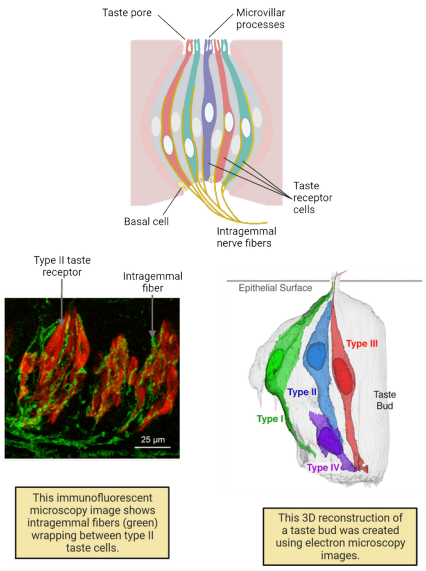

Figure 8.4 Taste bud anatomy Image credit: Taste bud diagram adapted based on: By OpenStax. Taste bud immunofluorescence: Kinnamon SC and Finger TE (2013) A taste for ATP: neurotransmission in taste buds. Front. Cell. Neurosci. 7:264. doi: 10.3389/fncel.2013.00264 CC By 3.0. 3D taste bud rendering from: Recent advances in taste transduction and signaling [version 1; peer review: 2 approved]. Each taste bud is a collection of 50 to 150 neuroepithelial cells and associated nerve fibers. These neuroepithelial cells are spindle-shaped or bottle-shaped with apical microvillar tufts that open into the lumen of the oral cavity in a structure called a taste pore. For the gustatory system to detect particular chemical stimuli, a chemical must first enter the taste pore so it can interact with proteins in the cell membrane of the microvillar process of these cells. Because these cells are the first element of the gustatory system that responds to chemicals, they are referred to as taste receptor cells (TRCs).

Anatomists studying the cells of taste buds have grouped them into three types based on characteristics observed by transmission electron micrography (Farbman, 1965) (see Methods: Transmission Electron Microscopy). These classifications based on micro-anatomy turn out to be functional, as different classes of chemicals activate Type I, Type II and Type III taste receptor cells. Type II and Type III cells will make occasional cytoplasmic contact with each other or nerve fibers but Type I cells enwrap the other cell types supporting them and helping degrade neurotransmitters released by the other cells. These functions have caused scientists to describe Type I cells as “glial-like.” Type IV cell is a designation given to basal cells in the bud that divide to replace the other taste receptor cell types that are lost to damage. The specialized anatomical arrangement of taste receptor cells allows taste buds to detect chemicals and selectively modulate either other cells in the taste bud or the associated nerve fibers to ultimately produce the familiar taste qualities of sweet, umami, bitter, salty, and sour.

Taste receptor cells and taste receptor proteins

But how does a taste receptor cell in a taste bud turn a chemical in your mouth into a signal that your brain can understand? Decades of research have helped us understand that the mechanisms for detecting and transducing a chemical into a neural signal are different for each of the half dozen or so taste qualities. This stands in dramatic contrast to the mammalian olfactory system, where hundreds of genes belonging to the same receptor family using the same basic transduction paradigm allow you to perceive an incomprehensible number of olfactory qualities. In the mammalian taste system, at least 4 different families of receptors are implicated in detecting the chemicals we perceive as sweet, umami, bitter, sour, and salty. An overall summary of these receptors and how those signals are transduced is provided in Figure 8.5.

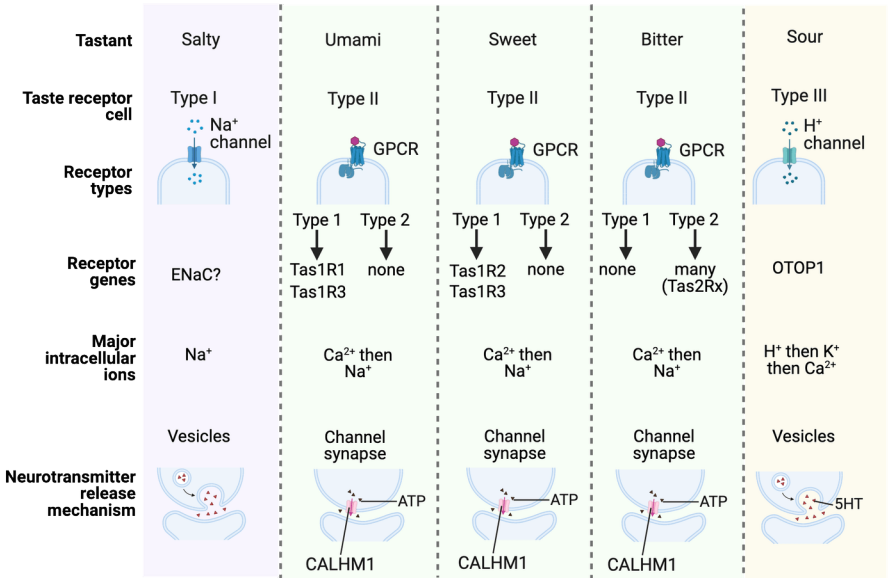

Figure 8.5 Taste receptor cell comparison

Three distinct groups of Type II taste receptor cells are responsible for detecting sweet, umami, and bitter chemicals using receptors from the GPCR super-family. The sweet and umami-sensitive taste receptor cells detect chemicals using taste receptors from subfamily 1, which is made up of 3 individual receptor genes designated Tas1R1, Tas1R2, and Tas1R3. To produce a functioning receptor protein from this family of receptors—either sweet or umami—two different receptor genes must combine to make a heterodimer: The sweet receptor requires both Tas1R2 and Tas1R3; while an umami receptor requires Tas1R1 and Tas1R3. The third group of type II taste receptor cells detects bitter compounds via taste receptor subfamily 2 (Tas2Rs), which consists of many more genes than subfamily 1 (e.g. humans have 25 Tas2R genes). Thus, sweet-sensitive type II receptor cells will express Tas1R2+Tas1R3, umami-sensitive type II receptor cells will express Tas1R1+Tas1R3, and bitter-sensitive type II receptor cells will express some combination of Tas2Rs. Activation of any of these receptors triggers lipid secondary messenger signaling that ultimately results in the release of ATP to activate gustatory nerve fibers.

Ion channels are responsible for the detection of sour and salty chemicals. Most sour chemicals are acids that dissociate to produce a proton (e.g. hydrogen ion) in solution. Type III taste receptor cells that are sensitive to sour chemicals express a proton channel Otopetrin 1 (Otop1). Protons flow into these cells through Otop1 and ultimately trigger a change in membrane potential resulting in the vesicular release of serotonin (5HT).

While scientists are still searching for the precise mechanism of salt detection, Epithelial Sodium (Na) Channels (ENaC) are widely considered to play an essential role in the depolarization of Type I taste receptor cells in the presence of sodium ions.

Identifying the receptor proteins TRCs utilize to detect chemicals is a prerequisite for a complete understanding of the taste modalities the gustatory system is capable of detecting. The involvement of at least four different families of receptor proteins and distinct transduction mechanisms in taste receptor cells highlights the inherently molecular nature of gustatory perception.

Taste transduction in depth

Part I: Umami, sweet, bitter

The chemicals we perceive as umami, sweet or bitter are detected by Type II taste receptor cells (TRCs). However, three distinct subsets of Type II cells in a taste bud respond to the amino acids, carbohydrates, and bitter chemicals that generate these tastes. The three subsets of Type II cells are defined by which combinations of two sub-families of G-protein coupled receptors or GPCRs they express.

Taste receptors in subfamily 1 (abbreviated either Tas1R or T1R) are responsible for detecting sweet or umami molecules. Type II cells that respond to sweet or umami molecules require the expression of two of the three different T1Rs genes to make a functional taste receptor. Umami-responsive receptors that bind amino acids like glutamate are produced by combining T1R1+T1R3. Sweet-responsive receptors that bind sugars, carbohydrates, and other compounds that taste sweet are produced by combining T1R2+T1R3. While there are 3 T1R genes in humans, there are 25 taste receptor genes in

subfamily 2 (abbreviated either Tas2R or T2R). Some T2Rs appear to be selectively activated by a single compound or class of compounds while others appear to be broadly tuned to multiple compounds. Type II taste receptor cells will either express one pair of T1Rs (either T1R1+T1R3 or T1R2+T1R3) or some combination of T2Rs. The table in Figure 8.6 shows how combinations of taste receptor genes will make a particular Type II taste receptor cell sensitive to sweet, umami or bitter molecules.

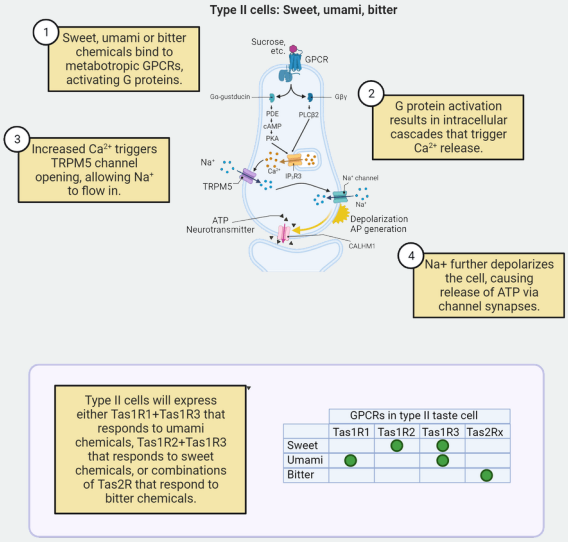

Figure 8.6

Regardless of receptor, when a Type II taste cell is stimulated by a tastant, the signaling pathway leads to an increase in intracellular calcium, via a pathway shown in the top of Figure 8.6. Two proteins in this pathway are particularly important to researchers because they can be targeted to modify Type II receptor cell signaling for experiments. The first of these proteins is gustducin, the G-protein subunit that couples to GPCRs. The other of these proteins is TRPM5, which is a cation channel primarily responsible for depolarizing type II cells. Knockout mice for gustducin or TRPM5 show major deficits in the ability to discriminate between umami, sweet and bitter foods suggesting that these proteins are essential for proper gustatory system functioning (see Methods: Transgenic Organisms). Since the gustducin-TRPM5 pathway is largely conserved among Type 2 taste receptor cells, these genes are commonly used as markers of Type II cells for neuroanatomy experiments or to drive genetic constructs for taste behavioral studies (see Methods: Immunohistochemistry, Methods: Optogenetics).

Part II: Salty and sour

In contrast to the molecules we perceive as umami, sweet and bitter, the chemicals we perceive as sour and salty are typically simple ionic compounds. Ionic compounds dissociate in water to produce at least one monatomic ion (e.g. H+ or Na+). Where other classes of tastants interact with GPCRs, these ions are detected by TRCs via direct interaction with ion channels. For decades, electrophysiological and physiological imaging have implicated Type III taste receptor cells as the sensory cell responsible for sour taste. However, over that period, several ion channels expressed by Type III taste receptor cells have been proposed as candidate sour receptors. After much speculation and experimentation, the proton-selective ion channel Otopetrin 1 (Otop1) has been identified as essential for the sour response of Type III taste receptor cells (Figure 8.7).

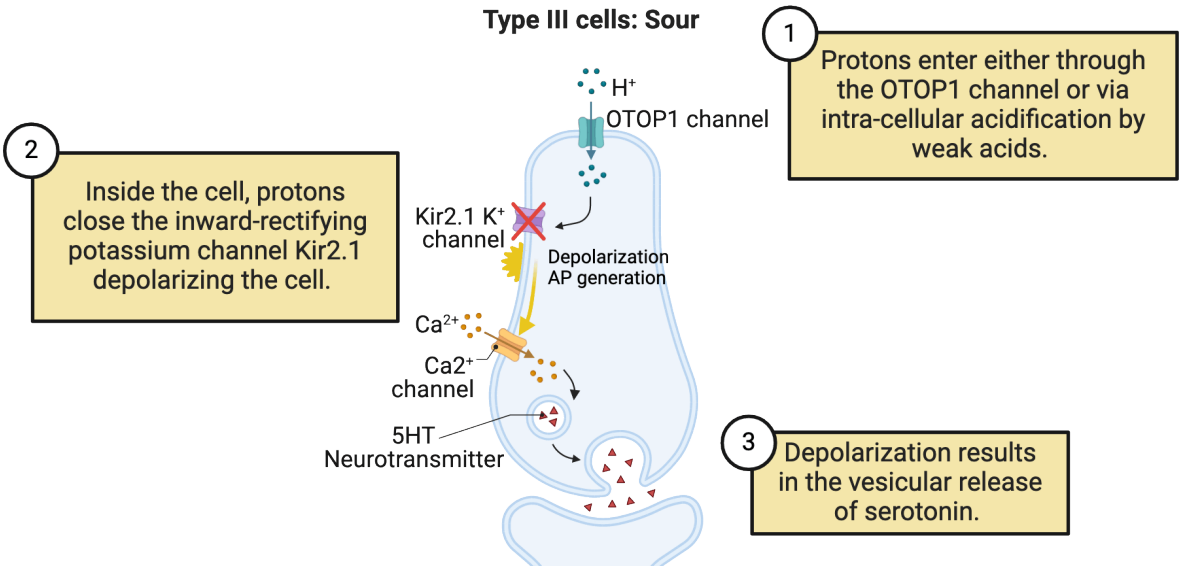

Figure 8.7

In sour taste, extracellular hydrogen ions enter the cytoplasm of Type III taste receptor cells through Otop1 channels and ultimately trigger an action potential and neurotransmitter release. When protons flood through Otop1 channels they lower the pH of the cytoplasm and block the inwardly rectifying potassium channels. In response to the blocked potassium currents, Type III taste receptor cells depolarize, an event that triggers voltage-gated sodium channels to generate action potentials that ultimately cause serotonin release.

While the molecular mechanism responsible for sour taste appears to have been elucidated, the molecular mechanisms underlying salty taste are arguably the least well understood of the five traditional taste modalities. Multiple factors contribute to the complexity of salty taste, not the least of which is the apparent existence of two distinct mechanisms that detect high and low concentrations of salt.

At lower concentrations, most terrestrial animals find salt appetitive (i.e. tasty). Most models of salt taste focus on epithelial sodium channels (ENaC) in Type I cells. The hypothesized mechanism is that Na+ from salt flows into the cell via ENaC, causing a depolarization that triggers opening of further Na+ channels in the Type I cell (Figure 8.8). That amplified depolarization from additional Na+ influx triggers neurotransmitter release.

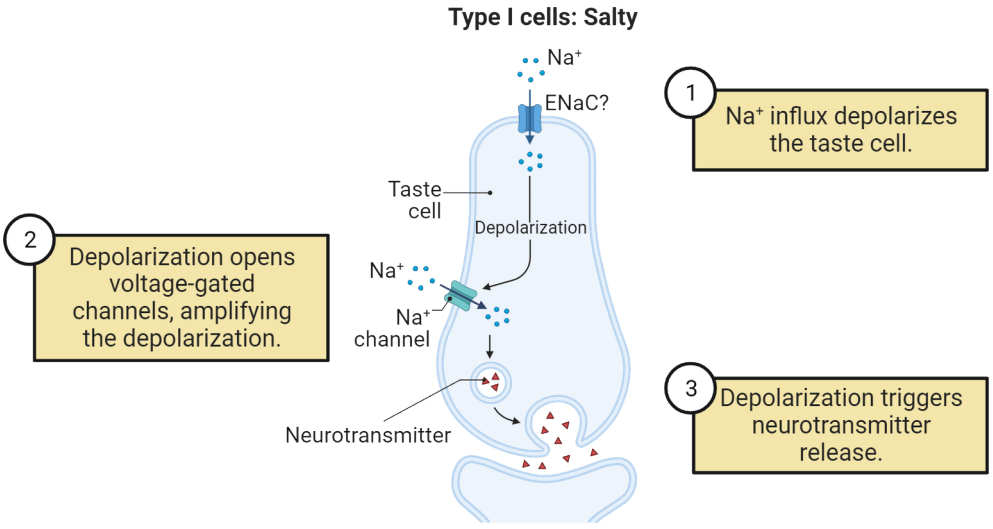

Figure 8.8

While low, appetitive salt levels require ENaC to stimulate Type I taste receptor cells, the taste of high concentrations of salt

is aversive, even after genetic knockout of ENaC subunits. This type of salt taste appears to involve both Type II and III taste receptor cells but our understanding of the mechanisms responsible for our ability to distinguish between heavily brined and slightly salted foods is incomplete.

Other possible taste modalities

Neuroscientists are continuously designing experiments to determine precisely what chemicals are detected by the gustation system. For example, given that carbohydrates and proteins are associated with primary taste qualities, the hypothesis that the gustatory system would also respond to energy-rich lipids is appealing. Several candidate receptors for fat taste have been identified in taste receptor cells and work in this area is ongoing (Besnard et al., 2016). The mechanisms by which the gustatory system may detect the flavor qualities described as astringent (Wu et al., 2022), metallic (Wang et al., 2019), kokumi/richness, or fatty is an active area of research.

Previously, there was a great scientific debate surrounding the perception of glutamate and if it met the criteria for a primary taste modality (Kinnamon and Finger, 2019). Ultimately, the identification of the T1R1+T1R3 heterodimer (Nelson et al., 2002) allowed genetic tools to be combined with anatomical, electrophysiological, and behavioral experiments to address this question. We can taste glutamate and we call this primary taste umami. Over the past decades, the Japanese loan-word umami has been so popularized that it is regularly mentioned on gourmet menus, on foodie blogs, and by celebrity chefs around the world. In contrast to its current popularity, the concept of umami and the identification of chemicals that produce the sensation was largely ignored in the English-speaking scientific community for nearly a century (Kurihara, 2015; Stańska and Krzeski, 2015). The scientific discoveries identifying T1R1+T1R3 as essential for the perception of umami have helped place it as one of the main tastes on menus around the world.

Gustation - neurotransmission and the central nervous system

After taste receptor cells detect chemical stimuli in the oral cavity, this signal must be transmitted to the nerves innervating the taste bud. These intragemmal (from the Latin gemma meaning bud, gem, or cup) nerve fibers enter the taste buds (shown in Figure 8.4), detect neurotransmitters released from taste receptor cells and conduct this information into the brain regions where the perception of umami, sweet, bitter, sour, and salty are represented. Before reaching gustatory cortex, taste information passes through 2 relays along the way: the nucleus tractus solitarius in the medulla and the posteroventral nucleus of the thalamus (Figure 8.9). Once this information has arrived in the gustatory cortex, an animal can make decisions about the palatability of the substances in the oral cavity. How the primary taste qualities are represented between the taste buds and brain remains one of the great open questions in sensory neuroscience.

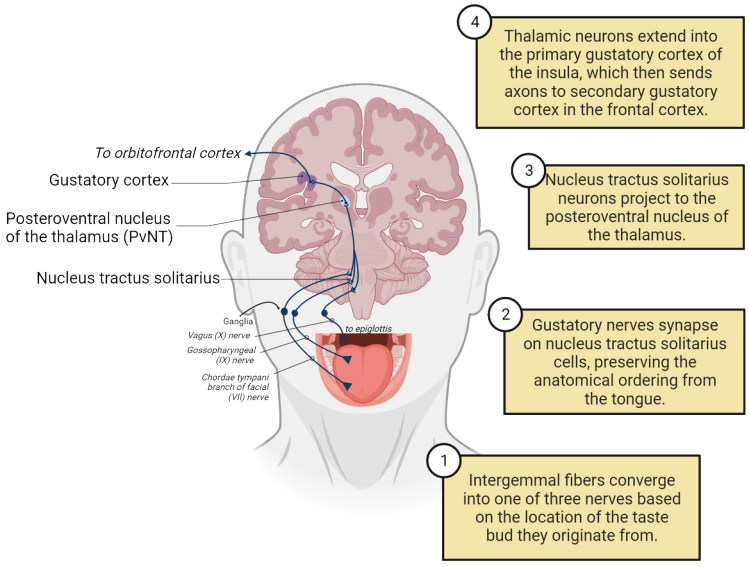

Figure 8.9 Neural pathways of taste

While the broad pathway of gustatory information is known, exactly how that pathway encodes different tastes remains uncertain. Historically, most hypothesized models for how the nervous system encodes primary taste qualities can be classified as either

labeled line coding or across-fiber pattern coding. In labeled line coding, there is a discrete pathway or circuit from the receptor cells to the afferent neurons, to higher brain regions for each of the primary taste qualities. In this coding model, a sweet chemical of adequate concentration would result in activity through the sweet "line" and would not trigger substantial activity in the circuits for other primary tastes. A classic example of a sensory system that uses label line coding is the somatosensory system (see Chapter 9 Touch and Pain).

In across-fiber pattern coding, any given pathway (e.g. receptor cells, nerve fibers, higher brain regions) is not associated with any individual primary taste quality; rather, a specific pattern of activity among overlapping neural pathways codes for each of the primary tastes. Across-fiber pattern coding allows the vertebrate olfactory system to represent an overwhelming number of olfactory modalities.

Figure 8.10 diagrams these two opposing models, using circles to represent neurons that might respond to sour, salt or both. As technological advancements allow scientists to examine the activity in gustatory circuits at an ever-increasing resolution, new refinements are constantly being made to theories of gustatory system coding.

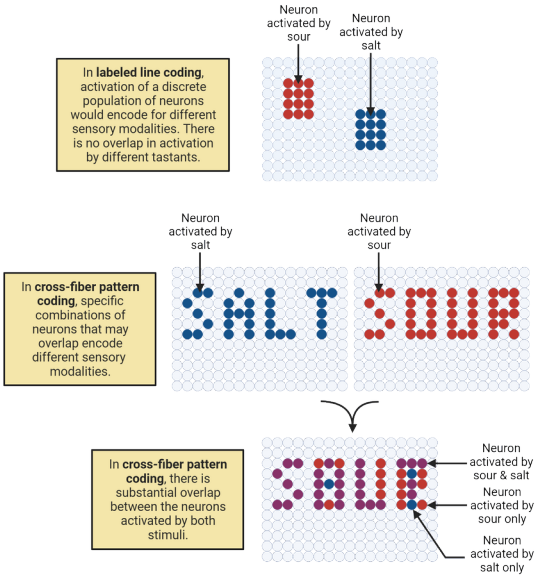

Figure 8.10 Labeled line coding Image credit: adapted from Wayne Silver (Wake Forest University).

Neuroscience in the lab: Studying taste receptor cell to neurotransmission

Recording action potentials from a nerve that primarily makes connections with taste buds provides an important assay for determining if chemicals are activating the gustatory system. The chorda tympani branch of the facial (VII) nerve and the glossopharyngeal (IX) nerve innervate the taste buds on the rostral ⅔ and caudal ½ of the tongue, respectively. In contrast to behavioral data, chorda tympani and glossopharyngeal nerve recordings in ATP receptor knockouts or animals treated with an ATP receptor blocker show decreased activity not just for umami, sweet and bitter tastants, but also for salty and sour compounds (Figure 8.11). Conversely, while knockout or pharmacological blockade of serotonin receptors results in no taste-related behavioral deficits in mice, it does decrease chorda tympani nerve response to MSG, sucrose, salts, and both weak and strong acids. Taken together, these data suggest that ATP release is necessary for taste receptor cell nerve neurotransmission for all taste modalities, while serotonin acts synergistically to intensify the neural response to certain taste qualities.

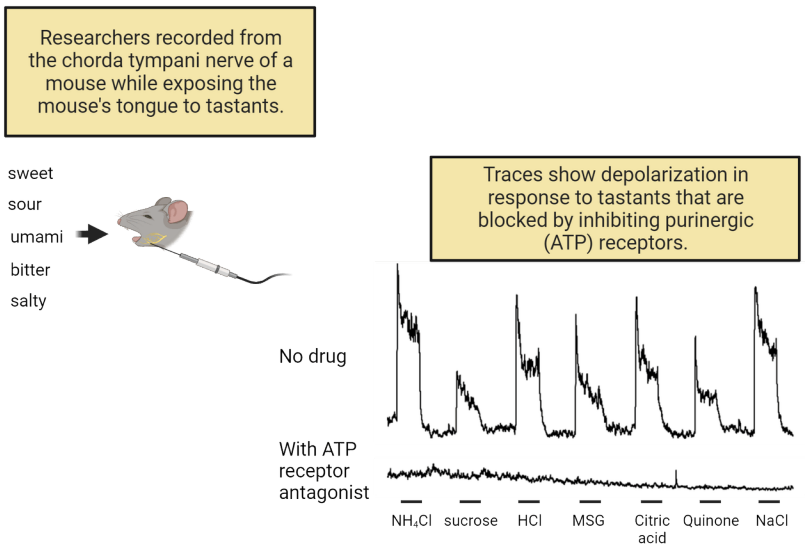

Figure 8.11 Chorda tympani nerve recording Image credit: Nerve recording data provided by Aurelie Vandenbeuch (University of Colorado, Anschutz Medical Campus).

However, this interpretation is difficult to resolve with the observation regarding transmitter release from taste receptor cells. Specifically, what is the source of ATP, if only type III cells are activated by sour tastants and those cells do not appear to release ATP or possess the proteins necessary for ATP's release? One hypothesis, which would explain these results, would be the existence of a currently unknown mechanism by which low levels of ATP could be packaged alongside serotonin. Another explanation is that the limited cell-to-cell contacts between type II and type III cells allow for serotonin signaling directly between taste receptor cells to modulate ATP release from type II cells in the presence of sour stimuli. However, this model must account for the serotonin's apparent inhibitory action on type II cells making ATP release from these cells less likely in the presence of sour stimuli.

Science as a process: Taste nerves and the nucleus of the solitary tract

As intergemmal nerve fibers exit taste buds, they merge into larger bundles until ultimately joining cranial nerves, which conduct taste information to the brainstem. A recently published connectome (a complete map of cellular and neural connections) of taste buds determined that 97% of intergemmal fibers innervate one taste receptor cell or the same taste receptor cell type (Wilson et al., 2022). Thus, each intergemmal nerve fiber is passing information from only one taste receptor cell type to the nucleus of the solitary tract in the brainstem.

Three cranial nerves innervate taste buds in distinct regions of the oral cavity: Taste buds on the rostral or anterior 2/3 of the tongue are innervated by the chorda tympani branch of the facial (VII) nerve, taste buds on the caudal 1/3 of the tongue and palate are innervated by the glossopharyngeal (IX) nerve and taste buds found on the epiglottis are innervated by the vagus (X) nerve. Chemosensory information from all three of these nerves is conducted to a region of the brainstem called the nucleus of the solitary tract.

The nucleus of the solitary tract (NTS, from the Latin nucleus tractus solitarii) is the primary gustatory and visceral chemosensory nucleus of the central nervous system. Gustatory information to the central nervous system projects to the most rostral portion of the NTS (Figure 8.12). Within the rostral NTS (rNTS) or gustatory nucleus, projections from the facial, glossopharyngeal, and vagal nerves are arranged rostrally to caudally reflecting their innervation of taste buds in the oral cavity. Chemosensory afferents projecting to the caudal NTS (cNTS) carry information from visceral chemoreceptors. This anatomy creates a rostral to caudal topographic map of chemosensory inputs from the mouth to the alimentary canal (i.e. digestive tract) and other internal organs along the NTS.

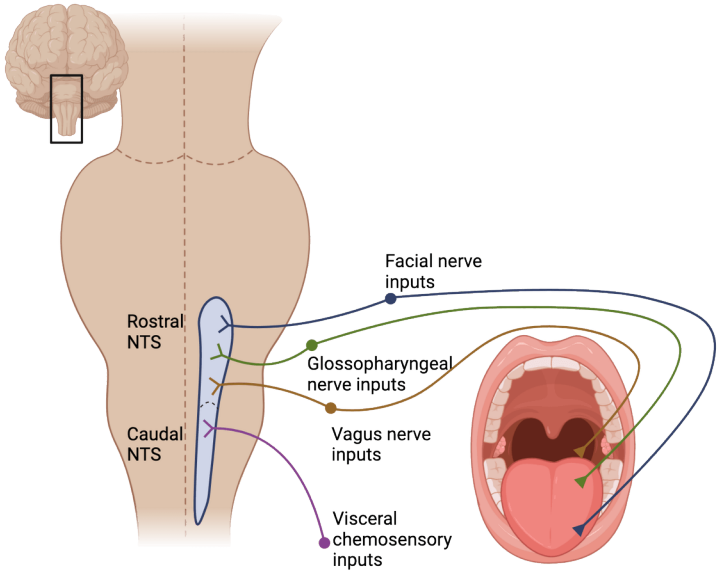

Figure 8.12 Nucleus of the solitary tract Inputs to the NTS, or gustatory nucleus, are arranged anatomically by the incoming nerve and which part of the oral cavity it innervates.

In addition to its anatomical map, investigators continue to define the chemotopic map or coding logic for taste qualities within the NTS. For example, most chemicals perceived as bitter trigger activity in neurons located in the medial rNTS. MSG and NaCl, which taste savory and salty, both activate the intermediate zones of the rNTS. Sweet chemicals produce diffuse activity along the nucleus. Sour chemicals, like citric acid, trigger activity in lateral-rostral and mid-NTS. One major challenge that researchers attempting to define the chemotopic map of the NTS face is determining the influence that non-gustatory inputs play in the coding logic of these taste qualities.

While the rNTS is the first relay of gustatory information in the central nervous system, it also receives and integrates other signals that can influence our perception of flavor. For example, contrary to its moniker as the gustatory nucleus, the rNTS also receives oral somatosensory information from the trigeminal nerve (see 4.4 How Do Connections Differ Across Species?). The temperature of solutions with identical chemical composition can modulate the firing neurons of the NTS, presumably through these somatosensory inputs. The result is that a particular rNTS neuron that fires action potentials at a specific rate to a specific chemical solution may increase or decrease its activity as the temperature of that solution changes. Figure 8.13 shows an example of this phenomenon.

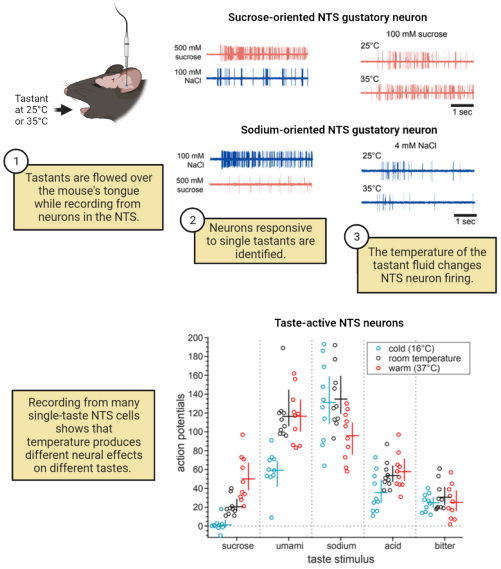

Figure 8.13 Mouse NTS response to tastants at different temperatures Image credit: Recordings and data panel provided by Jinrong Li and Christian Lemon (University of Oklahoma). Top panel based on data from Li J, Lemon CH. Influence of stimulus and oral adaptation temperature on gustatory responses in central taste-sensitive neurons. J Neurophysiol. 2015 Apr 1;113(7):2700-12. doi: 10.1152/jn.00736.2014. Epub 2015 Feb 11. PMID: 25673737; PMCID: PMC4416558. Bottom panel based on data from Wilson DM, Lemon CH. Modulation of central gustatory coding by temperature. J Neurophysiol. 2013 Sep;110(5):1117-29. doi: 10.1152/jn.00974.2012. Epub 2013 Jun 12. PMID: 23761701; PMCID: PMC3763089.

In this experiment, the activity of neurons in the NTS was recorded while fluids of different temperatures, containing different tastants were flowed over a mouse's tongue. The top of the figure shows firing of a sucrose-oriented NTS neuron in response to room temperature sucrose and warm sucrose, which results in more firing than the room temperature solution. The responses of NTS neurons to temperature are not all the same, though. The salt-oriented NTS neuron fires less to warm salt than room temperature salt, for example. The bottom on the figure shows more evidence of this variability across NTS neurons, with some tastants leading to more firing when warm, some leading to less and some seeming relatively insensitive to this temperature change. This anatomical and physiological arrangement is one biological explanation for the observation that temperature and other sensory information can have a profound impact on flavor perception.

Gustatory pathway and cortical processing

Ultimately the gustatory information from the NTS is relayed to the primary gustatory cortex (GC), where the conscious perception of taste occurs. In humans and other primates, fibers from the NTS project directly into the parvocellular division of the ventral posterior medial nucleus of the thalamus (VPMpc), and then into the GC.

The conscious perception of taste occurs in the GC. This cortical region can be viewed by separating the lateral sulcus and is found along the anterior insular lobe and frontal operculum (see Figure 8.9). In a variety of vertebrates, techniques from electrophysiology to cellular and functional imaging have established that neurons of the gustatory cortex demonstrate differential activity in responding to chemicals with different tastes. Additionally, some neurons in the region fire different patterns of action potentials in response to changing concentrations of tastants. Thus, both the identity and intensity of the chemical stimuli detected by the taste receptors of the tongue can be represented in the GC. From the GC, a large portion of gustatory information passed on to the secondary gustatory cortex, located in the caudolateral section of the orbitofrontal cortex and ultimately integrates gustatory signals with other sensations, including those of satiety.

Gustatory information is not just a one-way street to the primary and secondary GC, though. Interconnection with other sensory modalities, and even other non-sensory systems, occurs throughout the gustatory neural pathways. The gustatory connections to the limbic system are one, particularly important example of this cross-talk. Along the gustatory neural pathway, collateral and descending fibers pass gustatory signals back to the NTS and into the limbic system, modulating the limbic system's regulation of feeding behaviors (see Chapter 16 Homeostasis). For example, the neural connections between the GC and the lateral hypothalamus allows for gustatory signals to immediately modulate feelings of satiety.

Additionally, neural inputs to the amygdala mediate negative associations with foods that might have poisoned an animal. For

example, it is common for people who have suffered from food poisoning to avoid the food that has made them sick for a long time. This is a phenomenon called conditioned taste aversion and is observed in a variety of animals. In the lab, rodents will avoid a novel tastant if it is paired with a subcutaneous injection of KCl (which makes the animal feel sick) just a single time. A conditioned taste aversion is an important tool for designing experiments to assess if an animal perceives two chemicals as having similar tastes; specifically, if an animal that has a conditioned taste aversion to one chemical also avoids a different chemical, then the animal likely perceives the two chemicals as having the same or a very similar taste. This behavioral assay has been an essential tool for studying taste perception in animals.

Neuroscience Across Species: Non-mammalian gustatory systems

Across species, chemosensory cells that detect the same broad classes of biomolecules are almost always concentrated around the entrance to the digestive tract. So far, we have talked mostly about taste in animals like mammals, which sense chemicals they might ingest using taste buds in the interior of their mouth. In contrast, in the common model organism *Caenorhabditis elegans* (a roundworm of phylum Nematoda), chemosensory neurons are found associated with the lips that physically gate the digestive tract. Segmented worms like leeches and earthworms are literally covered in chemoreceptors (on their skin), but these cells are most concentrated on the prostomium—the scoop-like first segment with functions analogous to a tongue or proboscis. In radially symmetric octopodes, chemosensory cells are present inside the suckers on the 8 arms surrounding their beaked mouths (van Giesen, et al., 2020). Even among hydra (phylum Cnidaria), whose nervous system consists of a simple neural network (see Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy), chemical cues triggering feeding reflexes are influenced by internal metabolic states (Grosvenor, et al., 1996). Even filter feeders are often capable of modifying behavior in response to the chemical contents of their feeding substrate.

We know an especially large amount about how gustation occurs in the commonly-studied fly species *D. melanogaster*. The *D. melanogaster* exoskeleton is covered in hair-shaped sensory organs called sensilla. While hair on a human's body can provide mechanosensory information, an individual sensillum on a fly may be specialized for mechanoreception or *chemoreception*. Gustatory sensilla can be found on their wings, tarsi (legs), and body but are concentrated on the proboscis. This anatomical arrangement allows fruit flies to "taste" any surface they land on and, if appetitive chemicals are present, reflexively extend their proboscis (mouth parts) to feed.

While the anatomical location of gustatory sensilla in the fly is quite different than that of mammalian taste buds, how the two sensory cell systems work is analogous. Like taste buds, each sensilla contains neurons analogous to taste receptor cells; these gustatory receptor neurons (GRNs) detect different classes of chemicals. Each GRN is a bipolar neuron, whose cell body is inside the sensillum with an axon projecting to the insect's central nervous system, and a dendrite projected towards a taste pore at the sensillum tip. GRNs detect chemicals using a different receptor family than vertebrates—they are ligand gated ion channels, not GPCRs. These receptors are expressed in combinations that make different GRNs sensitive to sugars, simple ionic compounds (salts), pure water and alkaloids or other compounds humans perceive as bitter. It is worth noting here that despite this nomenclature, we do not know if a fly's gustatory experience of alkaloids (or any of these other compounds) is at all like what we humans would describe as "bitter!" We can say that flies typically avoid these and that their behavioral response to these compounds is similar to that of vertebrates. Notably, while there is controversy over how gustatory information gets organized centrally in mammals, in flies there is good evidence that information follows a labeled line coding model, where specific pathways mediate specific tastes all the way to the higher centers of the CNS.

2.3.14: The Olfactory System

Learning Objectives

By the end of this section, you should be able to

- 8.3.1 Define the relevant anatomy and cell types of the olfactory system.
- 8.3.2 Describe the neural circuitry involved at each layer of the processing hierarchy of the olfactory system and its relationship to odor perception.

Imagine the smell of freshly baked bread or a cup of coffee on a lazy weekend morning. Now turn your attention to the visual scenery that accompanies this thought. Your mind has probably already filled in many of the details for you. For many people, the sense of smell is so powerful it can even transport us back in time, conjuring vivid memories of people, places, and events.

The sense of smell, or olfaction, has a direct input to the emotional centers of the brain. With its direct input to the limbic system (see amygdala), the sense of smell is also critically involved in social behaviors across the animal kingdom. Olfaction arises from interactions between specialized sensory receptors and chemicals we encounter in the environment. In this section, we will explore how molecules inhaled into the nose are detected and encoded by the brain and how odors might elicit powerful memories and behaviors in some animals.

The nasal cavity

The primary sensory organ for the olfactory system is a sheet of tissue found deep within the nasal cavity called the olfactory epithelium (Figure 8.14). The olfactory epithelium within the nose is responsible for detecting airborne odorous molecules. These molecules, also called odorants, are the basic unit that can elicit the sensation of an odor.

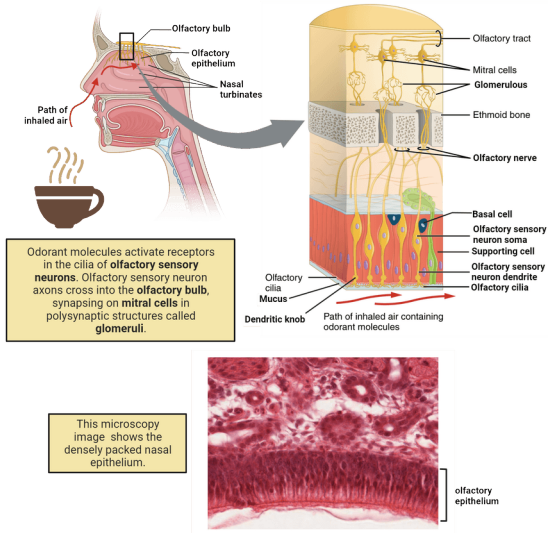

Figure 8.14 Olfactory epithelium anatomy Image credit: Modified from original image by adding/removing labels, adding basal cell, and reconstructing top left panel. Original image by OpenStax.

Odorants are typically small enough that they can become suspended in the air and drawn into the nasal cavities. Inside, odorants travel through intricate caverns called turbinates, which are formed of bone and cartilage. These structures filter, humidify, and warm inhaled air, but they also play a critical role in directing odorants onto the relatively restricted area of the nasal cavities which contains the olfactory epithelium.

The structure of the nasal cavities is highly variable between animal species. For example, many mammal species, like dogs and

bears, have evolved intricate nasal passages that play an important role in their ability to detect extremely low concentrations of an odorant. The large surface area of their turbinates ensures that small amounts of odorants are forcefully propelled onto the olfactory epithelium. In addition to specialized turbinates, dogs, bears, and many other animals have a larger olfactory epithelium than humans do, which contributes to their excellent sense of smell.

Olfactory epithelium and sensory neurons

Located deep within the nose, the olfactory epithelium is a specialized portion of the nasal cavity. The placement of this important tissue ensures that it is protected from damage caused by inhaling toxins and positions it close to the brain. There are three main cell types that make up the olfactory epithelium. Olfactory sensory neurons are the cells tasked with detecting odorants, supporting cells provide structure and surround the sensory neurons, and basal cells are the precursors from which regenerating sensory neurons arise (Figure 8.14)

Olfactory sensory neurons each have a single enlarged dendrite that extends outwards from the epithelium and terminates at the epithelial surface in a specialized structure called a knob. The knob is an integrative hub for fine hair-like structures known as cilia extending through the mucus lining that coats the olfactory epithelium. The cilia are important structures because olfactory receptors, the proteins that interact with odorant molecules, are found along the length of each of these projections. The olfactory receptors are part of a large gene family that varies by species. Humans have ~300-400 receptor genes, while mice and dogs have more than 1000! (Malnic et al., 2004; Zhang and Firestein, 2002).

Signal transduction in olfactory sensory neurons

Olfactory receptors are metabotropic receptors, meaning that they are coupled to a G-protein second messenger on the intracellular side of the neuron. The binding sites for odorants are, of course, on the extracellular side, exposed to the nasal cavity. In olfactory receptors, the G-protein is a specialized stimulatory G-subunit (G_{olf}). Figure 8.15 shows the intracellular signaling activated by odorant binding and G_{olf} activation.

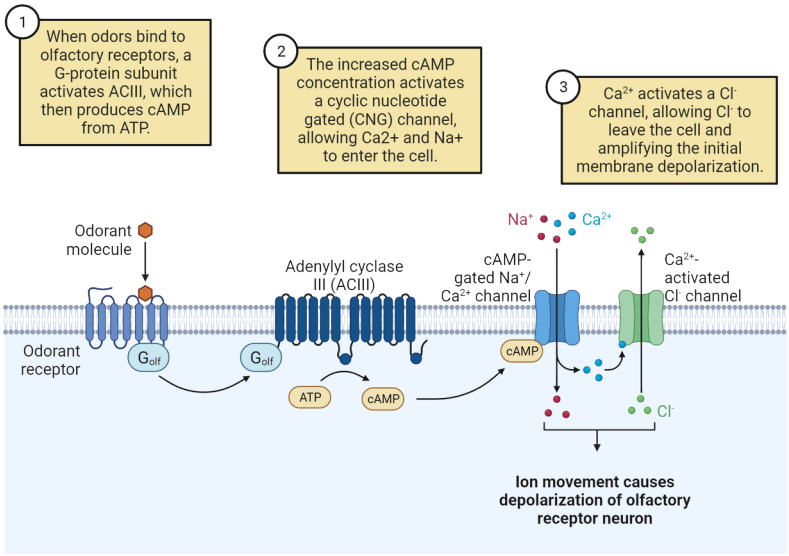

Figure 8.15 Olfactory receptor signaling

Once bound to an odorant, the olfactory receptor complex releases G_{olf} to the intracellular side of the membrane. When released from the receptor complex, G_{olf} then stimulates the activity of the catalytic enzyme adenylyl cyclase III (ACIII). The role of ACIII in this series of events is to then convert adenosine triphosphate (ATP) into cyclic adenosine monophosphate (cAMP). cAMP then serves as a ligand to cyclic nucleotide gated (CNG) channels, which are an entry point for Na^+ and Ca^{2+} ions into the sensory neurons. Because both Na^+ and Ca^{2+} carry a positive charge, this results in a membrane depolarization of the sensory cells bringing them toward the action potential threshold.

However, there is an additional step that has been proposed to amplify these initial membrane depolarizations through the CNG

channels. The increased intracellular abundance of Ca^{2+} ions begins to act on calcium-activated chloride channels (CaCC). With respect to the mucous that surrounds cilia, the internal cellular concentration of chloride is elevated. This means that when CaCCs are activated by Ca^{2+}, negatively charged Cl- ions flow out of the cell, thus amplifying the initial membrane depolarization from the CNG channels.

This molecular chain of events results in action potentials being generated near the soma of the sensory neurons that contain the receptor proteins on their cilia. We can think about odorant molecules as being similar to neurotransmitters that generate electrical activity between neurons within the brain. The signals then travel down sensory neuron axons that extend through perforations in the cribriform plate, a bony structure that separates the brain from the nasal cavities. The axons and their electrical signals then arrive at the brain in the olfactory bulb, where they synapse with the central processing circuitry of the olfactory system.

A key organizing principle of the olfactory system is the molecular logic by which the cilia of olfactory sensory neurons express olfactory receptor proteins. The genome of most animals encodes hundreds of olfactory receptors, each of which has a unique binding site that will recognize only a narrow range of chemical shapes. Though there are hundreds of receptor genes, only a single type is expressed on the cilia of each sensory neuron. Although each sensory neuron may express thousands of receptor proteins, each of them will be exactly alike (Figure 8.16).

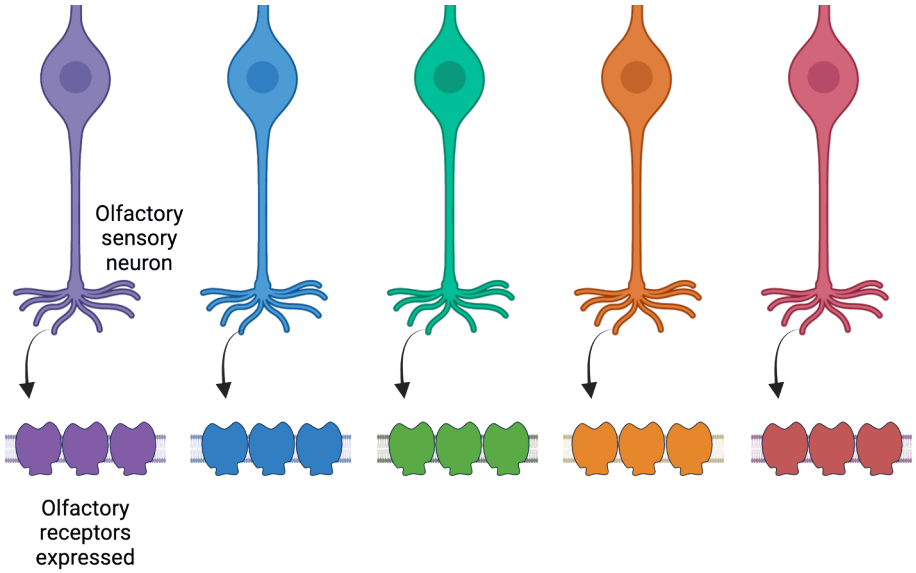

Figure 8.16 One receptor type per neuron in the olfactory system There are hundreds of unique olfactory receptor genes but an individual olfactory sensory neuron only expresses 1 receptor gene.

People behind the science: The discovery of olfactory sensory neuron genetics

We now know that the genes that encode the olfactory receptor proteins are the largest class of G-protein coupled receptors, including hundreds of unique protein types in humans, and over a thousand in rodents! However, the identity and function of these proteins were once a mystery in the field of biology. In 1991, Dr. Linda Buck, then a postdoctoral fellow, was working in the Laboratory of Dr. Richard Axel at New York's Columbia University. With the help of a then newly developed technology called polymerase chain reaction, she not only solved the mystery of how many receptor types there are in the olfactory system but also demonstrated that they came from a previously unknown superfamily of G-protein coupled receptors (Buck and Axel, 1991). Her discovery revealed the molecular diversity that underlies the peripheral olfactory system and the incredible wiring logic by which the system assembles during development.

This revelation was not only foundational for understanding the olfactory system but also had far-reaching implications across biological domains to fields including drug discovery, gene regulation, and the wiring logic of the brain. In 2004, Drs. Buck and Axel were awarded the Nobel Prize in Physiology or Medicine for their discovery.

OSNs are renewed throughout life

A special feature of the olfactory system is that, unlike other senses including vision and hearing, olfactory sensory cells are constantly regenerating. In fact, even without specific or acute damage, olfactory sensory cells are constantly turning over. It is speculated that, because the nose draws in numerous potentially damaging agents from the environment (dust, germs, pollution, etc.), frequent turnover of the sensory cells is a mechanism to ensure that the system remains in good working condition.

In the olfactory epithelium, stem cells line the nasal passages and give rise to newly generated sensory neurons that incorporate with the existing circuitry. As you will read below, sensory neurons of a common subtype must find a highly targeted and specific region of the brain to terminate. Exactly how newly regenerated sensory neurons find their way to the olfactory bulb is still a mystery, but some work tells us that the expression of receptor proteins outside of the sensory cilia may play an important role.

Unfortunately, as we age our body begins to lose its ability to regenerate sensory neurons. This ability is impacted by inflammation, disease, and injury, all of which accumulate as we get older. Because sensory neurons do not replenish with the same regularity, many people begin to lose their sense of smell in old age. In a later section, we will discuss how some well-known diseases affect our sense of smell.

Olfactory bulb circuitry

The olfactory bulb is responsible for the first stages of processing electrical signals as they arrive from the nose. Before arriving in the olfactory bulb, the axons of all sensory neurons that express the same type of receptor protein converge. Once in the bulb, the axons then form a spherical structure of nerve endings, dendrites, and synapses called a glomerulus. Because each glomerulus receives input from only a single type of olfactory sensory neuron, the input to these structures is receptor type specific. Each odorant activates a subset of olfactory sensory neuron types; therefore, many glomeruli are activated at the same time by a given odor. We can think of this as similar to how letters in the alphabet group together to form words. In this case, each letter represents an activated glomerulus, and their grouping as a word represents the perception of an odor. Importantly, words can be simple or complex depending on the number of letters they contain, just as an odor depending on the number of activated glomeruli.

It is still unknown how or if glomeruli are arranged in the physical space of the brain with respect to the chemical structure of the odorants that activate them. However, there is some evidence that there exist coarse groupings of glomeruli. Those that are activated by broadly similar odorant molecules tend to be located closer together. Furthermore, among animals of the same species, glomerular positioning and grouping is conserved (Soucy et al., 2009)

Glomerular layer neurons

Glomeruli are innervated by a number of cell types in addition to the nerve endings of olfactory sensory neurons. These cells include glutamatergic projection neurons that relay information to higher-order processing centers and inhibitory cells that help to process odor information within the olfactory bulb.

Projection cells of the olfactory bulb fall into two sub-classes of cells, mitral cells, and tufted cells. Mitral cells are the largest cells in the olfactory system and are found in a single row of cells sitting beneath the glomeruli. Each cell has a single apical dendrite that extends to one glomerulus where it ramifies extensively and receives input from olfactory sensory neurons, as well as other neurons within a glomerulus. While each mitral cell contacts only a single glomerulus, each glomerulus is innervated by ~10-20 mitral cells (Liu et al., 2016). Mitral cells also have characteristic lateral dendrites that extend deeper within the olfactory bulb, where they receive inhibitory input. Tufted cells share many of the same morphological characteristics as mitral cells, though their distribution is different. They also serve to relay information about odorants, as mitral cells do, but are more broadly tuned to odors and often can respond to lower concentrations than mitral cells.

In addition to these projection cells, the olfactory bulb hosts several classes of local interneurons. In general, these cells are thought to play an important part in refining the number of active glomeruli following an odorant encounter and coordinating the synchronous activity of olfactory bulb output neurons.

Cortical processing

Output from the olfactory bulb travels along the axons of the two classes of projection neurons: mitral cells and tufted cells.

Although these cells share many common features, they differ in both their responses to odorant stimuli and their projections to downstream processing centers of the brain. The primary targets of olfactory bulb output are the olfactory cortex, limbic system, and ventral striatum.

Piriform cortex

Mitral cells target a number of different brain regions, but perhaps the most predominant among them is the piriform cortex, also called the olfactory cortex. The organization of the piriform cortex is different from other sensory modalities because it contains three layers rather than the six typically found in other sensory cortices. Mitral cell axons from the olfactory bulb travel as a nerve bundle in the lateral olfactory tract and most densely target the anterior portion of the piriform cortex where they target broadly distributed and overlapping populations of neurons. Because neurons in the piriform cortex receive input from many different mitral cells, and each mitral cell can be associated with a different glomerulus, this is the first point in the olfactory system where stimulus information from the periphery is blended (Figure 8.17). However, unlike the olfactory bulb where some coarse relationship exists between glomeruli, the spatial distribution of cells in the piriform cortex has a minimal relationship to the odorants which activate them. This stands in contrast to other sensory modalities, like audition and somatosensation, where similar stimuli are represented in adjacent cortical fields (see Chapter 7 Hearing and Balance). Despite this seeming disorganization within the olfactory system, the ensemble of neurons that become activated in the piriform cortex upon encountering an olfactory stimulus is related to how the stimulus is identified, categorized, and perceived by an animal.

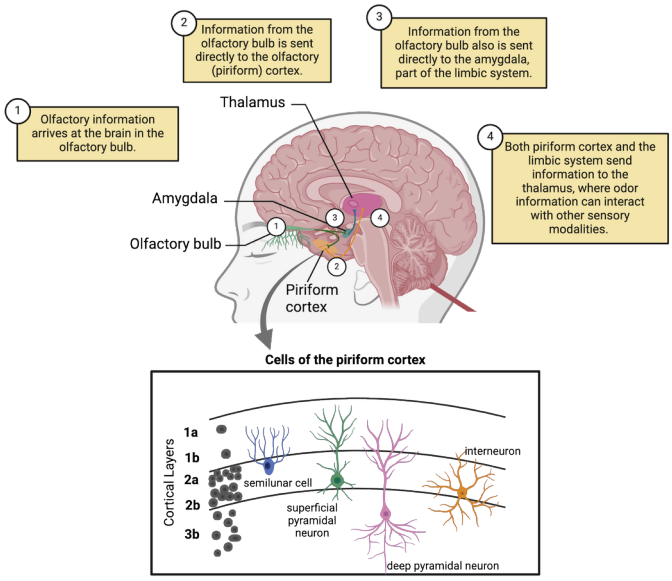

Figure 8.17 Neural pathways of olfaction

In addition to direct inputs from the olfactory bulb, the piriform cortex is a dense recurrent network and has extensive interconnections, called associational connectivity. The piriform cortex also contains local inhibitory connections that can oppose both inputs from the olfactory bulb and associational input. The local connectivity within the piriform cortex, both excitatory and inhibitory, allows the structure to perform important analytical functions like pattern completion, prediction, and odor categorization. While these functions allow animals to accurately interpret their environment, they also provide a mechanism for animals to make decisions about stimuli with only partial or incomplete information about a stimulus.

Anterior olfactory nucleus

The primary target of axonal projections from tufted cells is a structure known as the anterior olfactory nucleus (AON), which is found directly behind, or posterior to the olfactory bulb. The olfactory system is different from other sensory modalities in how the processing hierarchy is structured. While information from most senses is processed in the opposite brain hemisphere from which it was detected by sensory cells at the periphery, the olfactory system is lateralized. For example, the right olfactory bulb sends most of its projections to cortical areas in the right hemisphere, and the left olfactory bulb to the left hemisphere.

A key feature of the AON is that it sends projections that cross the brain through a nerve tract called the anterior commissure and terminate at contralateral brain hemispheres. Since this is one of the few places in the olfactory system where lateralization

is broken, it allows the AON to make comparisons between odor information arriving at each of the nostrils and may thereby play a role in orienting animals to an odor source. Similarly, because each AON receives bilateral input, it is thought that this structure may play an important part in odor navigation by allowing animals to make comparisons of stimuli that arrive at each of the two nostrils.

Amygdala and entorhinal cortex

Projections from the olfactory bulb target other brain regions that layer the rich texture that accompanies olfactory perception. Earlier, we discussed how odors can be linked with powerful memories and emotional states. These feelings arise through direct connections between the olfactory bulb and brain areas associated with memory, emotion, and reward. In addition to their projections to the piriform cortex, the axons of mitral cells branch and terminate in two structures contained within the limbic system, the amygdala and entorhinal cortex (Figure 8.17).

The amygdala is a powerful emotional center of the brain and its direct connection with the olfactory system is the reason that certain odors can provide powerful reminders of the emotional state in which they were encountered (see Chapter 13 Emotion and Mood). For example, the smell of your grandmother's homemade soup may precipitate a feeling of comfort and safety. The same is also true for negative emotions and may provide an important mechanism for animals to avoid predation or other dangers.

The entorhinal cortex is strongly tied to memory formation, consolidation, and recall. In addition to the input it receives from other memory structures, like the hippocampus, it also receives direct input from the olfactory bulb via mitral cells. In the introduction of this chapter, we described how smells can conjure vivid memories of people and places — connectivity between the olfactory bulb and the entorhinal cortex helps this to happen. When smelling your grandmother's homemade soup, in addition to your emotional state, you likely recall other details of how you experienced the soup. For instance, the wallpaper in grandmother's kitchen or the pattern on the dishware that the soup was served in. These details are filled in and completed by the entorhinal cortex.

Adaptation

Have you come home from school and noticed that the trash in the kitchen smelled bad? Maybe you got distracted and then forgot to take the garbage out, but after a while, you no longer notice the smell. Some people call this perceptual phenomenon "nose-blindness", which is a common name for the physiological process called adaptation. There is actually a very important reason for "nose-blindness", in addition to saving you from the smelly scent of your forgotten garbage. Adaptation helps animals pay attention to changing features in their environment rather than focus on constant but otherwise distracting stimuli.

In the olfactory system, adaptation arises from physiological processes at the two ends of the system, the nose at the front and the piriform cortex at the back end. In the nose, adaptation results from the desensitization of olfactory receptor proteins for the odorant ligands. The abundant presence of an odorant molecule results in conformational changes to the receptor protein, thereby decreasing its efficacy in binding with a ligand and transducing a message about the stimulus. In the olfactory cortex, the precise mechanism of adaptation is not clear, but nonetheless, the overall effect is that ensembles of principal cells become less responsive to odor stimuli upon repeated presentation of the stimulus, and the perception of an odor decreases (Kadohisa and Wilson, 2006).

The accessory olfactory system

Many animals secrete chemical signals called pheromones that trigger social responses in animals of the same species. Reptiles, amphibians, and mammals, including some non-human primates, have evolved a division of the olfactory system, called the accessory olfactory system, dedicated to detecting these substances. This system operates using many of the same principles as the main olfactory system but uses anatomically distinct structures with different cellular organization and projections to deep brain structures that guide behavior and physiological states.

Many pheromones are oily substances and are therefore unable to be carried through the air. This creates a problem where these compounds are incapable of reaching the olfactory epithelium. The vomeronasal organ is a collection of sensory cells found near the entrance to the nasal passages that detect pheromones and other social odors (Figure 8.18). For compounds to reach this structure, it is necessary for an animal to touch its nose to another animal, or a secretion it has left behind. Many of us have observed this behavior before. When dogs greet each other on the sidewalk, often their first instinct is to touch their nose to the other dog. Here they are using pheromonal cues to communicate.

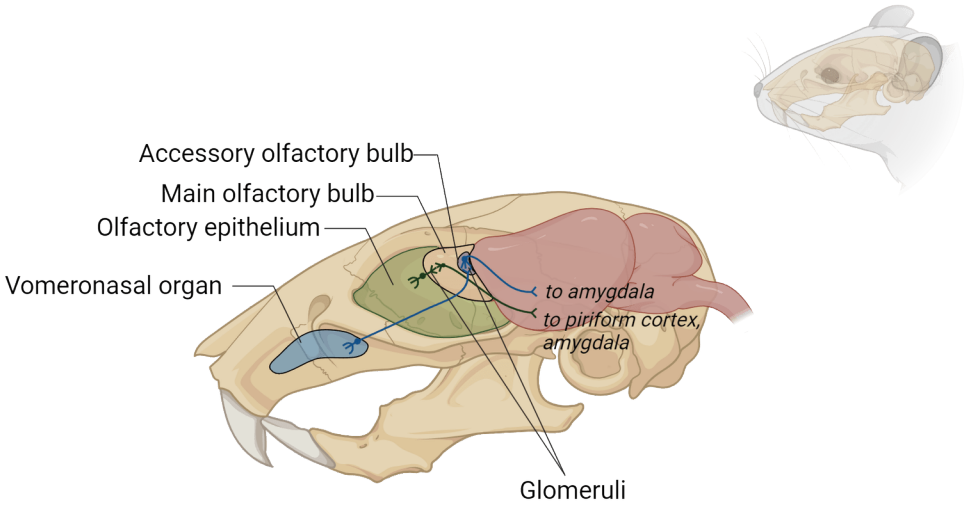

Figure 8.18 Accessory versus main olfactory bulb and epithelium connection

The vomeronasal organ is divided into two halves, one on each side of the nasal septum. Like the olfactory epithelium, it contains basal cells, supporting cells, and sensory neurons. The sensory neurons of the vomeronasal organ contain G-protein coupled receptors that are sensitive to specific social compounds depending on the type of receptor protein that they express. The sensory cells of the vomeronasal organ project axons to the dorsal posterior portion of the olfactory bulb where an accessory subdivision is found (accessory olfactory bulb) (Figure 8.18). The accessory olfactory bulb contains many of the same cell types as the main olfactory bulb; however, the circuit organization is somewhat different.

Neuroscience in the lab. Sex as a biological variable: Social odor detection in humans

It is quite intuitive how our sense of smell influences our food preferences or even the type of perfume that we like. But can our sense of smell also influence how we interact with other people, and does olfaction play a role in human mate selection as it does in many animal species? A Swiss biologist named Claus Wedekind set out to answer this question in an experiment known as the "sweaty T-shirt study." In his study, men were asked to wear a t-shirt for two days without bathing. Then, women participants were asked to sniff a hole in a box containing each shirt and rate the shirts as more or less appealing. When the genetic makeup of the men and women was compared, it was revealed that women selected t-shirts from men who had the most divergent genetic sequence for a set of genes called the major histocompatibility complex (MHC) (see Chapter 17 Neuroimmunology). MHC genes are part of the adaptive immune system, and in effect, women were selecting men in a way that might boost the fitness of their potential offspring by conferring greater immune selectivity. Although the exact mechanism is still a mystery, MHC genes are speculated to be linked to a body scent that can be detected by the opposite sex, even if subconsciously. Though it might be tempting to think this effect relies on pheromones and the vomeronasal organ, the vomeronasal organ is often absent from the nasal passages in humans. And if one is present, it likely only exists as a vestigial organ. In the case of humans, social odors are detected by the main olfactory system.

The olfactory system and disease

You might not think that the inability to smell would impact your day-to-day life; however, you would be woefully wrong. Do you remember the jellybean experiment? This would become your reality for every meal. Food would lack depth and your favorite meal would become uninteresting. Earlier, we learned about several animal behaviors that strongly rely on olfaction: navigation, nutrient sensing, and mate selection. Without the ability to smell, an animal's survival would be at risk. People with the inability to smell are also at a survival disadvantage. People with anosmia, the inability to smell, face a lifetime mortality rate four times higher than the average person (Pinto et al., 2014). These differences arise through difficulties in detecting hazardous circumstances like natural gas leaks, fires, chemical vapors, and decayed food. Unfortunately, for humans, there are several circumstances through which we may lose the ability to smell. These include normal aging, damage from a head injury, and disease. Below, we will discuss two causes of anosmia: neurodegenerative disease and Covid-19.

Olfactory dysfunction in neurodegenerative disease

Reduced olfactory capabilities and the loss of olfactory acuity is a leading indicator of two well-known neurodegenerative diseases. Alzheimer's disease is widely known for a profound deficit in both short and long-term memory, which has become a hallmark of the disease (see Chapter 18 Learning and Memory). In addition, disrupted olfactory sensation and anosmia are frequently reported by patients with Alzheimer's disease before they begin to experience memory deficits. Because of this, olfactory dysfunction is a leading indicator of the disease and there is great interest in using olfactory capabilities as a disease biomarker. Parkinson's disease is another neurodegenerative disorder that manifests with early olfactory deficits (see Chapter 10 Motor Control). In Parkinson's disease, dopaminergic neurons die, leading to that disease's hallmark motor deficits. The olfactory bulb also contains many dopaminergic neurons, as well as dopaminergic projections from other areas of the brain. Nearly all patients with Parkinson's disease experience deficits in their sense of smell, which often occurs years before the onset of motor symptoms. These symptoms can be used as a warning sign and if treatment is started early enough, medication can delay the progression of the disease.

Covid-19

The coronavirus pandemic that started in 2019 has brought increased attention to olfactory dysfunction. A symptom of many coronavirus infections has been transient anosmia that generally resolves as the viral infection is cleared. However, for some particularly unlucky people, a coronavirus infection has left them with persistent anosmia or sensations of unpleasant odors from otherwise innocuous smells.

Covid-19 is primarily transmitted as respiratory droplets, which means that as it is passed from person to person, it typically enters its next host through the nasal passages. Earlier in this section, we learned that the olfactory epithelium is found deep in the nasal cavities, and in addition to infecting and reproducing in respiratory tissues, coronavirus also infects cells in the olfactory epithelium. The receptor protein ACE2 is densely expressed in the supporting cells of the olfactory epithelium and is a target of Covid-19. When these supporting cells are infected, they become inflamed or damaged. Inflammation of the epithelium then disrupts the ability of nearby olfactory sensory neurons to transmit information about the odor environment to the brain. However, because sensory neurons themselves do not appear to be infected or destroyed by Covid-19, once the infection has passed, and inflammation of supporting cells subsides, normal olfactory function typically resumes.

Unfortunately, for some people, the Covid-19 induced inflammation of the olfactory epithelium becomes more than the tissue can handle and results in the death not only of the supporting cells, but also of the olfactory sensory neurons through indirect effects. We learned earlier that sensory neurons are constantly regenerating, and this is also true after a coronavirus infection. However, we also learned that sensory neurons must target their appropriate location in the brain for accurate odor recognition. When all or many of the olfactory sensory neurons die at the same time, they are no longer able to reliably find their correct location and glomeruli end up receiving mixed input from many different types of sensory neurons. When this happens, a person will regain their ability to smell, but it may not quite be the same. In this scenario, people often report unpleasant smells that accompany objects that otherwise would not smell bad. This is called parosmia. Some people will eventually recover from parosmia, while for others it can persist for years.

Insect olfaction and disease.

Neuroscience Across Speciess: Across the animal kingdom, different species have evolved unique strategies for sensing their chemical environment. Arthropods, including insects, lack sensory cells in their respiration pathways and instead have evolved olfactory sensors that are found along their body segments. In insects, olfactory sensors are found in specialized body segments attached to the head called antennae. Despite these differences, insects use the chemical senses for the same behaviors and functions as their vertebrate counterparts. Just as bees must find flowers to collect nectar, all insects seek to find nutrients, reproductive opportunities, and to avoid predation.

One of the most well-studied olfactory systems is the fruit fly, *Drosophila melanogaster*. You might be wondering, "why do scientists spend time thinking about a bug's sense of smell." It turns out there are some pretty good reasons. Insects like bees use olfaction to collect nectar from flowers, and at the same time spread pollen that helps to germinate fruit. Conversely, insects can also destroy food crops of all varieties through infestation. Developing aversive odorant-based repellents negates the need to use harmful pesticides to prevent these losses. Understanding insect olfaction is also an important public

health consideration. Infectious diseases including malaria, dengue, and Zika are spread by a remarkably common insect, the mosquito. As you may well have experienced, female mosquitoes require a blood meal before they can reproduce, and humans are often their target

2.3.15: Chemethesis, Spices, and Solitary Chemosensory Cells

Learning Objectives

By the end of this section, you should be able to

- 8.4.1 Define the sense of chemesthesis with examples.
- 8.4.2 Describe the role of the somatosensory system and TRP channels in producing sensations we commonly refer to as spicy.
- 8.4.3 Describe the role that solitary chemosensory cells and airway taste receptors play in protecting the vertebrate airway.

Imagine being served a hot bowl of chili after spending a snowy winter day outside; as you are handed the steaming bowl, it warms your icy hands. The aroma of the heavily spiced dish is mouthwatering, but it is likely at a scalding temperature. So, you take the time to let a spoonful cool before eating. The savory dish is just what the day calls for but as you chew the slightly warm spoonful of chili, your mouth starts burning. You quickly reach for a glass of water to quench the sensation only to find temporary relief. You now recognize this burning sensation has nothing to do with the temperature of the food but rather chemicals from the chili plants that give this dish its name. In this section, you will learn how some chemicals create the sensation of cooling and warmth that influence our perception of flavor and play an important role in innate immunity.

The somatosensory system plays a role in flavor perception

The primary role of the somatosensory system is to detect kinetic and thermal energy (see Chapter 9 Touch and Pain), but somatosensory neurons are also capable of responding to chemicals. In most parts of the vertebrate body, these sensory neurons are protected from the environment by skin; however, where these neurons innervate the mucous membranes (e.g. eyes, mouth, airway, digestive, and reproductive tracts) or when skin is damaged, chemicals are granted access to the underlying free nerve endings. When chemicals activate somatosensory nerves, you experience sensations that are described as burning, cooling, stinging, irritating or pungent.

The capacity of the somatosensory system to detect these chemicals is referred to as chemesthesis. When neuroscientists were initially studying these sensations, it was not clear what neural subsystem was responsible for them. Thus, the term common chemical sense was long used to describe the seemingly ubiquitous ability of tissues to detect chemicals like capsaicin (the “hot” chemical found in chili peppers) or low pH solutions. Once experimental evidence mounted to suggest that these sensations were entirely mediated by the somatosensory system, the term chemesthesis was suggested to distinguish between the more typical stimulation of the somatosensory system with kinetic and heat energy—referred to as somesthesis. Both somesthesis and chemesthesis contribute to flavor, but, of the two, chemesthesis is more often confounded with the sense of “taste.”

Chemesthetic chemicals make a substantial contribution to the flavor of many foods we eat. Nearly all the cooking ingredients we refer to as seasonings or spices (the obvious exception being salt) have been cultivated because they contain chemicals that selectively activate receptors on somatosensory neurons. The neurophysiological properties of these chemicals are so sought after that nations have been drawn into economic, political, and military conflicts over access to their botanical sources.

Scientists that study chemesthesis have noted that it seems counterintuitive for humans to seek out these chemicals. Most chemesthetic chemicals produce sensation by activating polymodal nociceptors: small diameter free nerve endings that respond to stimuli as different as plant metabolites, low pH, and heat energy. The stimulation of this neuron produces noxious or painful sensations. Most animals avoid substances that stimulate polymodal nociceptors and even humans that willingly consume spices often describe the sensation as painful.

Many hypotheses have been formulated to explain why some humans enjoy spicy foods. Most of them center around chemesthetic chemicals providing some health benefit; improved secretion of digestive enzymes, enhanced thermoregulation, and antimicrobial resistance have all been suggested. One popular theory asserts that individuals learn to enjoy spicy foods because the noxious sensations cause the release of endogenous opioids. Several studies have presented data that the opioid antagonist

naloxone decreases the preference for spicy foods as support for this theory. However, a preference for heavily spiced food is highly correlated with sensation and novelty seeking personality traits, and naloxone also blunts the enjoyment of other activities enjoyed by individuals that seek out novel sensations and do not directly involve noxious somatosensation, like gambling. Thus, the novelty or the intensity of spicy chemicals are more likely responsible for the involvement of the opioid system than any direct link with the noxious sensation produced by chemesthetic chemicals.

Thermal TRPs

Most chemicals that have chemesthetic properties selectively activate members of the Transient Receptor Potential (TRP) channel gene super family (Figure 8.19). TRP channels are ubiquitous in sensory systems, but several members of the family are activated at low or high temperatures. These thermal-TRPs are differentially expressed by sensory cells that allow animals to discriminate between different temperatures. Some of the thermal-TRPs are expressed by polymodal nociceptors; much of the polymodal capacity of these nerve fibers is due to the many different stimuli that can activate an individual TRP channel and the co-expression of multiple TRP channel family members on these free nerve endings.

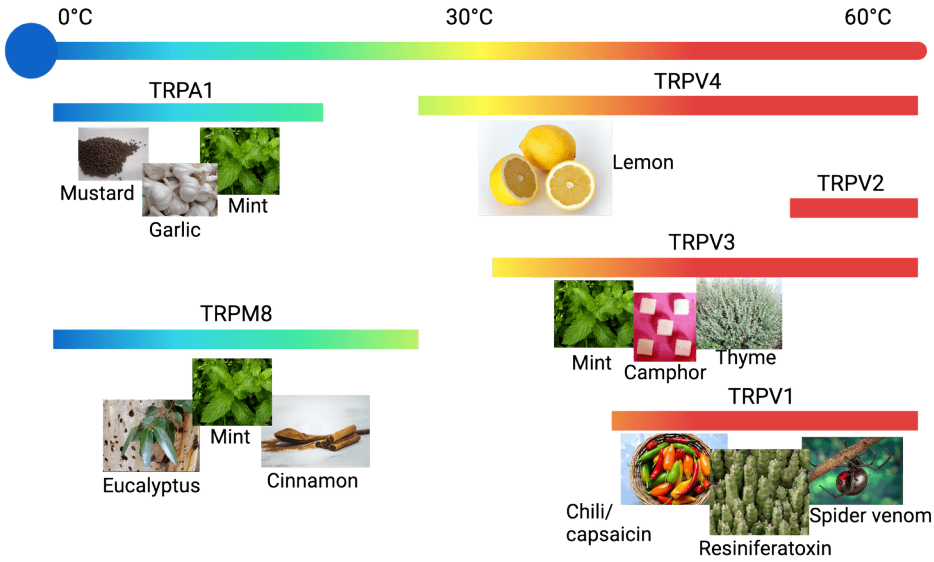

Figure 8.19 TRP channels These are plant metabolites that activate temperature-sensitive channels (TRPs), creating the perception of hot or cold temperatures. The most well-known chemical with chemesthetic properties is capsaicin, which is produced by chili peppers and related plants. Most mammals perceive capsaicin as noxiously hot because it activates TRP Vanilloid 1 (TRPV1) channels present on small-diameter peptidergic polymodal nociceptors (c-fibers). A similar channel, TRP ankyrin 1 (TRPA1), is found on a subset of these neurons and is activated by allyl isothiocyanate (AITC), which is the pungent compound in mustard plants, like horseradish and wasabi. Menthol, the cooling compound in mint, activates TRP Melastatin 8 (TRPM8) which is found on different nerve fibers that respond to cold. Many chemical compounds produced by plants are capable of shaping human and animal behavior because of their ability to interact with the receptors of the somatosensory system.

Solitary chemosensory cells

The most common chemesthetic compounds are lipophilic and pass-through epithelial cells to stimulate the underlying nerves, but some stimulate somatosensory nerves indirectly though specialized epithelial cells. These neuro-epithelial cells have a microvillar brush or tuft projecting apically, resembling isolated taste receptor cells morphologically. Due to these cells being

identified by independent research groups in a variety of tissues, they have alternatively been called tufted cells, microvillar cells, neuroendocrine cells, brush cells or solitary chemosensory cells (SCCs). They can be seen diagrammed as SCCs in Figure 8.20.

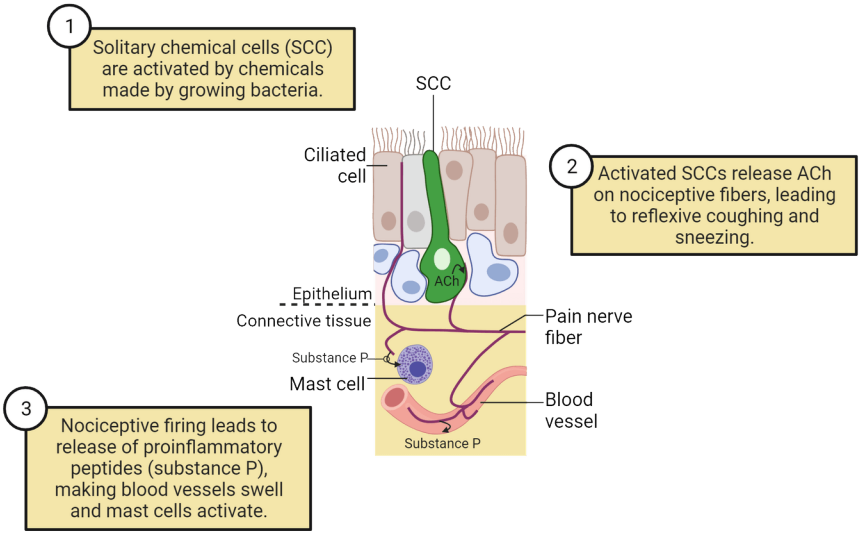

Figure 8.20 Taste receptors in the respiratory tract

SCCs form synapses with polymodal nociceptive fibers of the somatosensory system (shown as a pain nerve fiber contacting the SCC in Figure 8.20). This anatomical arrangement allows for SCCs to monitor the lumen of organs for chemicals that would not normally be detected by the nervous system.

SCCs have been identified in many hollow organs at risk of bacterial infection—from the nose, trachea, eustachian tube (middle ear), tear duct, periodontium (tooth socket), and the urinary bladder. The SCCs in the respiratory epithelium of the nose and trachea have been best characterized. In the airway, these cells appear to resemble bitter-sensitive type II taste receptor cells. These cells respond to traditionally bitter compounds, but, more remarkably, are also stimulated by a class of chemicals produced by reproducing gram negative bacteria, called acyl-homoserine lactones (AHLs). This allows SCCs to act as sentinels of epithelial tissues, monitoring the apical surface of epithelium for potentially dangerous bacterial infections.

When SCCs detect a growing bacterial infection, they trigger local epithelial defenses, recruit an immune response, and activate polymodal nociceptive nerve fibers. SCCs form synapses with nerves (Figure 8.20) and on stimulation release the neurotransmitter acetylcholine (ACh) to activate those nerves. Activation of nociceptors in the airway results in the local and central release of pro-inflammatory neuropeptides, which further sensitize the airway and recruit an immune response (see Chapter 9 Touch and Pain). More immediately, stimulation of airway polymodal nociceptors produces sensations of burning and stereotyped changes to the respiratory rhythm that we commonly call sneezing and coughing. Mice that have had SCC signaling disrupted spend more time in chambers with nebulized bitter chemicals than controls (Xi et al., 2023). Sneezing and coughing are behaviors that ultimately increase the velocity air is expelled from the airway making it more likely that microorganisms are dislodged and expelled. SCCs are responsible for generating a response to invading microbes on the tissue level and triggering behaviors that together guard against airway pathogens.

2.3.16: Influences That Shape Perception of Smell and Flavor

Learning Objectives

By the end of this section, you should be able to

- 8.5.1 Discuss how gustation, olfaction, chemesthesis and other senses influence the perception of flavor.
- 8.5.2 Describe how genetics differences can influence chemosensory perception.

Everyone has tastes or smells they love and tastes or smells they loathe. Think back to when you were younger, you may have hated a particular green vegetable to the point you had to be bribed to eat it. Now the sight and smell of the same dish may evoke ideas of a meal lovingly cooked by family members and be hungrily devoured. On the other hand, while even the fussiest eaters usually graduate away from sauropod-shaped processed-poultry, it is not uncommon to find that even the most experimental and pioneering foodie may detest a particular green vegetable or spice. Our chemosensory perceptions are influenced by our other senses, our memories, and our genetics, and therefore motivate some of the most personal behaviors in which a human being engages.

Flavor is a multimodal neural construct

A theme through this chapter has been that the perception of flavor is a gestalt of the multiple senses. The chemical senses of gustation, olfaction and chemesthesis all contribute to the sensations that we refer to as flavor, or sometimes erroneously as “taste.” The integration of these signals is partly due to the gross anatomy of the mouth and nasopharynx but is also a consequence of the convergent neuroanatomy of the three sensory systems. However, our perception of flavor can be influenced by almost every sense.

A common aphorism you hear from chefs is that “you eat with your eyes first.” Indeed, just the sight of food can trigger activity in the gustatory and olfactory cortex. However, how food looks can have a profound effect on an individual’s perception of the flavors. Specifically, individuals rate the odor of colorful liquids presented in an orthonasal manner as being more intense than colorless controls, but the opposite was true for liquids presented to individuals retronasally (e.g. those were perceived as being less intense than colorless controls). Sight can even trick the nervous system into perceiving the presence of chemicals that are completely absent; people who drink sweet-colored liquids will often perceive subsequent liquids of the same color as sweet even if they contain no sweet tastant. Blue food dyes in particular have been the focus of research because many scientists have speculated that blue is an uncommon color for naturally occurring foods. Many highly processed foods are brightly colored, which can influence food choice, and ultimately these dietary decisions can have an effect on an individual’s health.

In addition to the visual appearance of food, its texture can also have a profound impact on its flavor and palatability. We have already discussed the role the somatosensory system plays in modulating flavor via the detection of spices and temperature. Additionally, the tactile feedback when chewing has a profound influence on perceived pleasantness of foods—as anyone who has ever bit down on a soggy fry or a mushy potato chip will attest. Mouthfeel is the term for perception of the physical qualities of food. These qualities can be just as important as the chemical components of food in determining its palatably.

The mouthfeel component of flavor perception can even be influenced by the auditory system. For example, increasing loudness of crunching sounds during eating causes individuals to rate potato chips as having better flavor, even when those louder sounds are only played over headphones as the experimental subjects chewed (Roudaut et al., 2002). It is difficult to understate how critical the decision of what to eat is for the survival of an animal. Any detection of spoilage that prevents an animal from consuming foods infected by microorganism may prevent sickness and death. In this context, it should not be surprising that the totality of chemical senses are used to determine the palatability of our food.

Genetics influences the perception of taste and smell

How an individual perceives a particular odorant or tastant is heavily influenced by their unique genetic makeup. Genetics can influence different aspects of the gustatory and olfactory systems, from the density of papilla on the tongue on the macroscopic level, to sensitivity of particular olfactory and taste receptors to specific compounds on the molecular level. The best

characterized type of genetic variation that influences chemosensory perception is the single nucleotide polymorphism (SNP).

SNPs and Supertasters

A Single Nucleotide Polymorphism (SNP) is a variation in a single nucleotide in the DNA sequence that has been inherited by a substantial proportion of individuals. Sometimes this difference of a single nucleotide occurs in the non-coding region of a gene and probably has very limited effects; other times they can produce single amino acid substitutions when genes are translated into proteins that change the function of a gene. These changes in the genetic code can have a big impact on health, as SNPs can be used to predict an individual's response to certain drugs, susceptibility to environmental factors such as toxins, and risk of developing diseases. The best studied genetic trait that influences chemosensory perception in humans is a SNP in the *TAS2R38* gene.

The reason you may hate eating your green vegetables while your parents enjoy eating theirs may be due to the bitter taste receptor TAS2R38. This gene codes for a bitter taste receptor that responds to sulfur-containing compounds found in many cruciferous vegetables. Those vegetables include cauliflower, cabbage, kale, broccoli and brussel sprouts, which are often perceived as having a bitter flavor. In addition to those naturally occurring sulfur compounds, TAS2R38 also can detect the compounds 6-n-propylthiouracil (PROP) and phenylthiocarbamide (PTC).

There are three well-studied SNPs in TAS2R38 that result in three amino acid substitutions. Depending on which substitutions are present, TAS1R38 becomes more or less sensitive to PROP, PTC and the bitter chemicals in vegetables. Each person has two copies of each gene (one from each parent), so individuals will either have two copies of the same “tasting” receptor, two copies of the “non-tasting” receptor (having two identical copies of a gene is being homozygous) or have one copy of each (heterozygous). When you have a large number of individuals taste PROP or PTC and describe their experience, you will find there is a group of non-tasters who do not perceive the chemical, a group of tasters who find the chemicals moderately bitter, and a group of people who find the chemical intensely bitter who are called supertasters. Supertasters are often homozygous for the more sensitive version of TAS2R38, while non-tasters are often homozygous for the less sensitive version of TAS2R38. However, recent research indicates that there are other genetic traits that can also influence supertaster status.

The SNPs in TAS2R38 are only the best studied of many SNPs in taste receptor genes. Genetic variations across taste receptor genes are a likely reason that flavor preferences are so individualized. The implications of this heightened sensitivity are far reaching, as it can influence dietary choices and preferences, alter the willingness to consume drugs like caffeine and alcohol and may underlay cultural differences in food consumption.

People behind the science: SNPs and Specific anosmia

Like gustatory perception, the peculiarities of an individual’s olfactory perception are influenced by their genetics. Analogous to the taster paradigm is the phenomenon of specific anosmia, where individuals are “smell blind” or completely unaware of the presence of specific molecules.

Asparagus provides an interesting example of individual olfactory perception. Widely consumed in North America, Europe, and Asia, asparagus is a spring vegetable rich in many key nutrients and minerals. However, if you have ever eaten asparagus, you might recall a strange smell after using the bathroom. Through action on the kidneys, asparagus increases urine production, while at the same time, causing it to have a distinct and unpleasant odor. As our bodies digest a meal containing asparagus, it is broken down into several metabolites that contain sulfur, the same compound that gives rotten eggs their terrible smell. Your kidneys then help clear these smelly compounds from our body by depositing them into your urine. Unfortunately, these sulfur-containing metabolites are also extremely volatile, which means that while using the bathroom, they are easily carried into your nose and detected by your olfactory system.

Interestingly, not everyone who has eaten asparagus has this problem. You may have eaten asparagus plenty of times and never noticed anything amiss in the bathroom. It’s not that your kidneys are not properly removing sulfur from your body, but rather, that your nose cannot detect it! A SNP in the olfactory receptor gene (*OR2M7*) that binds to sulfur-containing chemicals results in some individuals never perceiving the smell. Not all people who cannot smell asparagus metabolites have an SNP in the same location in the sequence—there are several hundred distinct mutations known. However, for each of them, following translation, the nucleotide substitution results in a change to the receptor protein shape and causes an inability to bind to sulfur-containing compounds. This is a type of anosmia, but rather than being universal across all odors, it only affects certain odors which interact with a single olfactory receptor protein.

All animals rely on the chemical senses for their ability to survive and proliferate. Gustation alerts us to toxic or hazardous compounds in our foods, while at the same time evaluating their nutritional content. Olfaction works in concert with taste to help us locate and recognize food sources. Olfaction also alerts animals to the presence of both predators and potential mates, increasing survival and reproductive opportunities. Our sense of smell also serves to alert us to dangers in the environment like smoke from a fire. Our brain integrates signals from these and other sensory systems to produce the multi-modal perceptions we describe as flavor.

8.2 The Gustatory System

The anatomical and molecular differences between the vertebrate and insect gustatory systems are vast, but what is truly astounding are the commonalities between animals. Animals are responsive to the same broad classes of biomolecules despite utilizing different molecular mechanisms and sensory organs to detect them. Gustatory sensilla and tongues simultaneously provide both chemosensory and mechanosensory signals, which are co-processed in a primary gustatory relay that mediates critical reflexes involving feeding or swallowing. Fundamentally, the gustatory system and its integration with other sensory systems allows animals to learn associations and alter feeding behaviors based on the nutrient content of the food they encounter. Despite vast differences in body plans, life history, or anatomy, the commonalities of the gustatory systems and the essential behaviors it mediates in animals speaks to the profound importance of “taste.”

8.3 The Olfactory System

Like all sensory systems, the olfactory system is organized in a hierarchy. Chemicals are detected at the periphery and then processed in successive steps to extract relevant information for decision-making and behavioral output. Each of the cell types and neural areas described in this section play an important role in this process; however, as we learned, stimulus processing in the olfactory system is vulnerable to several diseases that can disrupt our sense of smell. While the olfactory system's cellular organization and processing capabilities in humans and other mammals are complex, we are not unique. Other animals like

insects share the same capabilities and rely on their sense of smell for survival.

8.4 Chemethesis, Spices, and Solitary Chemosensory Cells

While the somatosensory system mainly detects and discriminates between different types of kinetic energy, it is also capable of detecting chemical stimuli. Chemesthesis is the technical term for the ability of the somatosensory system to respond to chemicals. Most chemesthetic stimuli are produced by plants and activate TRP channels on polymodal nociceptors and produce sensations perceived as changes in temperature or described as irritating, burning, cooling, spicy, or pungent. In addition to stimulating free nerve endings directly, these nerve fibers can also be stimulated by solitary chemosensory cells through cholinergic synapses. SCCs detect growing bacterial infections and recruit innate defenses and trigger an immune response. Increasingly, functional chemosensory receptors are being described outside gustatory and olfactory systems and constitute part of the innate immune system that exists to detect infectious agents.

8.5 Influences That Shape Perception of Smell and Flavor

Chemicals are the building blocks of our world. From the sweet taste of an apple to the fresh smell of a newly cut lawn and even the burn of onion in our eyes, every substance we encounter requires us to interact with chemicals. The chemical senses allow us to build internal representations of the rich chemical environment that comprises our external world. Our repertoire of chemical senses directs us to energy-providing food, alerts us to danger, and helps many animals find mates. While the anatomical, cellular, and molecular features of the chemical senses vary between systems and comparatively between organisms and even individuals of the same species, each system serves a unique purpose in allowing animals to interact with and engage the chemical environment surrounding them.

2.3.18: Key Terms

8.1 The Chemical Senses are Several Distinct Sensory Systems

Signal integration, smell, taste, flavor, gustation, nutrients, olfactory system, pheromones, chemesthesis, retronasal olfaction, orthonasal olfaction

8.2 The Gustatory System

taste bud, tongue, papillae (filiform, foliate, fungiform, circumvallate), pharynx, taste pore, taste receptor cell (TRC), type 1 taste receptors (Tas1Rs, T1Rs), type 2 taste receptors (Tas2Rs, T2Rs), type 3 taste receptors (Tas1R3, T3Rs), otopetrin 1 (Otop1), epithelial sodium channels (ENaC), fat taste, intragemmal, labeled line coding, across-fiber pattern coding, chorda tympani branch of the facial (VII) nerve, glossopharyngeal (IX) nerve, nucleus of the solitary tract (NTS), chemotopic map, gustatory nucleus, primary gustatory cortex (GC), ventral posterior medial nucleus of the thalamus (VPMpc), secondary gustatory cortex, conditioned taste aversion, sensilla, gustatory receptor neurons (GRNs)

8.3 The Olfactory System

olfactory epithelium, odorants, turbinates, olfactory sensory neurons, supporting cells, basal cells, olfactory receptors, G_{olf}, adenylyl cyclase III (ACIII), cyclic nucleotide gated (CNG) channels, calcium-activated chloride channels (CaCC), olfactory bulb, glomerulus, mitral cells, tufted cells, piriform cortex, lateral olfactory tract, anterior olfactory nucleus (AON), anterior commissure, amygdala, entorhinal cortex, adaptation, accessory olfactory system, vomeronasal organ, accessory olfactory bulb, anosmia, Alzheimer's disease, Parkinson's disease, ACE2, parosmia

8.4 Chemethesis, Spices, and Solitary Chemosensory Cells

Free nerve endings, common chemical senses, somesthesis, olymodal nociceptors, Transient Receptor Potential (TRP) channels, thermal-TRPs, solitary chemosensory cells (SCCs)

8.5 Influences That Shape Perception of Smell and Flavor

Mouthfeel, single nucleotide polymorphism (SNP), TAS2R38, supertasters/non-tasters/tasters, specific anosmia

This page titled 2.3.18: Key Terms is shared under a CC BY-NC 4.0 license and was authored, remixed, and/or curated by Ivette Merced via source content that was edited to the style and standards of the LibreTexts platform.

2.3.20: Multiple Choice

8.1 The Chemical Senses are Several Distinct Sensory Systems

1.
Food with an umami flavor likely contains which essential nutrient?

a. Carbohydrates
b. Proteins and Amino Acids
c. Fats
d. Ions and electrolytes

8.2 The Gustatory System

2 .
Which statement about papillae is false?

a. Filiform papillae are cone-shaped, lack taste buds, and are found on the top surface of the tongue.
b. Fungiform papillae are mushroom-shaped and can be found scattered over the surface on the tongue; taste buds are located on top of their smooth domes.
c. Foliate papillae are found in the pharynx and lack in taste buds.
d. Circumvallate papillae are found lining the anterior surface of the tongue.

3.
Which statement about bitter taste compounds is false?

a. Bitter taste molecules include cocaine, caffeine, nicotine, and alcohol
b. Many bitter molecules have physiological or psychoactive effects on animals that could be potentially dangerous
c. Bitter taste molecules activate G-protein-coupled receptors
d. The bitter taste sensation is caused by acidic, low pH foods

4 .
Cells that express Channelrhodopsin-2 (ChR2) are stimulated by blue light. In a transgenic mouse that co-express ChR2 with T1R3, shinning blue light on the tongue would cause the mouse to experience which taste modalities?

a. The mouse would experience the sensations of sweet and umami taste simultaneously.
b. The mouse would not experience any taste sensations.
c. The mouse would experience the sensations of sweet, bitter, and umami taste simultaneously.
d. The mouse would experience the sensations of salty and sour simultaneously.

5.
Which of the following is NOT a proposed taste modality?

a. Fatty
b. Metallic
c. Floral
d. Kokumi/richness

6 .
Which statement about olfactory coding is false?

a. Cross-fiber pattern coding allows for a few receptors or lines to encode many modalities (as in the olfactory system), while labeled line coding requires a discrete circuit or line for each possible modality.
b. In labeled line coding a stimulus triggers the most efficient response through a discrete pathway or circuit starting from a specific type of receptor cells to specific neurons that pass to higher and higher brain regions where a single sensory modality is represented by activity in this “line” of cells.

c. In cross-fiber pattern coding, there is no overlap between the neurons activated by both stimuli
d. In cross-fiber pattern coding a stimulus triggers activity in multiple circuits or “lines” which together encodes for a particular sensory modality.

7.
All of the following nerves conduct gustatory information into the nucleus of the solitary tract, except:

a. the olfactory nerve.
b. the facial nerve.
c. the vagus nerve.
d. the glossopharyngeal nerve.

8 .
If drinking sweetened hot chocolate causes a sucrose-oriented NTS neuron to fire action potentials at a high rate, predict the pattern of action potentials fired by the same neuron when drinking cold chocolate milk containing a similar amount of sugar.

a. The neuron will likely fire at a higher rate when drinking cold chocolate milk.
b. The neuron will not fire when drinking cold chocolate milk.
c. The neuron will likely fire at the same rate when drinking cold chocolate milk.
d. The neuron will likely fire at a lower rate when drinking cold chocolate milk.

9.
Conscious perception of taste occurs in the primary gustatory cortex, which is located in the _____.

a. ventral posterior medial nucleus of the thalamus (VPMpc)
b. piriform cortex
c. anterior insular cortex
d. orbitofrontal cortex

10 .
Where in the brain are gustatory signals integrated with sensations of fullness or satiety?

a. Pyriform cortex
b. Caudolateral section of the orbitofrontal cortex
c. Amygdala
d. Hippocampus

8.3 The Olfactory System

11.
Which is not a behavior that is mediated by the olfactory system?

a. Navigation
b. Mate selection
c. Body position
d. Nutrient finding

12 .
The primary sensory organ for the olfactory system is called the olfactory _____?

a. Retina
b. Tympanic membrane
c. Cortex
d. Epithelium

13.
Which cells are the output neurons of the olfactory bulb?

a. Hair cells and Glia

b. Mitral cells and Tufted cells
c. Mueller cells and Pyramidal cells
d. Interneurons and Dopaminergic cells

14 .
Olfactory information crosses between the hemispheres of the brain at which structure?

a. The anterior olfactory nucleus
b. The piriform cortex
c. The olfactory bulb
d. The olfactory epithelium

15.
What division of the chemical senses is dedicated to communication and pheromone detection?

a. The main olfactory system
b. The tertiary olfactory system
c. The partial olfactory system
d. The accessory olfactory system

16 .
The inability to smell is called:

a. anosmia
b. parosmia
c. smell deafness
d. smell blindness

17.
The Covid-19 virus primarily targets which cell type in the olfactory epithelium?

a. Olfactory sensory neurons
b. Supporting cells
c. Glial cells
d. Basal cells

18 .
An ___ is a physical part of the environment, while an _____ is the perception of a stimulus.

a. Odorant; Olfaction
b. Odor; Odorant
c. Odorant: Odor
d. Sensation; Molecule

19.
_____ mediates the emotional aspect of olfactory perception.

a. The amygdala
b. The olfactory bulb
c. The entorhinal cortex
d. The olfactory trace

20 .
Social odorants are detected by the _____ olfactory systems in humans.

a. main
b. secondary
c. accessory
d. general

21.
Each glomerulus receives input from how many subtype(s) of olfactory sensory neurons?

a. One
b. At least 10
c. Zero
d. At least 100

22 .
_____ cells in the olfactory bulb respond to lower concentrations of odorants and are more broadly tuned to odorants than _____ cells.

a. Olfactory sensory / granule
b. Granule / tufted
c. Mitral / olfactory sensory
d. Tufted / mitral

8.4 Chemethesis, Spices, and Solitary Chemosensory Cells

23.
Which of the following chemicals activates TRPV1 to create the sensation of noxious heat (about 43C)?

a. Capsaicin
b. AITC
c. Menthol
d. Mustard Oil

24 .
Which of the following protective mechanisms is NOT triggered when solitary chemosensory cells are stimulated by acyl-homoserine lactones?

a. Recruitment of local epithelial defenses
b. Release of pro-inflammatory neuropeptides
c. Sneezing and coughing
d. Fever

2.3.21: Fill in the Blank

8.1 The Chemical Senses are Several Distinct Sensory Systems

1.
Chemicals called _____ are sensed through a specialized olfactory system and can influence reproductive behaviors.

8.2 The Gustatory System

2 .
The _____ system allows us to inspect the quality and concentration of a chemical substance before it is swallowed.
3.
_____ express ionotropic or metabotropic surface receptors that allow for the detection of different types of chemicals.
4 .
In _____ a discrete pathway from receptor to higher brain centers encodes a particular tastant.

8.3 The Olfactory System

5.
The _____ is found deep within the nasal cavity and acts as the primary sensory organ for the olfactory system.
6 .
One major target of mitral cells is the _____ or olfactory cortex.

This page titled 2.3.21: Fill in the Blank is shared under a CC BY-NC 4.0 license and was authored, remixed, and/or curated by Ivette Merced via source content that was edited to the style and standards of the LibreTexts platform.

2.3.22: Hearing

Hearing

Learning Objectives

1. Label key structures of the ear, identify their functions, and describe the role they play in hearing.
2. Explain how we encode and perceive pitch.
3. Explain how we localize sound.
4. Describe how hearing and the vestibular system are associated.

This section will provide an overview of the basic anatomy and function of the auditory system, how we perceive pitch, and how we know where sound is coming from. It has been argued that the human ear can hear a variety of sounds and can distinguish between a large variation of these sounds. The complex anatomy of the ear in humans can be divided into three sections (the three sections are shown in the image below). The neural impulses of these sound waves are sent to the brain and our past experiences integrate with those sound waves to help us make sense of the sounds we are hearing. The auditory system converts the sound waves into electrical signals that the brain interprets. The illustration below shows the complex system of the ear and how the anatomical structures lead to the ability to hear the sounds of nature, appreciate beauty of music and utilize language to communicate with others who speak the same language (see Figure 2.3.22.1).

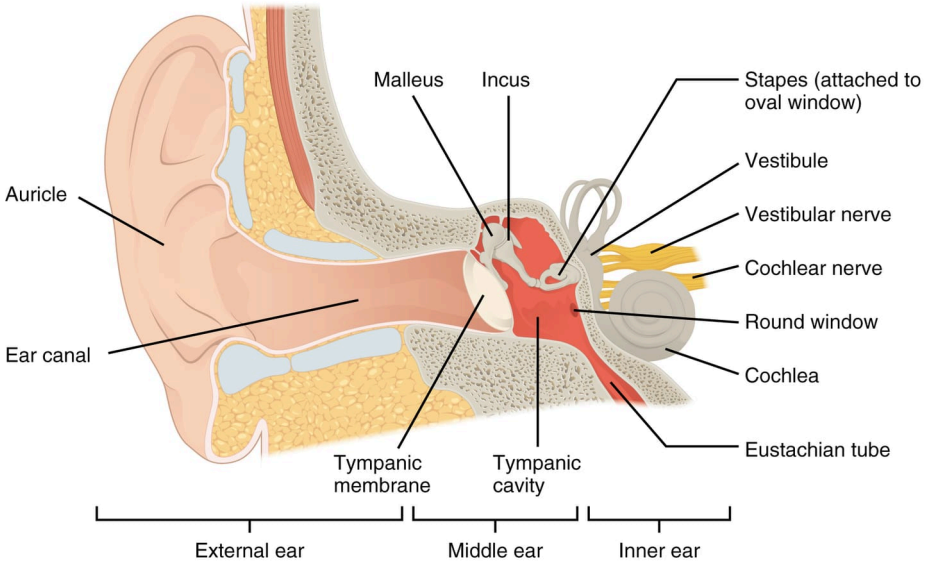

Figure 2.3.22.1 – ***Structures of the Ear:*** *The external ear contains the auricle, ear canal, and tympanic membrane. The middle ear contains the ossicles and is connected to the pharynx by the Eustachian tube. The inner ear contains the cochlea and vestibule, which are responsible for audition and equilibrium, respectively* https://open.oregonstate.education/a.../15-3-hearing/.

In particular, the human ear is most responsive to sounds that are in the same frequency as the human voice. This is why parents and mothers in particular are able to pick out the sound of their children's voice amongst other children's voices and we are often able to identify another person from the sound of their voice without having to see them physically. The complex system of the ear allows us to process sounds almost instantly.

Unlike light waves which travel in a vacuum, sound waves are transferred when molecules bump into each other in the air and produce sound waves that allow us to identify the source of the sounds that we encounter. These sound waves create different frequencies, with low frequency sounds being lower pitched and higher frequency sounds being higher pitched. There are a few theories that have been proposed to help account as to why individuals can distinguish between pitch perception and frequencies.

The **temporal theory** of pitch perception asserts that frequency is coded by the activity level of a sensory neuron. This would mean that a given hair cell would fire action potentials related to the frequency of the sound wave. While this is a very intuitive

explanation, we detect such a broad range of frequencies (20–20,000 Hz) that the frequency of action potentials fired by hair cells cannot account for the entire range. Because of properties related to sodium channels on the neuronal membrane that are involved in action potentials, there is a point at which a cell cannot fire any faster (Shamma, 2001).

The **place theory** of pitch perception suggests that different portions of the basilar membrane **(a stiff structural element within the cochlea of the inner ear)** moves up and down in response to incoming sound waves. More specifically, the base of the basilar membrane responds best to high frequencies and the tip of the basilar membrane responds best to low frequencies. Therefore, hair cells that are in the base portion would be labeled as high-pitch receptors, while those in the tip of basilar membrane would be labeled as low-pitch receptors (Shamma, 2001). In reality, both theories explain different aspects of pitch perception. At frequencies up to about 4000 Hz, it is clear that both the rate of action potentials and place contribute to our perception of pitch. However, much higher frequency sounds can only be encoded using place cues (Shamma, 2001).

Similar to the need for recognizing different pitches and frequencies, knowing where particular sounds are coming from (sound localization) is an important part of navigating the environment around us. The auditory system has the ability to use monaural (one ear) and binaural (two ears) cues to locate where a particular sound might be coming from. Each pinna interacts with incoming sound waves differently, depending on the sound's source relative to our bodies. This interaction provides a monaural cue that is helpful in locating sounds that occur above or below and in front or behind us. The sound waves received by your two ears from sounds that come from directly above, below, in front, or behind you would be identical; therefore, monaural cues are essential (Grothe, Pecka, & McAlpine, 2010).

Binaural cues, on the other hand, provide information on the location of a sound along a horizontal axis by relying on differences in patterns of vibration of the eardrum between our two ears. If a sound comes from an off-center location, it creates two types of binaural cues: interaural level differences and interaural timing differences. **Interaural level difference** refers to the fact that a sound coming from the right side of your body is more intense at your right ear than at your left ear because of the attenuation of the sound wave as it passes through your head. **Interaural timing difference** refers to the small difference in the time at which a given sound wave arrives at each ear, illustrated in Figure 2.3.22.2. Certain brain areas monitor these differences to construct where along a horizontal axis a sound originates (Grothe et al., 2010).

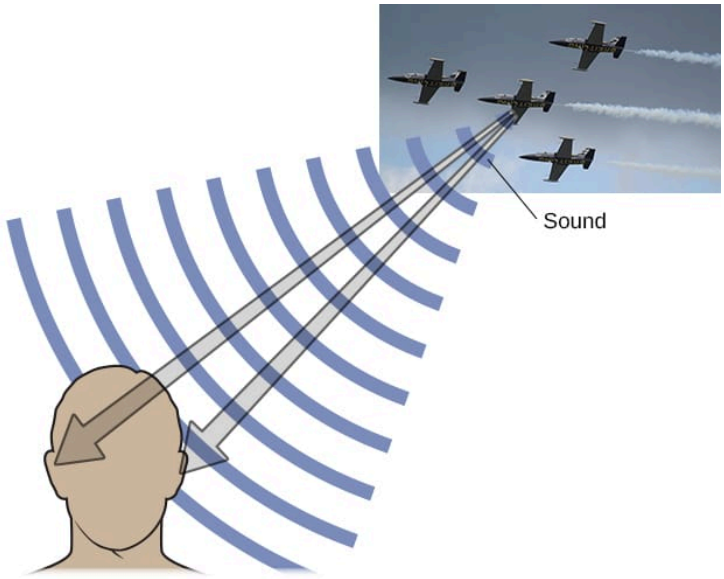

Figure 2.3.22.2: Localizing sound involves the use of both monaural and binaural cues. (credit "plane": modification of work by Max Pfandl)

Hearing Loss

Hearing Loss

- About 2 to 3 out of every 1,000 children in the United States are born with a detectable level of hearing loss in one or both ears (https://www.nidcd.nih.gov/health/sta...istics-hearing).
- More than 90 percent of deaf children are born to hearing parents (https://www.nidcd.nih.gov/health/sta...istics-hearing).

- Approximately 15% of American adults (37.5 million) aged 18 and over report some trouble hearing (https://www.nidcd.nih.gov/health/statistics/quick-statistics-hearing)

Conductive hearing loss can be caused by physical damage to the ear (such as to the eardrums); this condition reduces the ability of the ear to transfer vibrations from the outer ear to the inner ear. Conductive hearing loss can also be a result of fusion of the ossicles **(three bones in the middle ear)**. Sensorineural hearing loss, which is caused by damage to the cilia (of the hair cells) or to the auditory nerve, is not as common as conductive hearing loss but the likelihood of this condition increases with age (Tennesen, 2007). As we continue to get older damage to the cilia increases; by the age of 65 years old 40% of individuals will have had damage to the cilia (Chisolm, Willott, & Lister, 2003).

Individuals who have experienced sensorineural hearing loss may benefit from a cochlear implant. Data From the National Institutes of Health shows that as of December 2019, approximately 736,900 cochlear implants have been implanted worldwide. In the United States, roughly 118,100 devices have been implanted in adults and 65,000 in children The following video explains the process of a cochlear implant.

Cochlear implant surgeries and how they work:

https://www.youtube.com/watch?v=AqXBrKwB96E

Deafness and Deaf Culture

In most modern nations people who are born or become deaf at an early age have developed their own system of communication and culture amongst themselves and people close to them. It has been argued that encouraging deaf people to sign is a more appropriate adjustment as opposed to encouraging them to speak, read lips or have cochlear implant surgeries. However, more recent studies suggest that due to advancements in technology, cochlear implants increase the likelihood of a person being able to have and engage in some auditory and speaking activities if implanted early enough (Dettman, Pinder, Briggs, Dowell, & Leigh, 2007; Dorman & Wilson, 2004). As a result parents often face the difficult decision of whether to take advantage of new technologies and approaches of providing support to deaf students in mainstream classroom settings or utilizing American Sign Language (ASL) schools and encouraging more immersion in those settings.

Hearing and the Vestibular System

The vestibular system has some similarities with the auditory system. It utilizes hair cells just like the auditory system, but it excites them in different ways. There are five vestibular receptor organs in the inner ear: the utricle, the saccule, and three semicircular canals. Together, they make up what's known as the vestibular labyrinth that is shown in Figure 2.3.22.3. The utricle and saccule respond to acceleration in a straight line, such as gravity. The roughly 30,000 hair cells in the utricle and 16,000 hair cells in the saccule lie below a gelatinous layer, with their stereocilia projecting into the gelatin. Embedded in this gelatin are calcium carbonate crystals—like tiny rocks. When the head is tilted, the crystals continue to be pulled straight down by gravity, but the new angle of the head causes the gelatin to shift, thereby bending the stereocilia. The bending of the stereocilia stimulates the neurons, and they signal to the brain that the head is tilted, allowing the maintenance of balance. It is the vestibular branch of the vestibulocochlear cranial nerve that deals with balance.

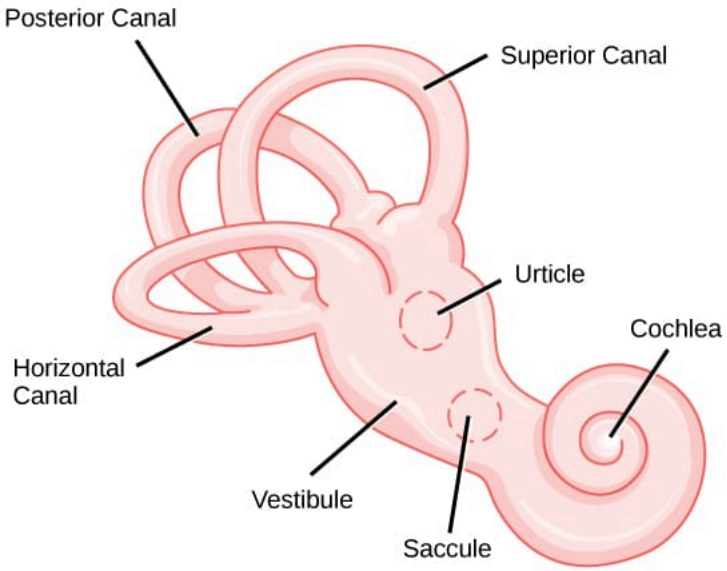

Figure 2.3.22.3 The structure of the vestibular labyrinth is shown. (credit: modification of work by NIH)

2.4: Taste and Smell

Taste and Smell

Learning Objectives

1. Explain why taste and smell are the most interconnected senses

2. Identify the five primary tastes in humans: sweet, sour, bitter, salty, and umami

3. Identify how the five primary tastes allow individuals to adapt to changes in the environment and increase chances of survival

4. Explain how olfactory receptors are responsive to different odorants

Being able to sense chemicals in the environment through taste (gustation) and smell (olfaction) can help an organism find food, avoid poisons, and attract mates. Humans can perceive five basic tastes: salty, sour, bitter, sweet, and umami. Bitter taste often indicates a dangerous substance like a poison, sweet taste signifies a high energy food, salty taste indicates a substance with high salt content, sour taste indicates an acidic food, and umami taste indicates a high protein food.

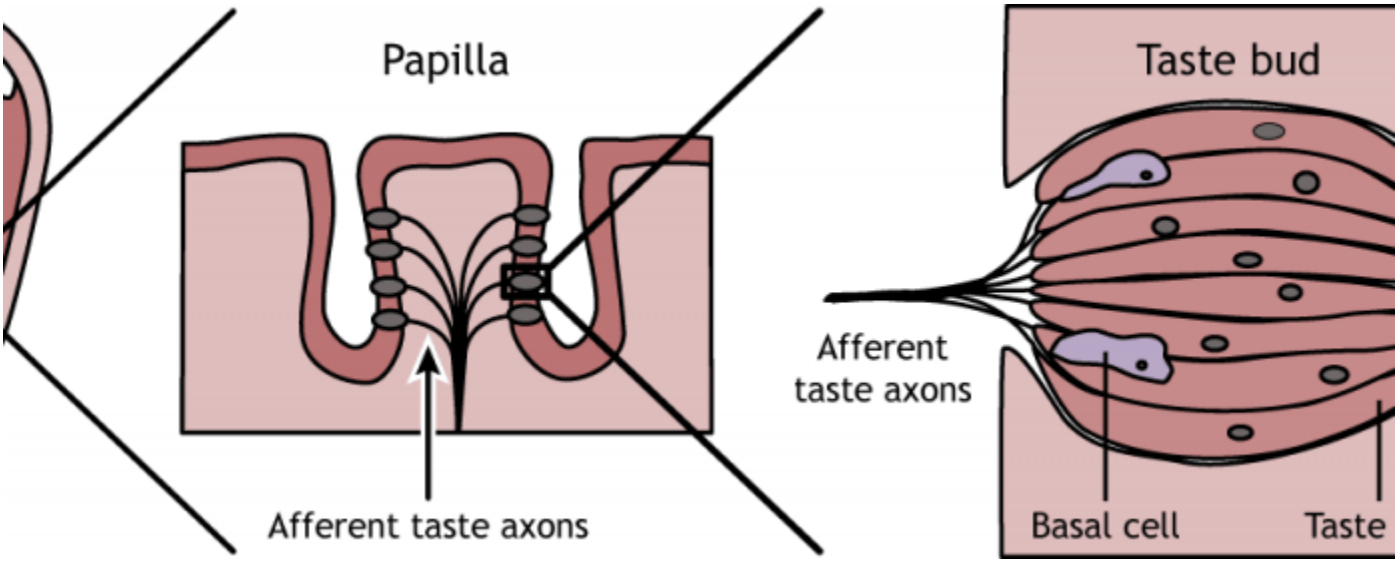

Figure 2.4.1: *The visible bumps on the surface of the tongue are papillae that house taste buds. Taste buds are made up of taste cells and basal cells. The taste cells synapse on afferent axons that send information to the central nervous system. Tastants in food access the taste cells via the taste pore, where the food particles interact with the microvilli of the taste cells. 'Tongue Anatomy' by Casey Henley is licensed under a Creative Commons Attribution Non-Commercial Share-Alike (CC BY-NC-SA) 4.0 International License.*

Taste and smell, are the most interconnected senses in that both involve molecules of the stimulus entering the body and bonding to receptors. Smell lets an animal sense the presence of food and other chemicals in the environment that can impact their survival. Similarly, the sense of taste allows animals to discriminate between types of foods. Different tasting foods have different attributes, both helpful and harmful. For example, sweet-tasting substances tend to be highly caloric, which could be necessary for survival in lean times. Bitterness is often associated with toxicity, and sourness is often associated with spoiled food. Salty foods are valuable in maintaining homeostasis by helping the body retain water and by providing ions necessary for proper cell function.

Smell

Odorants (odor molecules) enter the nose and dissolve in the olfactory epithelium, the mucosa at the back of the nasal cavity (as illustrated in the figure below). The **olfactory epithelium** is a collection of specialized olfactory receptors in the back of the nasal cavity that spans an area about 5 cm^2 in humans. Recall that sensory cells are neurons. An **olfactory receptor**, which is a dendrite

of a specialized neuron, responds when it binds certain molecules inhaled from the environment by sending impulses directly to the olfactory bulb of the brain. Humans have about 12 million olfactory receptors, distributed among hundreds of different receptor types that respond to different odors. Twelve million seems like a large number of receptors, but compare that to other animals: rabbits have about 100 million, most dogs have about 1 billion, and bloodhounds—dogs selectively bred for their sense of smell—have about 4 billion. The overall size of the olfactory epithelium also differs between species, with that of bloodhounds, for example, being many times larger than that of humans.

Olfactory neurons are **bipolar neurons** (neurons with two processes from the cell body). Each neuron has a single dendrite buried in the olfactory epithelium, and extending from this dendrite are 5 to 20 receptor-laden, hair-like cilia that trap odorant molecules. The sensory receptors on the cilia are proteins, and it is the variations in their amino acid chains that make the receptors sensitive to different odorants. Each olfactory sensory neuron has only one type of receptor on its cilia, and the receptors are specialized to detect specific odorants, so the bipolar neurons themselves are specialized. When an odorant binds with a receptor that recognizes it, the sensory neuron associated with the receptor is stimulated. Olfactory stimulation is the only sensory information that directly reaches the cerebral cortex, whereas other sensations are relayed through the thalamus.

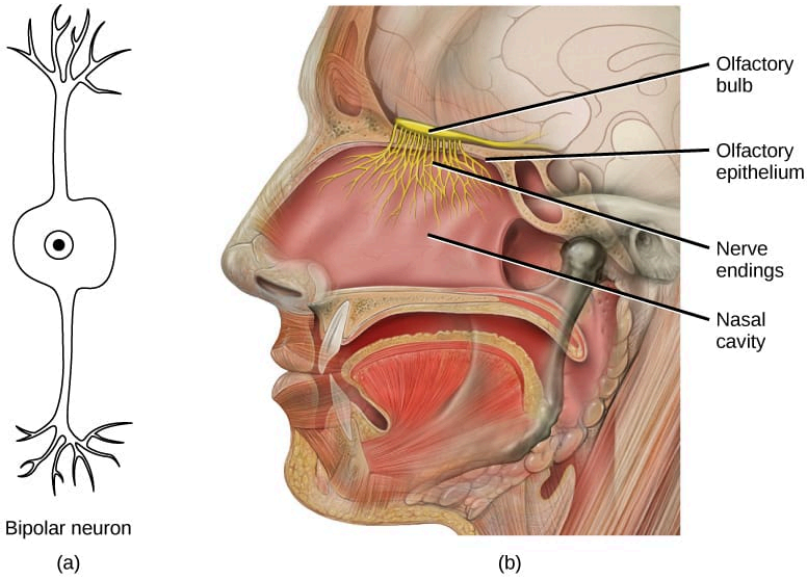

Figure 2.4.2: In the human olfactory system, (a) bipolar olfactory neurons extend from (b) the olfactory epithelium, where olfactory receptors are located, to the olfactory bulb. (credit: modification of work by Patrick J. Lynch, medical illustrator; C. Carl Jaffe, MD, cardiologist)

Taste

Detecting a taste (gustation) is fairly similar to detecting an odor (olfaction), given that both taste and smell rely on chemical receptors being stimulated by certain molecules. The primary organ of taste is the taste bud. A **taste bud** is a cluster of gustatory receptors (taste cells) that are located within the bumps on the tongue called **papillae** (singular: papilla) (illustrated in the figure below). There are several structurally distinct papillae. Filiform papillae, which are located across the tongue, are tactile, providing friction that helps the tongue move substances, and contain no taste cells. In contrast, fungiform papillae, which are located mainly on the anterior two-thirds of the tongue, each contain one to eight taste buds and also have receptors for pressure and temperature. The large circumvallate papillae contain up to 100 taste buds and form a V near the posterior margin of the tongue.

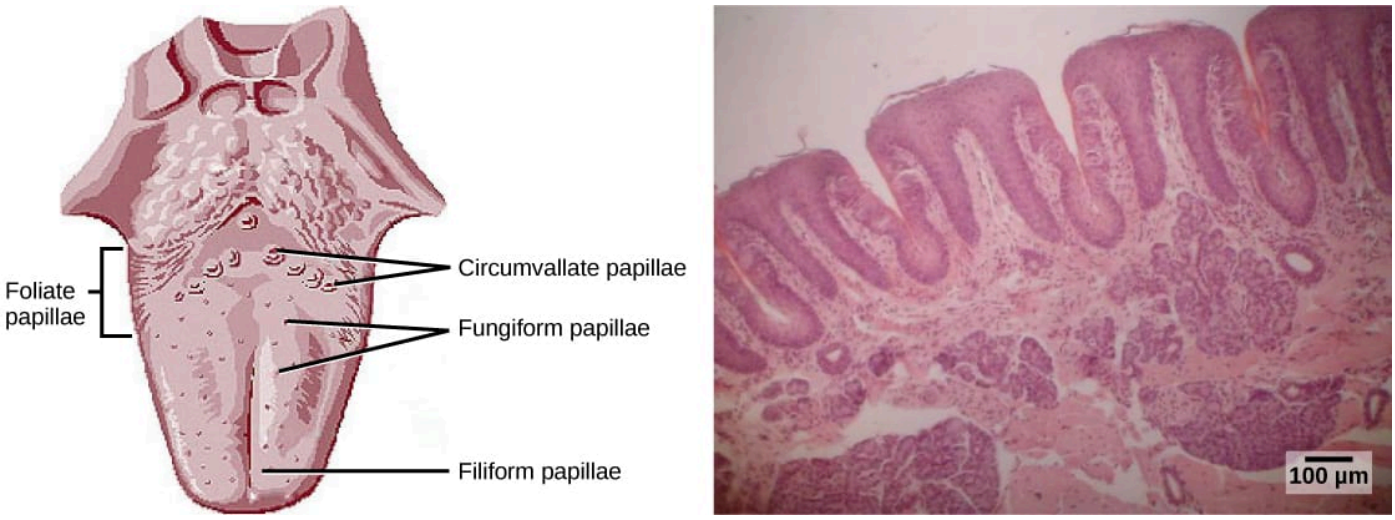

Figure 2.4.3: The human tongue. (a) Foliate, circumvallate, and fungiform papillae are located on different regions of the tongue. (b) Foliate papillae are prominent protrusions on this light micrograph. (credit a: modification of work by NCI; scale-bar data from Matt Russell)

Each taste bud's taste cells are replaced every 10 to 14 days. These are elongated cells with hair-like processes called microvilli at the tips that extend into the taste bud pore. Food molecules (**tastants**) are dissolved in saliva, and they bind with and stimulate the receptors on the microvilli. The receptors for tastants are located across the outer portion and front of the tongue, outside of the middle area where the filiform papillae are most prominent.

In humans, there are five primary tastes, each receptor is specific to its stimulus (tastant). Transduction of the five tastes happens through different mechanisms that reflect the molecular composition of the tastant. These tastants bind to their respective receptors, thereby exciting the specialized neurons associated with them. Tasting abilities and sense of smell change with age. In humans, the senses decline dramatically by age 50 and continue to decline. A child may find a food to be too spicy, whereas an elderly person may find the same food to be bland and unappetizing.

Meet the Author

Yuan B Peng, MD PhD

Yuan B Peng

Imagine that you were on a bus or metro in the busy morning hour. Somebody steps on your toe. It is painful; not only painful (a sensory experience), but makes you upset (an emotional response). However, the person immediately apologizes for his/her accident. Even if you are still in pain, the sincerity of the apology can make your emotion subside. Just a second later, though, the same person steps on your toe again. With the same painful stimulus, your emotion will go through the sky. Why?

The somatosensory system is unique among the five sensory systems in our body. It enables us to feel a variety of inputs—touch, pressure, temperature, pain, and itch—all of which help us sense the external environment and also protect our body from injury or potential injury. Here, we will learn how the somatosensory system is organized. We will start with the special structures called sensory receptors that are located in the skin, muscle, joints, internal organs, and all over the body. We will then learn how this sensory information is passed along unique sensory pathways from the periphery all the way to our brain. Finally, we will gain a greater understanding of how that sensory information is modulated and used by our brain in ways that can make the same stimulus have different meanings to you, such as what happened in the repeat toe injuries example above.

2.5.2: Somatosensory Receptors

Learning Objectives

By the end of this section, you should be able to

- 9.1.1 Describe the anatomical properties of different sensory receptors.
- 9.1.2 Identify the physiological properties of different sensory receptors.
- 9.1.3 Describe the anatomy and neurotransmitter usage of primary afferents to the spinal cord.

When you lift a hot pot of boiling water from the stove, not only do you feel the temperature but also vibration due to the boiling content. Further, you may also notice the texture of the handle. How does this happen? How can you sense so many properties at once? Among all five senses, the body sense (somatosensory system) starts with the largest variety of different unique receptors. Each receptor connects via an axon to the central nervous system to transmit information to our brain to enable perception. This section will review how these receptors transduce such a variety of skin signals into neural signals headed to the central nervous system.

Peripheral receptors and functional modalities

Each somatosensation starts with the activation of one or more types of peripheral somatosensory receptors. Peripheral receptors include several major types, such as the Merkel disk, Meissner's corpuscle , Ruffini endings, Pacinian corpuscle , free nerve endings, and hair cells (Figure 9.2). These different sensory receptors enable us to feel touch, pressure, vibration, pain, and temperature.

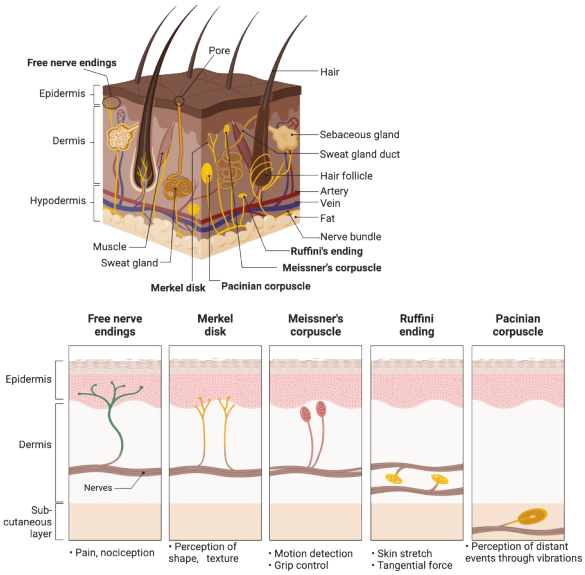

Figure 9.2 Mechanoreceptory types In this example from the skin, there are Merkel disks and Meissner's corpuscles in the superficial part of the skin. Hair follicles, Ruffini endings and Pacinian corpuscles sit in the deeper part of the skin. All of these use large myelinated Aβ-fibers. Unmyelinated C-fiber Free nerve endings are found throughout the skin.

Touch receptors

Merkel disk, Meissner's corpuscle, Ruffini endings, and Pacinian corpuscle all serve to transduce features of touch sensation. These disks and corpuscles are specialized structures in the skin that are connected to axons that send touch information to the spinal cord. These terminal structures are the starting points of the somatosensory system, so they are also called "sensory receptors". Here the term "receptor" is different from the neurotransmitter receptor on the cell membrane (much smaller, one

protein molecule). The sensory receptor is a much larger structure (composed of many proteins). Within these specialized endings sit mechanosensitive cation channels which activate in response to mechanical pull from sensations like touch, pressure, and vibration. These channels, also called piezo channels, are permeable to Na^+, K^+, Ca^{2+}, and Mg^{2+}, with a slight preference for Ca^{2+}. Figure 9.3 shows the protein structure of two major piezo channels. They both are made of 3 proteins that come together to form a central pore, through which ions move, with blade-like structures surrounding the pore. The discovery of piezo channels led to a Nobel prize in 2021 for Dr. Ardem Patapoutian, the scientist who first described them (Coste et al., 2010) (Figure 9.3). Figure 9.4 shows how these channels open in response to mechanical force. The influx of ions through these channels leads to the generation of action potentials which propagate via highly myelinated Aβ fibers to the spinal cord.

Figure 9.3 Piezo channel structure Signals responsible for mechanosensation are transmitted by piezo channels. Piezo channels are composed of three proteins forming blades around a central pore.

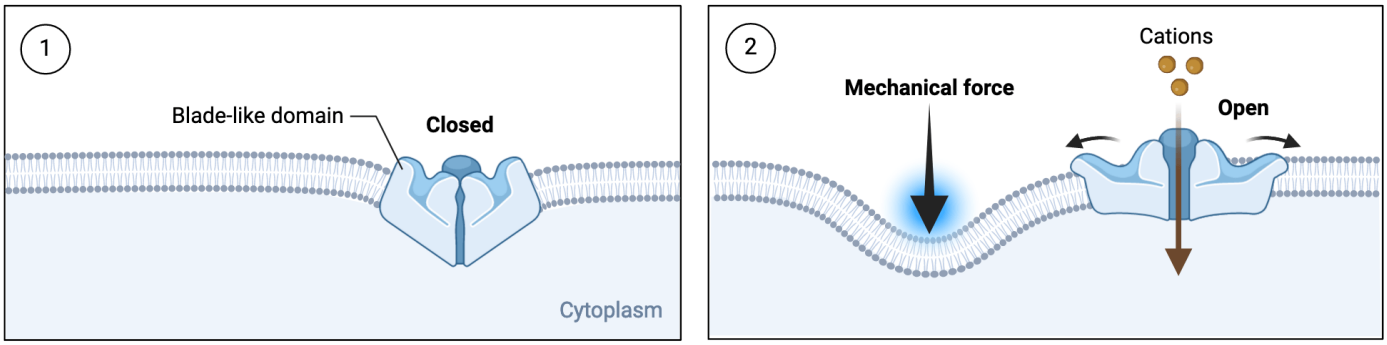

Figure 9.4 PIEZO Channels: How Do They Allow Mechanosensation? PIEZO1 and PIEZO2 are both mechanically-activated cation channels. Based on protein structure, it was predicted that the 'blades' of the PIEZO channels undergo a lever-like flattening motion upon application of mechanical stress. This opens up their central pore, allowing an influx on positive charge. The exact mechanism by which mechanical force leads to the central pore opening is not fully understood.

The four major mechanoreceptors (Merkel disks, Meissner's corpuscles, Ruffini endings, and Pacinian corpuscles) are each sensitive to different kinds of touch. The location and shape of each receptor structure supports these different sensitivities. Figure 9.5 summarizes these key features of the 4 receptor types. Next, we will review some key structural features of these receptors and how they support the receptor function.

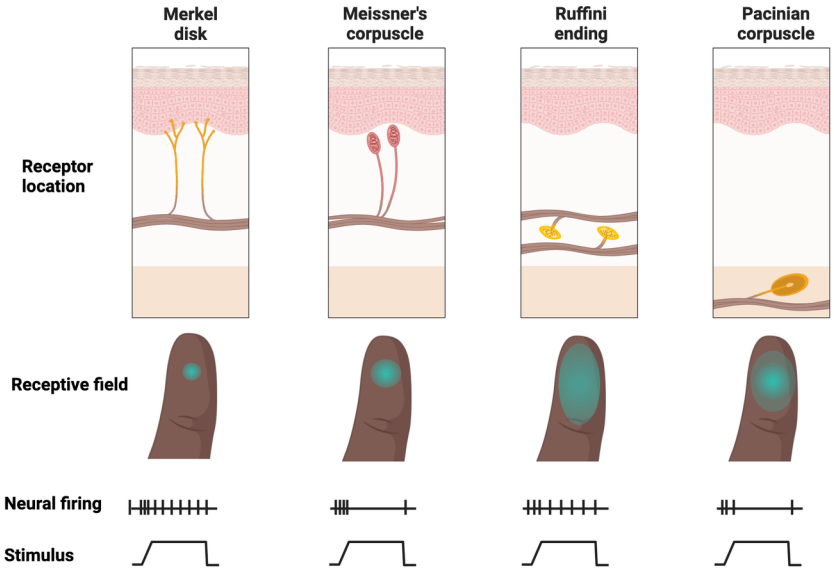

Figure 9.5 Mechanorecpetor receptive fields and adaptations

	Merkel disk	Meissner's Corpuscle	Ruffini ending	Pacinian corpuscle
Skin location	Superficial	Superficial	Deep	Deep
Adaptation	Slow	Rapid	Slow	Rapid

Table 9.1

First, their different locations in the skin help determine how large or small their receptive fields are, which for touch receptors means the area of the skin in which touch can activate them. Merkel disks and Meissner's corpuscles are located more superficially around the epidermis and therefore have a smaller and clearly-defined receptive field. Ruffini endings and Pacinian corpuscles are located more in the deeper part of the skin (with a larger, blurry receptive field), near where hair follicles are located.

Second, the shape and composition of each touch receptor help determine how long they respond to stimuli, dividing them into rapid adapting versus slowly adapting receptors. The slowly adapting receptors include Merkel disk and Ruffini endings. When a force or stimulus is applied in their receptive field, those receptors will be constantly activated and generate electrical activities (e.g., pressure). On the other hand, the rapidly adapting receptors such as Meissner's corpuscle and Pacinian corpuscle only respond or generate electrical activities when there is a dynamic change of forces or stimuli, such as vibration (Johansson and Vallbo, 1983; Koerber and Mendell, 1988). These adaptation properties combine with the receptive field to give the unique sensitivity of each of these 4 receptor types to specific touch modalities described in Table 9.1.

Nociceptors

The specific receptor for sensing a high-threshold stimulus that is damaging or threatens damage to normal tissues is called a nociceptor. Free nerve endings serve as nociceptors, or receptors that transmit pain signals related to mechanical, thermal, or chemical sources. Free nerve endings are different from the preceding four mechanoreceptors. The role of free nerve endings is related to sensing pain and temperature. Free nerve endings lack any specialized structures around their terminals and are connected to or in continuation with unmyelinated C-fibers and myelinated Aδ fibers. There are separate types of nociceptors responding to each modality (i.e., mechanical, thermal, and chemical), but also polymodal receptors that respond to all. Below we will discuss further how nociceptors sense tissue damage and temperature specifically.

Some free nerve endings transmit pain signals related to tissue damage (Figure 9.6). For example, if someone cut their finger, the direct and indirect damage of the nerve terminals (C- or Aδ fibers) at the primary injury site will excite and generate action potentials, which will not only propagate to the spinal cord (generating pain perception), but also propagate through the axonal branch points to spread to other axonal terminals that connect to the same main axon. The invasion of action potentials to the nearby uninjured axonal terminals will lead to the release of several key neural peptides, CGRP (calcitonin-gene related peptide) from Aδ fiber and SP (Substance P) from C-fiber, which cause vasodilatation (redness and temperature) and plasma extravasation

(edema). This phenomenon is called axonal reflex, a mechanism contributing to neurogenic inflammation. The primary injury also breaks blood vessels, leading to the accumulation of white blood cells, especially the mast cell. Mast cells can also release these neuropeptides and stimulate the axonal terminals and capillaries, leading to redness (*rubor*), heat (*color*), swelling (*tumor*), pain (*dolor*), and loss of function (*functio laesa*), cardinal signs of inflammation.

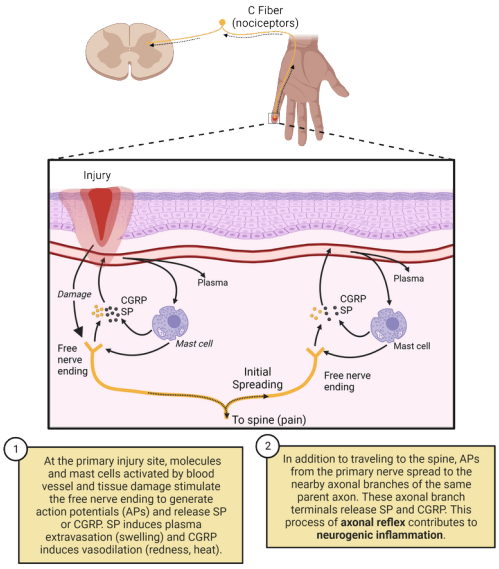

Figure 9.6 Local mechanisms of nociception

Other free nerve endings contain transient receptor potential (TRP) channels, which are temperature-sensitive mechanoreceptors. TRP channels open in response to temperature and come in a variety of types, each one sensitive to a different temperature. Figure 9.7 reviews the temperature sensitivities of several kinds of TRPs. Dr. David Julius, also pictured in Figure 9.7, shared the 2021 Nobel Prize in Physiology or Medicine for his description of these channels. Figure 9.8 shows an example of how heat causes a warm-sensing TRP channel to open, allowing in positive ions that activate the free nerve ending, which then relays signals to the brain via the spinal cord.

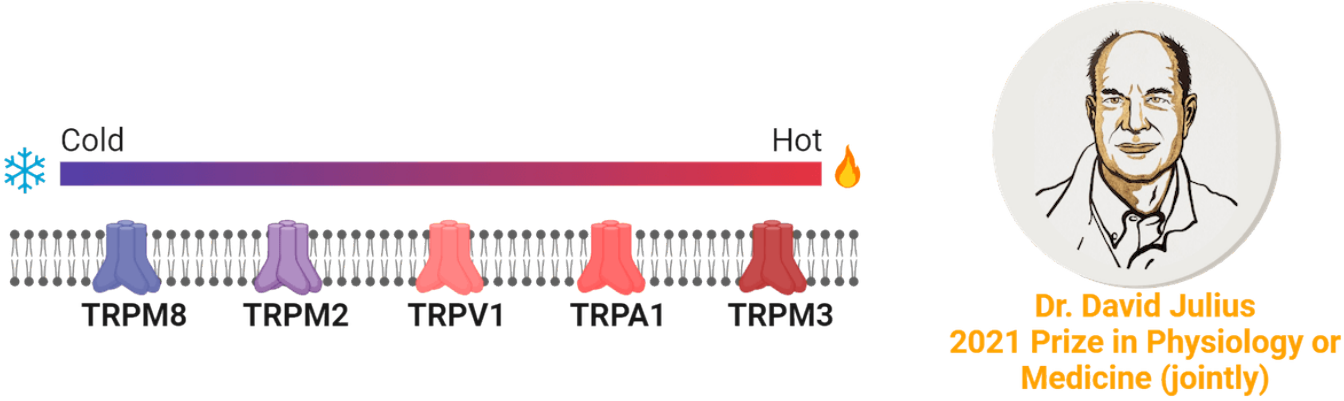

Figure 9.7 The TRP ion Channels Signals responsible for temperature and pain sensation are transmitted by transient receptor potential (TRP) channels that activate across different temperature ranges.

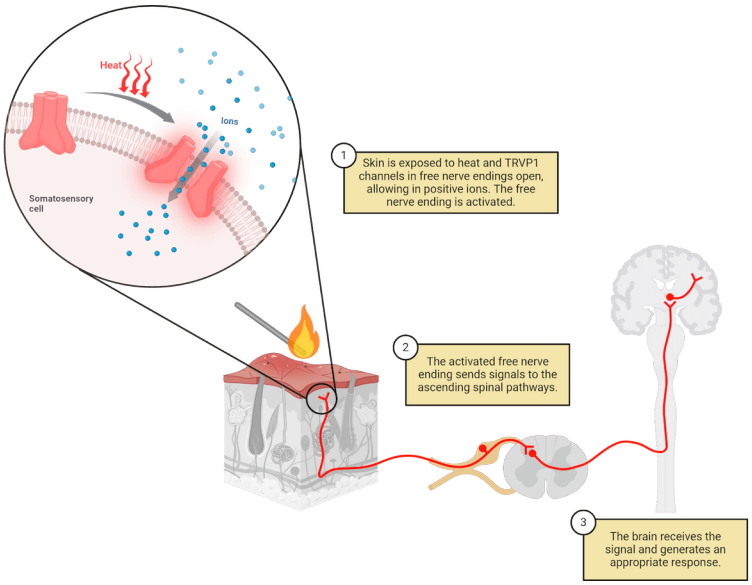

Figure 9.8 TRP channels transduce temperature information

One notable example of a TRP channel is the capsaicin receptor. Capsaicin is the key chemical ingredient in hot chili peppers. When it binds to the capsaicin receptors, it activates a TRP channel (Samanta et al., 2018) that allows calcium ions to flow into the cell, leading to depolarization (Caterina et al., 1997; Julius, 2013). This is the same channel activated by hot temperatures, which is why a spicy pepper feels hot . A similar, but separate TRP channel activates in response to cold temperatures, as well as chemicals in foods that feel cold, like mint. Activation of TRP channels, therefore, transmit information about temperature, and also are part of our experience of temperature sensations associated with a number of chemicals (see Chapter 8 The Chemical Senses).

Hair follicle mechanosensation

Throughout our body, the skin can be divided into hairy and glabrous skin (mainly on the palms and soles). In the hairy skin, an axonal terminal wraps around the bottom of the hair, the hair follicle, in the dermis. The reason why we can feel a breeze blowing across our faces is that all those tiny hairs (vellus hair, or peach fuzz) are bent by the airflow. The force is transduced to the hair follicles in the skin, causing the slightest displacement (in terms of nanometers). The follicle displacement causes a stretch of the axonal membrane wrapped around the follicle. There are many mechanosensitive Na^+ channels in this wrapping axon, which open in response to this stretch. That is how we can feel the movement of hair. If the hair is pulled too hard, it can generate pain.

Proprioceptors

Imagine that in the middle of the night, you feel thirsty. Without turning on the light, you extend your arm to reach for a bottle of water. Even though there is no visual guidance, you grab the water without knocking it over or missing and grabbing air. Your ability to accurately target your hand to that water bottle with little visual or touch feedback relies on your proprioceptors. These specialized receptors exist in various muscles, tendons, and joint capsules, providing information about body position and movement. The muscle spindle and Golgi tendon organ are two of the most prominent proprioceptors that you use every day (Proske, 1979; Boyd, 1980; Hulliger, 1984). The muscle spindle is a specialized muscle fiber that is activated by muscle stretch; whereas the Golgi tendon organ is located in the tendon to sense the tension during muscle contraction. These receptors are connected to large diameter, A-alpha fibers. Together, they give you constant information about the location and trajectory of your limbs through space. More information on these sensory receptors is in Chapter 10 Motor Control.

Primary afferents

As mentioned throughout the previous section, the different types of somatosensory receptors are connected to specialized axons with different diameters and myelination (Aβ, Aδ, C fibers, for example). Figure 9.9 shows the pathways these fibers take from the receptors (e.g., in the skin) into the spinal cord. These first-order axons are also called primary afferents (Crawford and Caterina,

2020). The cell body of the primary afferent fiber is located in the dorsal root ganglion (DRG), from which a pseudo-unipolar neuron sends out a parent axon that splits off into a peripheral branch and a central branch (Lin and Chen, 2018; Haberberger et al., 2019). The peripheral branch is long and projects to the skin where it receives signals from a specific receptor, whereas the central branch is short and enters the nearby spinal cord through the dorsal root. The short branch ends with synapses onto the spinal cord dorsal horn neurons where neurotransmitters are released, or projects directly up the dorsal column of the spinal cord toward the brain. The spinal cord neurons also project up to various levels in the brain.

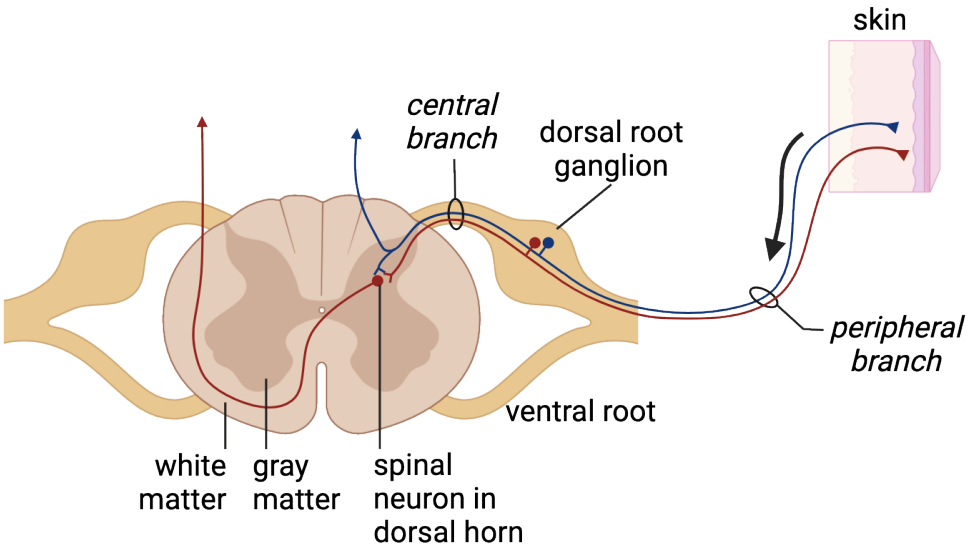

Figure 9.9 Primary sensory afferent anatomy Primary sensory afferents have cell bodies in the dorsal root ganglion. Their unipolar process splits into the peripheral branch, which goes to the sensory receptor and the central branch goes into the dorsal horn to synapse on spinal cord neurons.

While the primary afferents all follow a similar path to the spinal cord, they each propagate electrical signals along that path at different speeds. The A-fibers are a family of myelinated axons with different axonal diameters and extent of myelination. As we learned in Chapter 2 Neurophysiology, the larger the diameter, the faster the conduction of the action potential. Figure 9.10 provides a visualization of how these afferents compare in myelination and conduction speed. From large to small, they follow the order: Aα (12-20μm, 72-120 m/s), Aβ(6-12μm, 36-72 m/s), Aδ (1-6μm, 4-36 m/s), and unmyelinated C-fibers (0.2-1.5μm, 0.4-2 m/s). It is the difference of a racing car (120 m/s = 268 miles/hr) versus a fast walking (2 m/s = 4.5 miles/hr). Due to the difference in electrical signal conduction speed, even though both C-fibers and Aδ-fibers contribute to pain perception, Aδ-fibers are involved in fast and pricking pain, whereas C-fibers are involved in more slow and dull pain (Hunt and Mantyh, 2001; Julius and Basbaum, 2001).

2.5.3: Somatosensation in the Central Nervous System

Learning Objectives

By the end of this section, you should be able to

- 9.2.1 Describe the anatomy of the spinal cord, thalamus, and somatosensory cortices.
- 9.2.2 Define the ascending and descending pathways that are involved in transmitting somatosensory information.
- 9.2.3 Explain the Gate Control theory.
- 9.2.4 Describe how information flow to the limbic system contributes to the emotional response to pain.

From the cutaneous sensory receptors, action potentials travel through the dorsal horn to reach the lowest part of the central nervous system, the spinal cord. Axons with various levels of myelination and diameter synapse on the spinal cord dorsal horn or dorsal medulla neurons, then ascend to other levels in the brain, including the major relay station in the thalamus, and finally reach the primary somatosensory cortex where sensory perception happens. In this section, we will explain how sensory information is organized and processed from the dorsal horn of the spinal cord up to the brain, where we consciously perceive it.

Spinal Cord

The spinal cord is the lowest component of the central nervous system. It facilitates the transmission of body sensory information to the brain, as well as transmission of motor commands and autonomic nervous system modulation of internal organs from the brain to the body.

Anatomy of the spinal cord and dermatomes

The spinal cord has 31 segments, divided along the rostral-caudal axis into cervical (8), thoracic (12), lumbar (5), sacral (5), and coccygeal (1) segments. The spinal cord can also be divided into the dorsal versus ventral parts. While the ventral part is mainly involved in the processing of the motor system, the dorsal part is mainly sensory input. As covered in Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy and reviewed in Figure 9.11, in the spinal cord, the central part (shaped like a butterfly) is composed of neuronal cell bodies and dendrites (gray matter), which are surrounded by axons (white matter). Each segment of the spinal cord has two pairs of nerve bundles, the dorsal roots for sensory input and the ventral roots for motor output, as well as for sympathetic output. Because of this unique organization, the body surface is represented by different segments of the spinal cord, each of which is called a dermatome (Figure 9.11) (Joseph and Loukas, 2015). In the spinal cord, the primary afferent axons synapse on the spinal cord neurons, or head straight up to the brain. The dorsal horn neurons can be subdivided into several laminae (or layers), each of which relays specific aspects of touch (laminae III-V) or pain (laminae I&II).

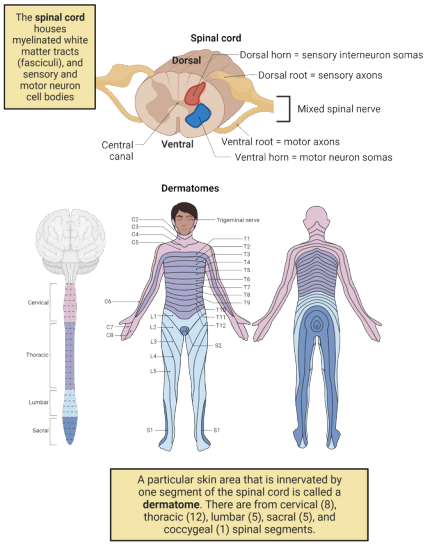

Figure 9.11 Spinal cord organization

Neurotransmitters and receptors in the spinal cord

A variety of neurotransmitters serve somatosensation in the spinal cord. Though we often represent touch information as traveling directly from the receptors on through to the brain, in reality, multiple types of neurons are involved in a complex communication within the spinal cord, helping to determine what sensory information is conveyed to higher centers in the brain or to local reflex circuits. The participating neurons include the primary afferent terminals we already discussed, along with descending fibers coming from the supraspinal origin, and intrinsic neurons inside the spinal cord. Neurotransmitters from each of these classes of neurons work in combinations to maintain the excitability of the spinal sensory neurons. In general, all primary afferent fibers use glutamate as the major excitatory neurotransmitter; Aδ fiber and C fibers also contain CGRP and SP, respectively. CGRP and SP can also be released in peripheral tissue by primary afferents, which we discussed earlier when we learned about their role in axonal reflex and neurogenic inflammation (Figure 9.6). Descending fibers and spinal interneurons can release a variety of neurotransmitters, many of which will sound familiar from other chapters, such as glutamate, GABA, neurokinins, nerve growth factor, ATP, neuropeptides (e.g., substance P), CGRP, bradykinin, cannabinoids, endorphins, cytokines, nitric oxide, ATP. These neurotransmitters interact with a variety of different types of receptors resulting in excitation, inhibition, or neuromodulation. The end result is a complex network of regulation within the spinal cord to determine what sensory signals pass to the brain and what signals do not.

Gate control theory

Gate control theory provides an example of the kind of communication that can occur within the spinal cord to determine what information is passed on to the brain. This theory was proposed by Ronald Melzack and Patrick D. Wall in 1965 (Melzack and Wall, 1965). It indicates that somehow in the spinal cord there is a gate that only allows so much information to flow forward to the brain at any given point in time. In this theory, a gate for pain information is controlled by two different types of inputs, neurons carrying primary sensory information (touch or pain), and an inhibitory interneuron, both of which combine to influence whether a projection neuron sends pain information towards the brain.

Figure 9.12 diagrams this theory. In this model, activity of a pain projection neuron is controlled by a nociceptive C fiber, as well as a non-nociceptive A-fiber and an inhibitory interneuron. In response to a painful stimulus, the unmyelinated C-fiber that is responsible for pain activates the projection neuron and inhibits the inhibitory interneuron in the spinal cord. Both of these activities open the gate to increase pain (Figure 9.12). The gate can be closed by the large myelinated A-fiber. The A-fiber, which transmits touch and vibration sensation, has 2 connections in this circuit: it excites the projection neuron weakly and it excites the inhibitory interneuron strongly. Strong A-fiber activation net inhibits the pain projection neuron through activation of more inhibitory interneuron activity in the spinal cord. This inhibition shuts down the gate, relieving the pain.

If you happen to hammer your finger, almost immediately you will shake your hand or rub or blow air to your injured finger to reduce pain. When you do this, you are using the “Gate Control Theory”. While shaking or rubbing, Aα/Aβ fibers are activated.

Although there is an increased input from C-fibers as the result of injury for increased pain, activation of Aα/Aβ fibers will excite more inhibitory interneurons that will release GABA to the projection neurons to counteract or inhibit the injury-elicited pain. Though there are some aspects of pain sensation that have been found to contradict the Gate Control theory since its proposal in 1965, it remains the single most critical model of pain sensation processes.

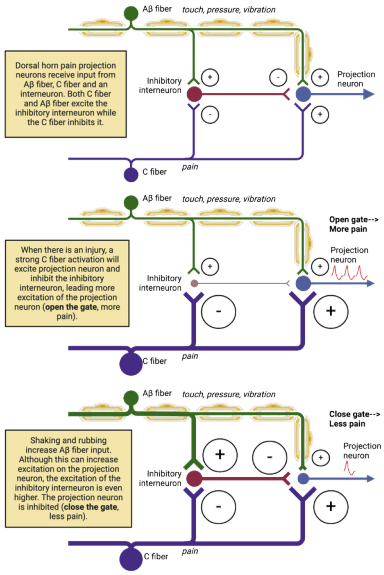

Figure 9.12 Gate control theory of nociception

Ascending pathways and their roles: from the spinal cord to the thalamus

As the sensory information comes to the spinal cord from the periphery, it will be processed inside the spinal cord first, then it will take two major systems to reach the brain. The first one is the dorsal column-medial lemniscal pathway for touch and pressure sensation and proprioception as shown in Figure 9.14. In this pathway, the primary afferent fibers ascend in the dorsal column ipsilaterally all the way to the medulla. They then synapse on the dorsal column nuclei in the medulla (i.e., nucleus gracilis and nucleus cuneatus). The axons from these dorsal column neurons in the medulla (2nd order neurons) project to the contralateral side to form a bundle, the medial lemniscus, which synapse on third-order neurons in the thalamus. From there, the thalamocortical projections from these thalamic neurons go to the primary somatosensory cortex (S1).

The second major pathway for somatosensation to the brain is the anterolateral system (i.e., located at the anterior and lateral part of the spinal cord), which originates in the spinal cord cells receiving pain and temperature input. The anterolateral system projects to the supraspinal areas through five main pathways (Willis, 1985; Willis and Westlund, 1997). The spinothalamic tract (STT) is the most prominent pain and temperature pathway (Figure 9.15). It originates from nociceptive-specific and wide dynamic range neurons in the dorsal horn of the spinal cord, and ends at the contralateral ventral posterolateral nucleus of the thalamus. Unlike the touch pathway, the STT crosses the midline in the spinal cord, at the same spinal level where primary afferents entered through the dorsal horn. In the STT, the projections from the spinal neurons proceed up the contralateral spinal column, to the thalamus.

Figure 9.13 provides a side-by-side comparison of this major difference in where each of these major pathways crosses the midline. Note how ascending touch information is in the ipsilateral spinal cord, while pain and temperature information is in the contralateral spinal cord to where the sensory information originated. For an interesting clinical implication of this difference between pain and touch pathways, try to do internet research on Brown-Sequard Syndrome and see if you can explain the clinical symptoms and signs.

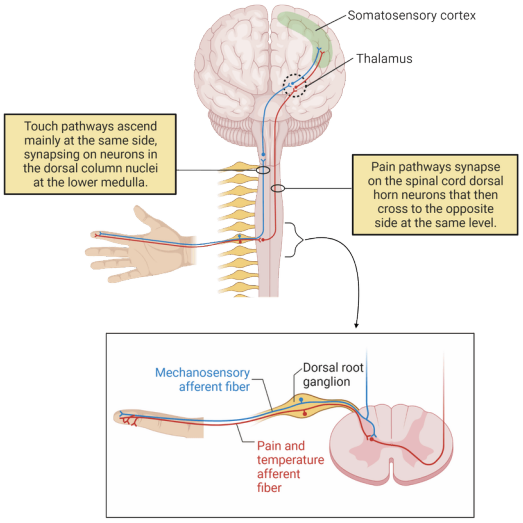

Figure 9.13 Pain versus touch pathways

The remaining four pathways of the anterolateral system deal mostly with emotional and autonomic aspects of pain, and frequently project bilaterally in the brain. They are the spinoreticular tract (arousal), the spinomesencephalic tract (affective components of pain), the spinohypothalamic tract (to the autonomic control centers for fight or flight), and the cervicothalamic tract (playing a minor role).

Because of these different tracts that contribute to the sensory information propagation from the periphery to the brain, we will be able to not only sense the location and the intensity of somatosensory input but also generate emotional responses. Imagine that you are hiking in the late afternoon. It is getting dark, and you are tired. Every step you have is almost automatic. Then you step into a pothole, and sprain your ankle... The C-fiber or Aδ-fibers around your ankle constantly send action potentials to your spinal cord, activating the dorsal horn neurons. Through STT system, your brain knows where the pain is coming from and how strong it is. Activation of the spinoreticular system will boost your arousal level (see Chapter 15 Biological Rhythms and Sleep), whereas activation of the spinohypothalamic system will raise your sympathetic activity to increase your heart rate and blood pressure. Finally, if you are lucky and have a strong network of descending inhibitory systems (see below), through the spinomesencephalic tract, brainstem structures will be activated and send inhibitory signals to the lumbar spinal cord to reduce the spinal cord dorsal horn neuron activity, a self-built “closed-loop feedback” system that helps the individual to cope with pain.

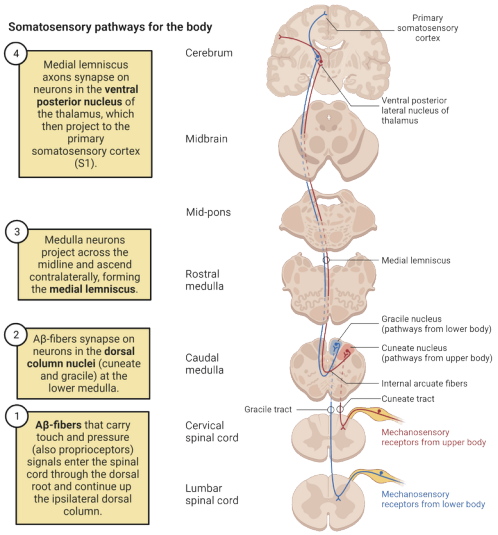

Figure 9.14 Somatosensory pathways for touch and pressure

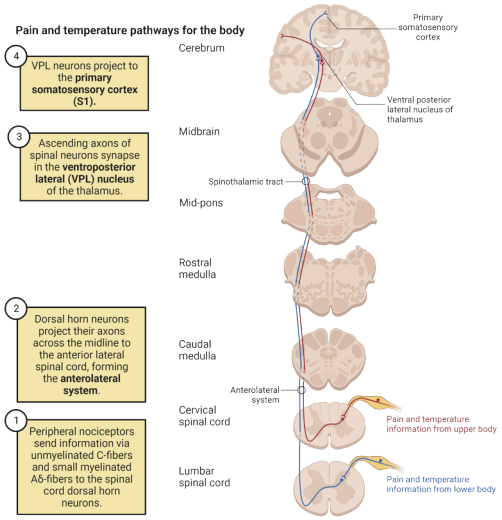

Figure 9.15 Pain and temperature pathways

Descending inhibitory pathways

As we mentioned in our earlier discussion of the neurons that control spinal-level transmission of sensory information, our brain is organized in a way to not only receive ascending input from the periphery, but also to manage inputs through a descending system sending projections downward at different levels (Sandkuhler et al., 1987; Jones and Gebhart, 1988; Millan, 2002). This protective measure enables the individual's ongoing performance without being distracted by pain. For example, when injuries happen to soldiers on the battlefield or athletes in sports competitions, they do not feel that much pain due to the strong activation of the descending inhibition. It is believed that the center controlling the descending inhibition is located in the periaqueductal gray (PAG) in the midbrain (Figure 9.16).

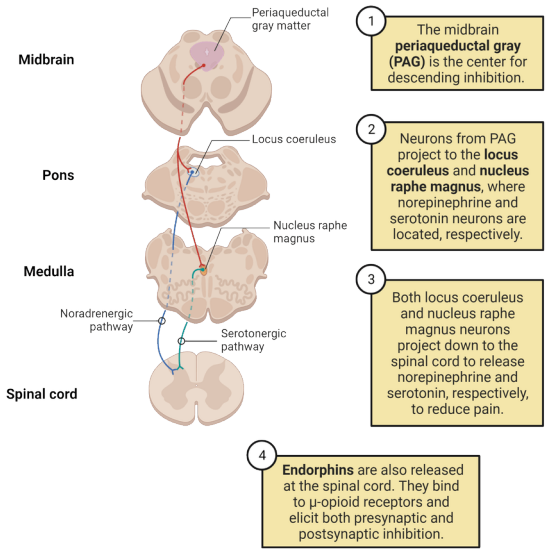

Figure 9.16 Descending pain modulation

Three major inhibitory systems contribute to the descending inhibitory system that originates in the PAG. The first one is the endogenous opioid system that releases endorphins, which can inhibit the activities of the spinal cord dorsal horn pain projection neurons to reduce or block signals to the brain. The second one is the serotonergic system, with the cell bodies located in the nucleus raphe magnus (NRM) in the brainstem, which projects their axons to the spinal cord at different levels to release serotonin. When serotonin binds to their receptors in the spinal cord projection neurons, it suppresses their activity. The third system is the noradrenergic system. The cell bodies are located in the locus coeruleus (LC), or 'blue spot', a structure in the

brainstem. The axons of the LC project down to the spinal cord and release neurotransmitter, norepinephrine/noradrenaline, which suppresses the activity of the spinal projection neurons. With the contribution of these three major descending inhibitory systems, a closed-loop of pain coping mechanism is established. However, it may vary from person to person. See more in emotional components of pain in the next main section.

Thalamus and other projections

The thalamus is the major gateway in our brain that processes not only somatosensory information but also auditory, visual, as well as gustatory information. There are several major subdivisions of the thalamus. It also contributes to modulating motor activities by communicating with the basal ganglion and the cerebellum. The major subgroup that relays the somatosensory information is the ventral posterior lateral (VPL) and ventral posterior medial (VPM) nuclei. The VPL is responsible for relaying signals coming from the trunk and extremities and is shown as the major relay in Figure 9.15. The VPM is just medial to the VPL and receives information from the head area. Neurons in either VPL or VPM are the third-order neurons that project to the primary somatosensory cortex (S1) for the perception of the sensory information in the body.

Cortical process of touch and pain

Somatosensory information first reaches the cortex in the primary somatosensory cortex (S1), in the postcentral gyrus in the anterior part of the parietal lobe. The sensory receptive areas of the body are represented on S1 as an inverted little person lying along the sulci and gyri of the cortical surface, shown in Figure 9.17. This person, known as a homunculus, is a distorted representation of a human body with the size of each body part proportionate to that area's amount of sensory innervation. For example, the hand requires more cortical resources, and it, therefore, gets more surface area (and more neurons) dedicated to its representation. S1 sends most of its projections to the secondary somatosensory cortex (S2) for further sensory processing, though there is also a communication between S1 and the motor cortices in the frontal lobe for sensory-guided motor function.

The mainstream of information after S1 and S2 flows posteriorly to reach the posterior parietal cortex, then to the temporal association cortex, parahippocampal cortex, and the cingulate cortex. The posterior parietal area receives information not only from the somatosensory cortex but also from auditory, and visual cortices. Information can therefore be integrated here from multiple modalities and then project to the prefrontal area where the integrated information can be analyzed, a decision can be made, and the motor response can be planned. Projections to the limbic system also play a critical role in processing our emotional response to somatosensory information, particularly pain or itch (Bushnell et al., 2013). The contribution of the combination of limbic system activities enables the individual to experience and integrate their emotion (e.g., anger, fear, anxiety, depression) in response to peripheral input (e.g., visual, sound, pain) or retrieval from the past experience (memory), to generate physiological responses (heart rate and blood pressure) or psychological experiences (Gilam et al., 2020). We will discuss this limbic component of pain more in the next section.

2.5.4: Pain and Itch

Learning Objectives

By the end of this section, you should be able to

- 9.3.1 Define pain.
- 9.3.2 Identify the different types of pain.
- 9.3.3 Describe the neural structures involved in emotional pain.
- 9.3.4 Describe the overlapping nature of brain areas that contribute to both pain and depression.
- 9.3.5 Explain the cause of itch and the difference from pain.

Pain and itch are specialized somatosensory experiences that are both transmitted by shared neural pathways that start with C- and Aδ fibers in the periphery. While pain can happen in the cutaneous as well as deep tissues, itch predominantly occurs in the superficial tissue, such as the skin. We already discussed the neural pathways of touch and pain in 9.1 Somatosensory Receptors. However, there are some unique aspects of pain and itch that require separate consideration, which we will discuss here. Pain, in particular, comes with a strong emotional component. In our example of getting stepped on while on the bus, a core part of the response to the pain is our feelings of anger. This emotional component of pain gives it relevance to a variety of diseases and disorders of the brain, as we will learn in this section.

Pain definition and types

Pain is defined as: “An unpleasant sensory and emotional experience associated with, or resembling that associated with actual or potential tissue damage (Raja et al., 2020).” Some of the key points included in this definition include that pain is always a personal subjective experience that is influenced to varying degrees by biological, psychological, and social factors. Although pain usually serves an adaptive role, it may have adverse effects on function and social and psychological well-being. Verbal description is only one of several behaviors to express pain; the inability to communicate does not negate the possibility that a human or a nonhuman animal experiences pain.

Pain can be subdivided into several categories depending on the duration (acute or chronic), location (e.g., lower back pain, migraine), and causes (nociceptive, inflammatory, or neuropathic). Nociceptive pain results from the direct activation of nociceptors in the skin or soft tissue in response to tissue injury and usually arises from accompanying inflammation. Neuropathic pain results from direct injury to nerves in the peripheral or central nervous systems and often involves a burning or electric sensation (reflex sympathetic dystrophy, postherpetic neuralgia, phantom limb, and anesthesia dolorosa). Although acute pain is usually protective, chronic pain serves no purpose but only makes patients miserable. Please see details for pain treatment in 9.4 Pain Relief.

Congenital insensitivity to pain

There is one genetically determined condition in which patients do not experience pain but do experience the normal sensation of light touch and deep tendon reflexes. It comes in two forms: congenital insensitivity to pain (CIP), or congenital insensitivity to pain with anhidrosis (CIPA). Insensitivity to pain in CIP is caused by mutation of the voltage-gated sodium channel α-subtypes Nav1.7, which are used heavily by pain fibers (Goodwin and McMahon, 2021; MacDonald et al., 2021). Because of the loss of protective mechanism provided by pain, children with CIP usually suffer multiple injuries on the body surface, joint damage, and bone fractures. In CIPA patients, in addition to the symptoms described above, they also experience anhidrosis (no sweat) as the result of sensory and autonomic neuropathy, leading to death within the first 3 years of life because of hyperpyrexia (high body temperature) (Rosemberg et al., 1994; Gong et al., 2021). The example of CIP is instructive for the adaptive value of pain. Though the subsequent sections will describe maladaptive aspects of pain, the root value of pain as a survival signal should not be forgotten.

Psychological contribution to pain

Pain involves not only physiological processes but also emotional responses, cognitive evaluations, and behavioral responses. Both physiological and psychological factors are integrated into the experience of pain and our emotional, cognitive, and behavioral responses to it (Gamsa, 1994; Baliki et al., 2006; Borsook and Becerra, 2009; Linton and Shaw, 2011; Bushnell et al., 2013; Gilam et al., 2020). These two factors are so intertwined that pain in the absence of injury, which is assumed to be purely psychological, activates similar brain pathways as pain originating in bodily damage. The feedback between psychological responses to pain and subsequent perception of pain is complex and extensive.

Pain disorders demonstrate the complex interchange between psychological responses and pain perception. Both physical pain from injury and pain that is psychological in origin can lead to pain disorders, or the experience of severe stress due to chronic, debilitating pain. The American Psychiatric Association (2022) recognizes this with two psychiatric diagnoses associated with pain in the Diagnostic and Statistical Manual of Mental Disorders V-TR: pain disorder associated with psychological factors either with or without a diagnosed medical condition (medical conditions such as rheumatoid arthritis, appendicitis, fractures, sprained ankle, infections, cancer, etc.). As these diagnostic categories imply, both psychological factors and a general medical condition have important roles in the onset, severity, exacerbation, and maintenance of pain. As an example, it has been found that pain (such as that from an injury or physical illness) attracts attention and that increased attention to pain also enhances the painfulness of nociceptive stimulation. This positive feedback loop (pain begets attention, which begets more pain) is attributed to the reduction of activation in key regions of the pain matrix, including the thalamus, insula, and parts of the anterior cingulate. Of course, psychological processes (such as distraction) can also reduce pain perception. The areas involved in distraction during the processing of nociceptive stimulation seem to be mediated by a prefrontal–cingulate top-down modulation of the brainstem structures. The inhibition of ascending nociceptive input comes from the powerful descending pain modulatory pathways originating in structures such as the amygdala, hypothalamus, insula, anterior cingulate cortex, periaqueductal grey, and rostroventral medulla. Projections from these higher structures contribute to descending inhibition of spinal cord dorsal horn neurons, reducing incoming transmission of pain information.

Limbic system contribution to emotional aspects of pain

The limbic system forms a rim (Latin limbus) in the medial wall of the hemispheres (Rolls, 2015). It includes the various cortical areas that make up the limbic lobe (especially medial areas of the temporal and frontal lobes) and the subcortical regions connected with these cortical areas, such as the amygdala and hypothalamus (Chapter 13 Emotion and Mood). Somatosensory system input to the limbic system is what makes things like itch or pain feel unpleasant and causes people to feel agitated, angry, or depressed. Figure 9.18 shows one example of how sensory information such as pain can influence limbic structures, which in turn help create subjective feelings and coordinate bodily responses. – Do you still recall the hypothetical situation if someone steps on your toe twice (at the beginning of this chapter)? Activation of your limbic system is a key step in creating your emotional response to the painful toe steps.

This connection between pain and emotion-associated brain regions may be relevant to psychiatric disorders. For example, there is quite an extensive overlap between the neural circuitry active in chronic pain and the network of some psychiatric disorders. Both circuitries for chronic pain and depression, for instance, can show similar activation patterns. On the other hand, reduced prefrontal activity often observed in schizophrenia patients can suppress the experience of pain.

Sex as a biological variable: Sex Differences in Pain Process

In addition to factors such as medical conditions and psychiatric disorders, there is another important factor that affects pain perception and processing: genetic/hormonal sex (see Chapter 11 Sexual Behavior and Development). In humans, several clinical pain conditions are more prevalent in women than men, such as pain conditions involving the head and neck, of musculoskeletal or visceral origin, and of autoimmune cause. The greater rates of these disorders in women suggests potential sex differences in pain systems, something which experimental studies of pain perception have confirmed. Specifically, in studies where people are exposed to the same painful stimulus (such as dunking your hand in ice water), women are on average more sensitive to pain, and report pain more frequently, for longer duration and of greater severity than men (i.e., lower threshold and tolerance in some modalities of pain). The average greater sensitivity of women to painful stimuli occurs across modalities: women report more sensitivity to thermal, pressure, electrical, and chemical stimuli than men. These findings imply sex differences in pain perception do not rely on a single sensory pathway.

Sex differences are also evident in pain experience in animal models of nociception, suggesting that at least some of the differences in humans are not about gendered human socialization but have evolutionarily conserved roots across species (Sorge & Strath, 2018). A common way pain is tested in animal models is a simple reflex withdrawal behavior. In these kinds of tasks, animals are exposed to something that could become painful, such as an increasingly hot surface or an increasingly sharp and strong poke on the paw. Researchers start with a low level of the potentially painful stimulus and then increase it over trials to see when the animal starts to withdraw (pulling its paw away, for example). When withdrawal happens, the interpretation is that the stimulus has reached a level of being painful. Interestingly, in tasks like reflex withdrawal, rodents do not show sex differences under normal circumstances. However, in models where the animals show preexisting inflammation or nerve injury, females show greater reflex withdrawal responses to the same level of stimulus (Cook & Nickerson, 2005; Dance, 2019; Dominguez et al., 2009; Gaumond et al., 2002; Kim et al., 1999; LaCroix-Fralish et al., 2005; Lu et al., 2009; Mogil, 2020; Presto et al., 2022; Wang et al., 2006). Many biological factors have been found to contribute to these kinds of sex differences in nociceptive behavior, such as genetics or gonadal hormone differences and experimental variables (e.g., type of test and tissue tested). In humans, sex differences in pain probably stem both from the types of differences in immune and hormonal systems (e.g., menstrual cycle) that we can model in animals, as well as from biopsychosocial factors that are more unique to humans (Fillingim et al., 2009; Greenspan et al., 2011; Hoffmann et al., 2022; Racine et al., 2012a, 2012b; Ruau et al., 2012).

Chronic pain and depression

While brief pain may help us in many situations, chronic pain is almost always detrimental. Based on the criteria of the Diagnostic and Statistical Manual of Mental Disorders, chronic pain can be associated with broad categories of other clinical conditions (co-morbidity), including affective disorders, anxiety disorders, post-traumatic stress disorder, substance dependence, sleep disorders, cognitive disorders, malingering, personality disorders, suicidality, fatigue, obesity, etc. Here, we will further discuss the link between chronic pain and depression, which is prevalent and well-established.

Chronic pain and depression are intertwined with each other. About 8% of the U.S. population is depressed. In contrast, of those with chronic pain, 18–35% have been reported to be depressed and 6.3% have a major depressive disorder (MDD). Conversely, when surveying people with MDD, painful physical symptoms have been reported to occur in 50–66.3% of patients, a rate which is much higher than in the general population. Research into the connection between chronic pain and depression has revealed numerous clinically important facets to their interdependence: 1) depression is associated with chronic pain; 2) chronic pain can exacerbate depression; 3) in predisposed individuals, pain may be etiologically related to the onset of depression; 4) depression can affect pain perception; 5) treatment of depression can improve disability, and 6) improving pain can improve depression.

The intertwining of depression and chronic pain seems to be rooted in shared monoamine neurocircuitry. For example, it has been found that the dysfunction of the brain's serotonin system is related to both pain and depression (Bair et al., 2003; Hilderink et al., 2012; IsHak et al., 2018; Zhou et al., 2019). Serotonergic system dysfunction is associated with depression and many mainstream treatments of depression target serotonin. Coincident with this role in depression, the serotonergic neurons of the dorsal raphe nucleus send serotonergic afferents to and receive input from limbic structures involved in cognitive and emotional functions. However, dorsal raphe serotonergic neurons also send projections to the spinal cord via descending pathways, resulting in inhibition of spinal nociceptive processing. Serotonergic activity can therefore not only regulate mood states, but also reduce pain perception. There is likely a similar role for norepinephrine systems as well. As evidence of the role of serotonin and norepinephrine in chronic pain, venlafaxine and duloxetine, both selective serotonin and norepinephrine reuptake inhibitor antidepressants, have demonstrated efficacy in reducing pain in patients with diabetic neuropathy. These findings are a good reminder how important it is to always keep in mind the role of the limbic system in regulating not just psychological or psychiatric disorders but also our perception of pain (Figure 9.18).

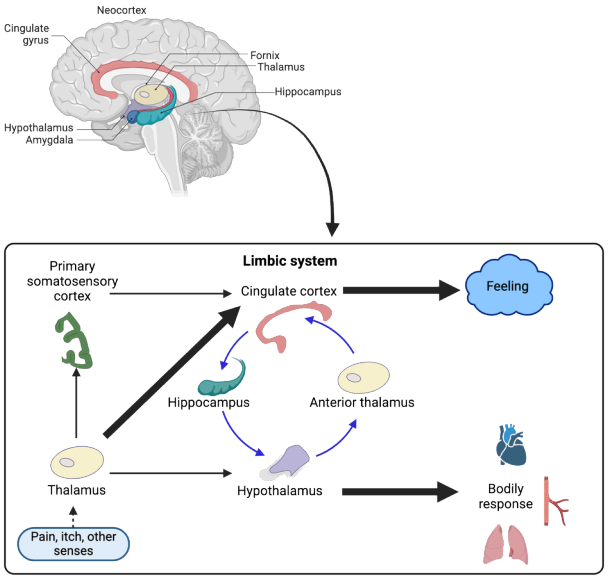

Figure 9.18 Limbic system response to somatosensation Areas in the temporal and frontal lobes contribute to the limbic system, which is critical to emotional responses to somatosensory stimuli, especially pain. Itch mechanisms and treatment

Itch sensation (also known as pruritus) plays an important protective role for an individual just like pain. Itch lets us know there is something unexpected and possibly dangerous on our skin, such as a parasite or foreign plant matter. Itch is thus useful because it directs you to scratch the itchy area and remove whatever is irritating your skin. However, as with chronic pain, chronic itch can disable an individual. The neural mechanisms for itch sensation are not fully understood. As a mechanism for the itch, some neurotransmitters or peptides (such as histamine and cowhage spicules) are suggested to bind to their specific receptors on free nerve terminals underneath the skin, thereby stimulating C-fiber and Aδ-fibers (Ikoma et al., 2006; Potenzieri and Undem, 2012; Bautista et al., 2014; Lamotte et al., 2014). But transmission from there to the spinal cord, as well as to the brain, is unclear.

Let's use a mosquito bite as an example of what we do understand about itch (Figure 9.19). The mosquito saliva contains proteins that are immunogenic to humans. By triggering a local immune response, mast cells are aggregated around the biting site and release histamine. Histamine increases the permeability of the capillaries, leading to bumps, and increases vasodilatation, leading to redness. It also binds to histamine receptors (especially the H1 subtype) to activate a G-protein, in turn causing depolarization of primary C-fiber and Aδ-fibers afferent terminals, leading to the sensation of itching.

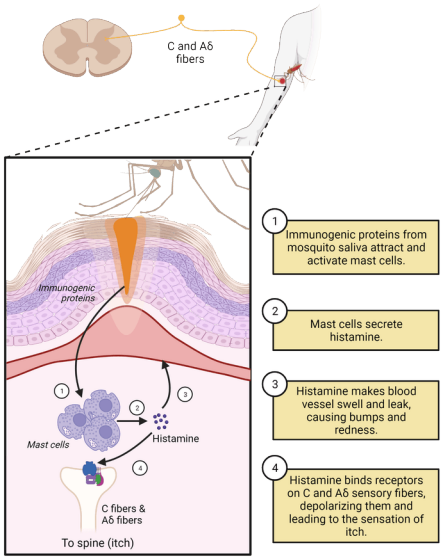

Figure 9.19 Local mechanisms of itch

Cowhage is a bean-like plant that provides another example of itch-inducing stimuli. The tiny needle-like spicules on the pods are the ones that cause itch from cowhage. Insertion of cowhage spicule(s) into the superficial skin is frequently applied as an itch model in research. The active component of cowhage, termed mucunain, is a novel cysteine protease (Reddy et al., 2008). By binding to the protease-activated receptors (PAR) a member of the G-protein coupled receptor family, it mobilizes Ca^{2+} ions and excites the C-fibers and Aδ-fibers nerve terminals. Both of these examples demonstrate our understanding of major itch mechanisms at the level of skin receptors.

How itch transmits and is processed within the central nervous system is unclear. The sensation of the itch is transmitted much slower than the sensation of touch and, though itch appears to use C-fibers (pruriceptors) and Aδ-fibers, it does not seem to be a subclassification of pain. There exist two lines of evidence that itch is different from pain. (1) Vigorous scratching produces mild pain and pain inhibits itch. (2) Opiates reduce pain and increase itch. This inhibitory relationship between pain and itch is evidence that itch is not a type of pain. In addition, molecules that induce pain do not elicit an itch sensation or vice versa (Lamotte et al., 2014). When primary afferent activity relaying itch reaches the spinal cord, it has been suggested that the spinal parabrachial pathway plays a critical role in itch processing that leads to itch-induced scratching behaviors (Bautista et al., 2014; Mu et al., 2017; Dong and Dong, 2018). Yet, we still understand very little about how it signals centrally.

The treatment of minor itch includes: Applying cold compresses, using moisturizing lotions, taking lukewarm or oatmeal baths, using over-the-counter hydrocortisone cream or antihistamines, and avoiding scratching, wearing irritating fabrics, and exposure to high heat and humidity. For severe or chronic itch, prescribed medication, including antihistamines and topical steroids, or more rarely steroid pills and antibiotics, may also be needed.

2.5.5: Pain Relief

Learning Objectives

By the end of this section, you should be able to

- 9.4.1 Describe several pain treatment strategies.
- 9.4.2 Define what a placebo is.
- 9.4.3 Differentiate between pain treatment modalities and their mechanisms of action.

There are various ways to treat pain. For acute pain, people can use over-the-counter medication including acetaminophen, aspirin, and ibuprofen. Physical therapy, massage, acupuncture, etc. are also popular, widely available pain relievers. In more severe cases, a prescription drug can be used, such as potent and effective opiate medication. Of course, though opioids are effective, they are also highly addictive, and users quickly develop tolerance, causing them to use more and more (see Chapter 14 Psychopharmacology). The recent opioid epidemic in the United States is a result of these properties of opioids, which lead people to overdose after consuming higher and higher doses.

In most cases, if the pain is due to infection of the tissue, or actual injury of the tissue, after the infection is treated or the injury is healed, the pain will be relieved. If pain is not relieved after healing, and chronic pain emerges, there are several treatments available beyond those typically used for acute pain. Opioids are one possibility, though the potential for addiction is high when taken chronically. For some people, an integrative biopsychosocial cognitive therapy can be helpful (Gatchel et al., 2007). Some non-invasive treatments are also potentially useful, such as magnetic stimulation, transcranial electrical stimulation, and transcutaneous electrical nerve stimulation (TENS). If any of these treatments are not effective in relieving chronic pain, surgical intervention, or implantation of electrodes for electrical stimulation in peripheral nerve, spinal cord, or brain areas will serve as the last option. In this section, we will review these major approaches to pain management

Placebos

One of the most perplexing aspects of pain treatment is the placebo effect—this is when pain is relieved just because someone *think*s they are receiving treatment, even when the "treatment" does not actually have any biological action on its own. A placebo is, by definition, inactive, and yet produces analgesia, i.e., pain relief (Klinger et al., 2014, 2018; Wager and Atlas, 2015; Mundt et al., 2017; Schafer et al., 2018; Vase and Wartolowska, 2019). (See Chapter 14 Psychopharmacology). A placebo can take the form of a dummy tablet, nasal spray, sham surgical procedure, magnetic treatment, or topical cream. The fact that the most effective analgesic placebo manipulations are (1) the presence of sensory cues that have been associated with effective treatment or pain relief in the past and (2) the expectation of pain relief, suggests that placebo effects are tied to learned associations with previous pain relief.

A placebo analgesic effect can be elicited acutely in a very large percentage of individuals in both experimental and clinical contexts. In many ways, the effect of a placebo is very real. Placebo analgesia has been linked with activity in the prefrontal cortex, and endogenous opioid release in both the descending antinociceptive systems and forebrain structures. In addition, placebo-induced reduction of responses to noxious stimulation in regions of the anterior cingulate and insular cortex, thalamus, and spinal cord correlate with reported pain relief. Placebo analgesic effects have been consistently demonstrated for pain conditions, such as dental postoperative pain, post-thoracotomy pain, low back pain, IBS pain, chronic neuropathic pain, and experimental somatic pain caused by noxious heat, electric shock, intramuscular saline injections, and exercise under ischemic conditions. Proper estimation of the placebo effect during the treatment of pain should be carefully considered, due to ethical issues. And just because the placebo effect can provide genuine relief of pain temporarily, it should not be relied on as a clinical tool by itself.

Over-the-counter treatments, physical therapy, and massage

The easiest and most common starting point to treat pain is over-the-counter (OTC) drugs, which mostly work by reducing inflammation. Aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs) like ibuprofen (Motrin), and acetaminophen (Tylenol) work by blocking the production of inflammatory molecules, which in turn reduces pain, inflammation, and fever. While the inflammatory response is critical to fighting pathogens and stimulating tissue healing (see Chapter 17 Neuroimmunology), it

can also go overboard, lasting too long (chronic pain) or being too intense (excessively high fever). Anti-inflammatory NSAIDS can therefore be an effective and beneficial tool that reduces pain while facilitating recovery. Physical therapy and massage (e.g., physical manipulation of the area, ultrasound therapy, thermal therapy, dry needling, etc.) can work by relaxing and/or strengthening muscles that modulate sources of pain. In addition, traditional Chinese acupuncture is an alternative option. It involves the insertion of extremely fine needles into the skin at specific "acupoints." This may relieve pain by releasing endorphins, or through activation of the Gate Control theory.

Opioids and endorphins

The use of opium as a drug dates back thousands of years BC. Morphine is one of the oldest drugs known and has become the “gold standard” analgesic to which all others are compared. Opioids produce their analgesic effects by binding to their three main (or “classic”) opiate receptors—mu, delta, and kappa–as well as one more recently identified ORL1 receptor. These receptors are located at a number of sites within the central nervous system, including the spinal cord and several specific supraspinal structures (Corder et al., 2018; Bagley and Ingram, 2020). These receptors do not exist to respond to opioid drugs, of course. They evolved to respond to our own endogenous opioid-like neurotransmitters, endorphins. Endorphins (β-Endorphin, enkephalins, dynorphins, nociceptin/orphanin FQ) bind to mu, delta, kappa, and ORL1 receptors, respectively (see Chapter 3 Basic Neurochemistry). Table 9.2 reviews the major endogenous opioids and also introduces morphine and naloxone as major exogenous opiates. While morphine (the agonist) mainly binds to the mu receptor, naloxone (the mu receptor antagonist) blocks all three receptor sites. Naloxone is most commonly used to counteract opiate overdoses in emergency settings. It can restore breathing in someone who has slowed or stopped normal breathing due to excessive intake of opioids such as heroine, fentanyl, oxycodone (OxyContin®), hydrocodone (Vicodin®), codeine, and morphine. It does this by out-competing the ingested opioid to bind to receptors, stopping current receptor activation and preventing further activation while the body metabolizes the remaining ingested opioid.

Classic endogenous (see Chapter 3 Basic Neurochemistry)			
Family	**Precursors**	**Peptides**	**Receptors**
Endorphins	Proopiomelanocrtin (POMC)	α-Endorphin β-Endorphin γ-Endorphin	μ-Opioid
Enkephalins	Proenkephalin (PENK)	Met-Enkephalin Leu-Enkephalin	Δ-Opioid μ-Opioid
Dynorphins	Prodynorphins (PDYN)	Dynorphin A Dynorphin B α-Neoendorphin β-Neoendorphin	κ-Opioid
Exogenous opiate system drugs			
Drug	**Precursor**	**Action**	**Receptors**
Morphine	Opium	Agonist	μ-Opioid
Naloxone	Morphine	Antagonist	μ-Opioid Δ-Opioid κ-Opioid

Table 9.2

All opioid receptors are activated through G protein-coupled receptor (GPCR) mechanisms (see Chapter 3 Basic Neurochemistry). Via GPCRs, opioids inhibit voltage-dependent calcium channels or activate inwardly rectifying potassium channels, thereby decreasing neuronal excitability. Opioids also inhibit the cyclic adenosine monophosphate pathway and activate mitogen-activated protein kinase cascades, both activities affecting cytoplasmic events and transcriptional activity of the cell.

Figure 9.20 summarizes the changes at the level of nociceptor neurons and the spinal cord due to opiate exposure. The left side of the image shows normal sensory input from a nociceptor neuron to a spinal projection neuron. The right side shows the changes that occur in both the nociceptor neuron primary afferent and projection neuron with opiates present. Opiates like morphine or endorphin can bind to the mu receptors in the presynaptic terminals of the primary afferents, or to spinal

cord projection neurons. Binding to the presynaptic terminals elicits presynaptic inhibition, leading to reduced neurotransmitter release (e.g., glutamate or SP); on the other hand, binding to projection neurons will directly inhibit their activity. Both presynaptic and postsynaptic inhibition contribute to spinal analgesia.

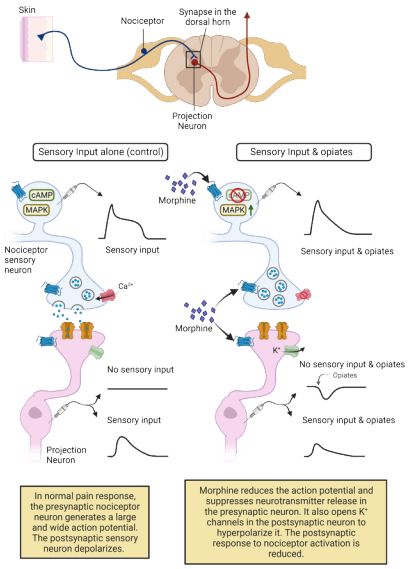

Figure 9.20 Opioid receptor mechanism in the spinal cord

Opiates also have effects at supraspinal sites such as the thalamus, the amygdala, and the sensory cortex. Opiate activity in these areas are likely to play key roles in the overall analgesic state. The midbrain and brainstem structures (i.e., the periaqueductal gray [PAG] and the rostroventral medulla [RVM]) are particularly important central regions where opioids act. We first learned about these regions as part of the descending inhibition pathways for pain (Figure 9.16). Figure 9.21 shows how direct injection of morphine into either of these sites causes antinociception (pain relief) via increased activity in the descending inhibitory effect on the dorsal horn of the spinal cord.

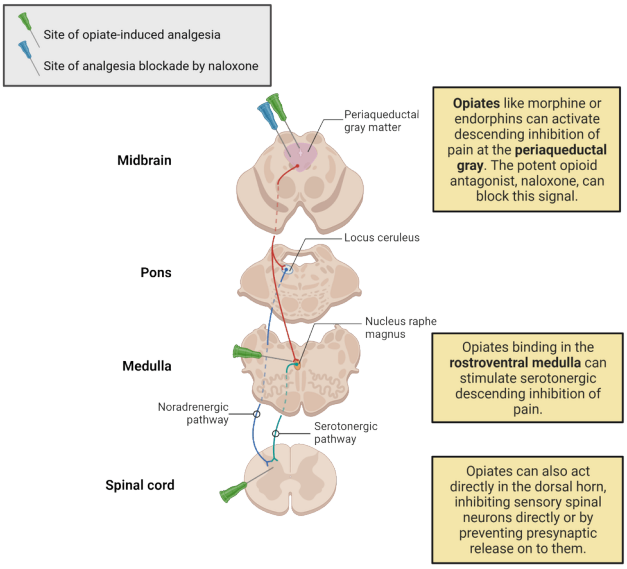

Figure 9.21 Central analgesia targets

Cannabinoids

Marijuana is from a plant called hemp. Its main, active ingredient is THC (short for delta-9-tetrahydrocannabinol). THC is active in modulating pain because it interacts with our endogenous cannabinoid (endocannabinoid) system. The most commonly studied endocannabinoid systems include anandamide, and 2-arachidonylglycerol (2-AG). Both anandamide and 2-AG bind to receptors

(cannabinoid receptor-1, and -2 (CB1-R, CB2-R)) found throughout the body and nervous system. CB1-Rs are mainly in the brain, particularly in the substantia nigra, the basal ganglia, limbic system, hippocampus, and cerebellum, but are also expressed in the peripheral nervous system. Figure 9.22 shows an example of CB1-R distribution in the human brain. CB2-Rs are mostly expressed in immune cells, the spleen and the gastrointestinal system, and to some extent in the brain and peripheral nervous system.

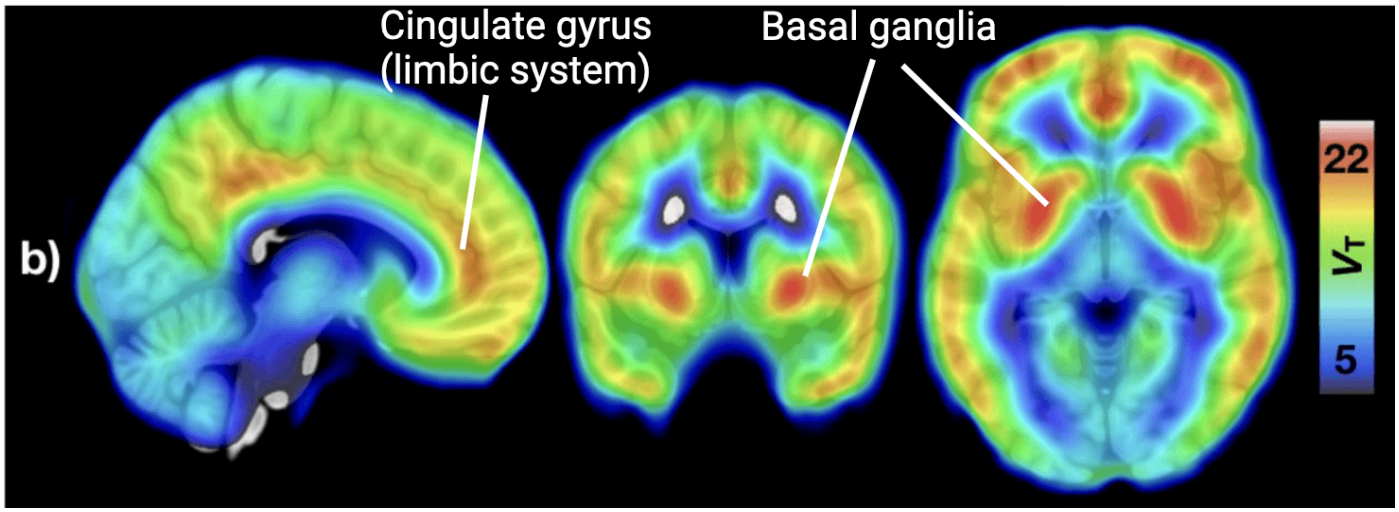

Figure 9.22 Cannabinoid receptor distribution Binding of CB1 receptor averaged over 35 men shows high binding in many brain regions, including basal ganglia and cingulate gyrus. Image credit: Kantonen, T., Karjalainen, T., Pekkarinen, L. et al. Cerebral μ-opioid and CB1 receptor systems have distinct roles in human feeding behavior. Transl Psychiatry 11, 442 (2021). https://doi.org/10.1038/s41398-021-01559-5. CC BY 4.0

CB1-R modulates pain signaling in several regions in the peripheral and central nervous system, including the primary afferent terminals, the dorsal root ganglion (DRG), the dorsal horn of the spinal cord, the periaqueductal gray matter, the ventral posterolateral thalamus, and cortical regions associated with central pain processing, including the anterior cingulate cortex, amygdala and prefrontal cortex (Hill et al., 2017). Figure 9.23 shows how CB receptor activation inhibits presynaptic release, a reminder of processes we learned about in Chapter 3 Basic Neurochemistry. Through activation of the G-protein mechanism, CB1-Rs modulate the activity of a number of ion channels via inhibiting presynaptic voltage-dependent Ca^{2+} channels to reduce synaptic vesicle release, and also opening inwardly rectifying K^+ channels to hyperpolarize the presynaptic terminal.

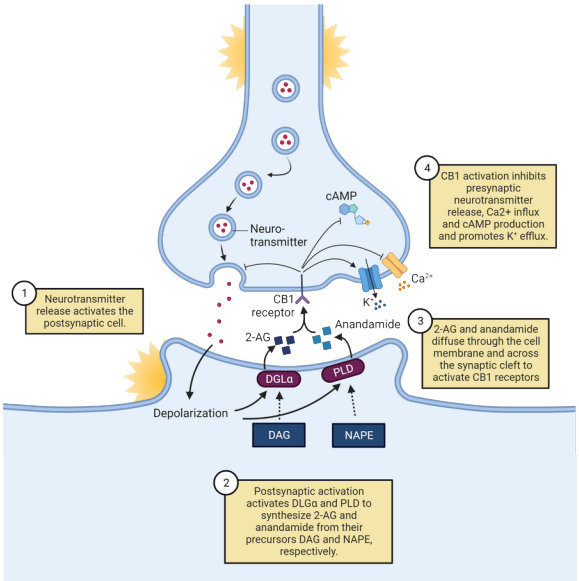

Figure 9.23 Function of endocannabinoid receptors

The net consequence of the CB1-R is therefore to augment membrane hyperpolarization and inhibit the release of neurotransmitters in several central and peripheral regions responsible for mediating pain signals. Exogenous cannabinoids, such as the THC in marijuana, can tap into this endogenous pain modulation network by activating CB receptors in the brain, spinal

cord, and peripheral sites. For example, cannabinoid-induced analgesia has been demonstrated for both neuropathic pain and cancer pain (Atakan, 2012; Whiting et al., 2015; Stockings et al., 2018; Lossignol, 2019; Bouchet and Ingram, 2020; Finn et al., 2021).

Capsaicin

Capsaicin is the main active ingredient of the hot chili pepper. We first introduced the capsaicin receptor when we learned about its role in activating temperature sensitive TRP channels. TRP channels belong to a superfamily of 28 cation permeable channels and each one is sensitive to a specific range of temperatures (Samanta et al., 2018). Many of them also activate in response to specific chemicals. In 2021, a Nobel prize was awarded to the scientist who discovered a TRP channel that specifically responded to capsaicin (Caterina et al., 1997) (see Figure 9.7). This transient receptor potential vanilloid type 1 (TRPV1, formerly VR1) receptor is also activated by heat and protons (lower pH or acidic). It is located in both peripheral and central nervous systems. In the PNS, it is mainly presented in the C-fibers and Aδ fibers.

TRPV1 channels are non-selective cation channels that are permeable to Ca^{2+}, Na^{+}, and K^{+}, meaning they net depolarize a cell. Activation of enough TRPV1 channels can ultimately result in action potential generation, leading to nociception. Interestingly, although the sensation associated with capsaicin in the short term is pain, in the long term, repeatedly treated tissue can become desensitized to subsequent noxious stimuli. Excessive Ca^{2+} influx leads to excitotoxicity (literally death from too much excitation) that causes nerve degeneration and loss of pain sensation. It has been found that baby rats treated with capsaicin lose their nociceptive behavior after they grow up (Ruda et al., 2000; Peng et al., 2003). This property has been explored for analgesic purposes (try to find capzasin cream over the counter in any pharmacy). This is also why people can build up a tolerance to spicy foods by eating them repeatedly.

Surgical treatment

Surgical approaches to treating pain fall within four broad classes: decompression, reconstruction, ablation, and modulation.

Decompression procedures are commonly performed to release entrapped sensory structures and potentially relieve pain. For example, carpal tunnel for the median nerve and fibular head for the common peroneal nerve is the most common place where the nerve can be compressed leading to pain. Cutting the carpal tunnel ligament can release the compression of the median nerve, which in turn, relieves pain.

Reconstruction refers to attempts to directly repair injured neural elements, such as the nerve grafting following peripheral nerve transection or nerve root replantation following brachial plexus avulsion (a tear of the nerve roots from the cervical segments due to extensive lateral bending of the head or pull of arm).

Ablation procedures aim to disrupt or transect the pain-signaling pathways in the periphery (e.g., peripheral neurectomy, dorsal rhizotomy, dorsal root ganglionectomy), spinal cord (e.g., anterolateral cordotomy, to cut the anterior lateral part of the spinal cord), brainstem, or pain-processing centers in the diencephalon and telencephalon. Cingulotomy (disconnecting the cingulate cortex from the rest of the brain) is a CNS ablation technique that evolved from frontal lobotomy (chop off a part of a lobe) that was developed to avoid the neurocognitive complications of lobotomy. The anterior cingulate cortex is a structure that has been implicated in contributing to the emotional aspects of pain. However, caution should be taken since bilateral cingulotomy for chronic pain showed side effects of worse executive function, attention, and self-initiated behavior, though language, motor control, and memory were not affected.

Modulation aims to alter pain signaling or processing either electrically (nerve stimulators) or pharmacologically (intrathecal drug pumps). The next section discusses stimulation-based pain relief in more detail.

Electrical/magnetic stimulation

Electrical stimulation of nerves, spinal cord, and/or brain can be used to relieve pain. Magnetic stimulation of the brain has also been successfully used to treat pain (Tan and Kuner, 2021).

Peripheral nerve stimulation can be used to relieve pain via both invasive and non-invasive methods. Transcutaneous electrical nerve stimulation, TENS, is a non-invasive method for stimulating the peripheral nerve. In TENS, electrodes on the skin transmit small electrical pulses to provide pain relief (Figure 9.24).

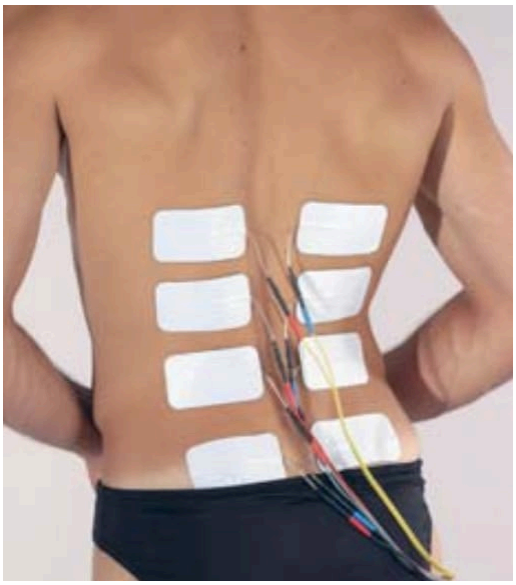

Figure 9.24 Transcutaneous electrical nerve stimulation for pain In transcutaneous electrical nerve stimulation, electrodes are placed on the skin and small electrical pulses are delivered to relieve pain. Image credit: By Wisser68, CC BY-SA 3.0, https://commons.wikimedia.org/w/inde...curid=30217768)

Spinal cord stimulation (SCS) emerged as a direct clinical application of the gate control theory of Melzack and Wall published in 1965. It was designed to be effective in suppressing pain of a nociceptive nature (both acute and chronic), and has been in use since the early 1970s. It is now one of the mainstream treatments of neuropathic pain. This technique is based on the original idea that antidromic (against the action potential propagation direction) stimulation of the large fibers in the dorsal columns may activate the proposed gating mechanisms in the dorsal horn. It is also called dorsal column stimulation because of this focus on stimulating dorsal pathways. Figure 9.25 shows an example of this kind of electrode placement. The frequency is usually 60–100 Hz, and the pulse width is between 100 and 500 µsec. The effective amplitude varies but should be set to produce comfortable paresthesias, usually in the range of 2–6 V for "constant-voltage" systems (Sdrulla et al., 2018; Rock et al., 2019; Schmidt, 2019; Fontaine, 2021; Sun et al., 2021).

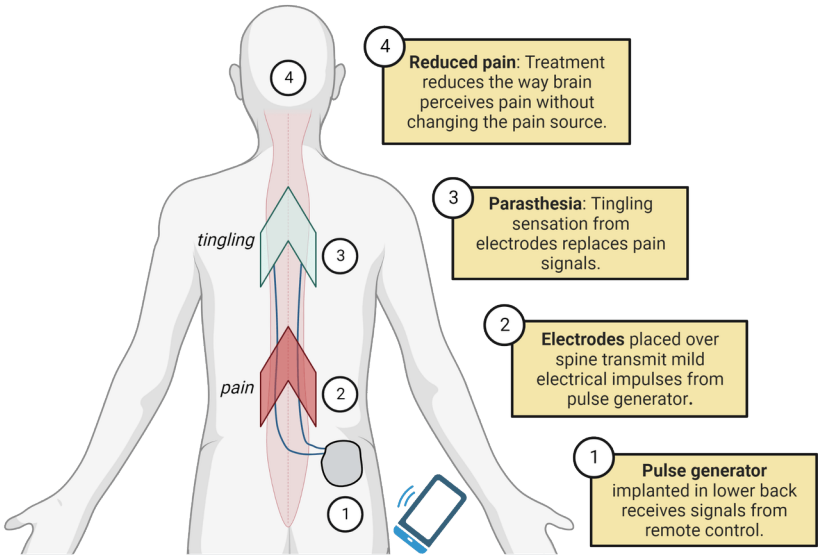

Figure 9.25 Spinal cord stimulation (SCS)

Motor cortex stimulation (MCS) has been found to be effective against some otherwise extremely therapy-resistant pain conditions: central post-stroke pain (as the consequence of damage of the thalamus by stroke) and trigeminal deafferentation pain (results from injury to the trigeminal nerve from trauma or surgery). Notably, central post-stroke pain is one of the most therapy-resistant neuropathic pain conditions, and MCS is one of the only treatments that have been shown to provide relief in this condition.

Intracerebral stimulation, or deep brain stimulation (DBS), is also useful for the management of pain otherwise resistant to any therapeutic modality. Two major target regions for stimulation are shown in Figure 9.26: (1) the sensory thalamic (STh) nuclei (ventral posterior medial [VPM], ventral posterior lateral [VPL]), and (2) the PAG/PVG region. There is solid evidence that stimulation in the sensory thalamus is selectively effective for neuropathic (deafferentation) pain whereas PAG/PVG stimulation appears to preferentially influence nociceptive or mixed forms of pain (Lefaucheur, 2017; Hussein et al., 2018; Senatus et al., 2020; Knotkova et al., 2021; Nüssel et al., 2021; Ramos-Fresnedo et al., 2022).

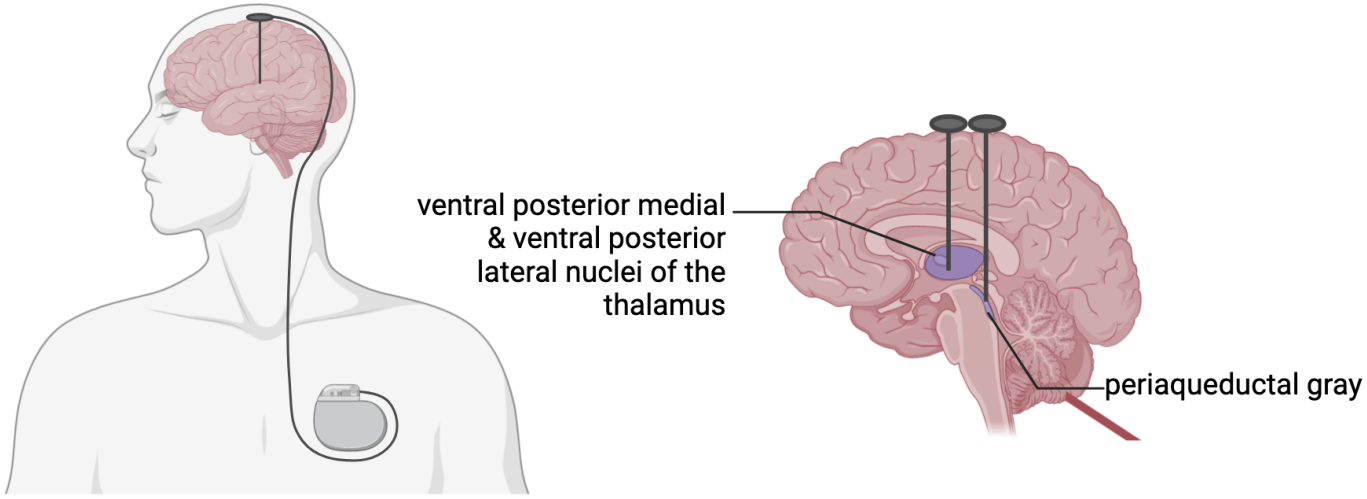

Figure 9.26 Deep brain stimulation for pain Two common sites for deep brain stimulation to relieve chronic pain are the sensory nuclei of the thalamus and the periaqueductal gray.

Repetitive transcranial magnetic stimulation (rTMS) is a non-invasive and relatively painless tool that has been used to treat chronic pain, in addition to studying various cognitive functions with various neuropsychiatric disorders. It uses an electromagnetic coil to generate a magnetic field that passes easily and painlessly through the skull and into the brain (see Figure 9.27) (see Methods: rTMS). These pulses induce changes in cortical excitability at the stimulation site and transynaptically at distant areas to achieve its effect. It is found that rTMS is beneficial for treating neuropathic pain of various origins, such as central pain, pain from peripheral nerve disorders, fibromyalgia, and migraine (Gatzinsky et al., 2021; Zang et al., 2021).

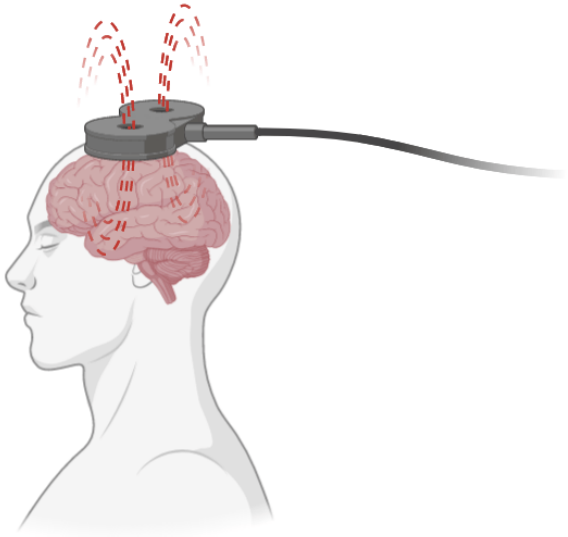

Figure 9.27 Repetitive transcranial magnetic stimulation for pain In repetitive transcranial magnetic stimulation, an electromagnetic coil generates a magnetic field that changes electrical activity of cortical neurons. This can relieve chronic pain in some conditions.

2.5.6: Section Summary

9.1 Somatosensory Receptors

This section summarizes the neural structures in the peripheral sensory system as the starting point to receive, transduce, and propagate various modalities of somatosensory information to the central nervous system. Understanding various types of sensory receptors, their axon types, cell body location, and major neurotransmitters used will provide a solid foundation for understanding at the next level of neural transmission, the central nervous system.

9.2 Somatosensation in the Central Nervous System

This section covers the anatomical organization of the spinal cord, pathways to the brainstem and thalamus, and the primary somatosensory cortex, in addition to the gate control system, descending inhibitory system, and limbic system. With this knowledge, not only do we understand the somatosensory information flow to the brain to enable perception, but also understand how the peripheral stimulation to the body (touch, burning, pain, and other inputs) can generate emotional responses. Returning to our example from the beginning of this section, we can appreciate how getting stepped on once activated our physical and emotional response to pain, but we could use our posterior parietal cortex to integrate multiple sources of information (the apology) and plan a calm response (using our prefrontal cortex). But when we get stepped on again, the same stimulus integrates with our memories to yield a stronger emotional response the second time. This example shows how sensation is more than just the activation of peripheral receptors; it interacts with multiple brain systems to help guide our behaviors.

9.3 Pain and Itch

The emotional experience of pain is contributed to significantly by the limbic system structures, which also play a critical role in the regulation of our emotions, such as depression. Clinically, increased pain will make depression worse, and vice versa; proper treatment of one will also relieve the other. Anatomical and physiological evidence suggests that they share the same neural circuitry.

Although pain and itch share similarities in activities in both C- and Aδ-fibers and both are subjective in nature, their functional mechanisms are quite different. While pain can be elicited by various stimulation (mechanical, thermal, chemical, and electrical), itch is mainly induced by chemical stimulation.

9.4 Pain Relief

Treatment of pain can be delivered through various strategies, from the over-the-counter medication to prescription drugs, behavioral cognitive treatment to physical therapy, and other instrumental measures including invasive or non-invasive stimulation of the nervous system (peripheral and central), and finally, surgical options.

2.5.7: Key Terms

9.1 Somatosensory Receptors

somatosensory receptors, primary afferents, free nerve endings, Merkel disk, Meissner's corpuscle, Ruffini endings, Pacinian corpuscle, hair cells, mechanoreceptor, nociceptor, glutamate, substance P (SP), calcitonin gene-related peptide (CGRP), capsaicin, vasodilatation, plasma extravasation, TRPV1, piezo channels

9.2 Somatosensation in the Central Nervous System

Dorsal root, dorsal root ganglion, dorsal horn neuron, Gate control theory, STT, VPL/VPM of the thalamus, PAG, LC, NRM, S1, S2, posterior parietal cortex, limbic system

9.3 Pain and Itch

Pain, nociceptive pain, neuropathic pain, itch, histamine, cowhage Congenital insensitivity to pain (CIP), congenital insensitivity to pain with anhidrosis (CIPA) , Limbic system , DSM-IV, major depressive disorder (MDD), dorsal raphe nucleus (DRN), serotonin (5-HT), norepinephrine (NE)

9.4 Pain Relief

Placebos, opioids, endorphins, cannabinoids, capsaicin, magnetic stimulation, spinal cord stimulation (SCS), transcranial electrical stimulation, motor cortex stimulation (MCS), transcutaneous electrical nerve stimulation (TENS), decompression, ablation

This page titled 2.5.7: Key Terms is shared under a CC BY-NC 4.0 license and was authored, remixed, and/or curated by Ivette Merced via source content that was edited to the style and standards of the LibreTexts platform.

2.5.9: Multiple Choice

9.1 Somatosensory Receptors

1.
Jill has suffered a bad burn on an area of her skin. She has damaged the epidermis and upper part of the dermis. The deeper dermis layers are intact and undamaged. Which touch receptors are likely to be impaired?

a. Ruffini endings and Pacinian corpuscles
b. Merkel disks and Pacinian corpuscles
c. Merkel disks and Meissner's corpuscles
d. Ruffini endings and Meissner's corpuscles

2 .
What is the stimulus that activates touch receptors?

a. Chemical transmitters binding to the receptors.
b. Physically pulling open protein complexes in the cell membrane.
c. Photons of light.
d. Temperature-dependent changes in protein shape.

3.
Which receptors have small, accurate receptive fields and are encapsulated?

a. Free nerve endings
b. Pacinian corpuscles
c. Meissner's corpuscles
d. Ruffini's endings

4 .
You are testing a touch receptor to see what kind of stimulus it responds to. You apply a constant touch stimulus and find that the receptor fires rapidly at first but then stops firing, even though you have continued to provide the constant touch stimulus. Based on this information, what kind of receptor could this be?

a. Meissner's corpuscles only
b. Pacinian corpuscles only
c. Neither Meissner's nor Pacinian corpuscles
d. Both Meissner's and Pacinian corpuscles

5.
Nociceptors transduce which kind of sensory information?

a. Mechanical pain
b. Thermal pain
c. Chemical pain
d. All of the above

6 .
Which of the following does NOT have a role in nociception following tissue injury?

a. Mast cells
b. C-fibers
c. Pacinian corpuscles
d. A-delta fibers

7.

Which of the following fibers has the fastest conduction speed?

a. A-alpha
b. A-beta
c. A-delta
d. C fiber

8 .
Why do A-alpha fibers have the fastest conduction speed of the 4 major sensory fibers?

a. Because they have the widest diameter.
b. Because they have the most myelination.
c. Both A and B.
d. Neither A nor B.

9.2 Somatosensation in the Central Nervous System

9.
Pain and touch:

a. are transduced by the same receptors.
b. follow the same spinal pathways.
c. use only myelinated fibers
d. none of the above.

10 .
In the Gate Control Theory of pain, why does touch sensation reduce pain sensation?

a. Because the brain centers for interpreting pain can only handle limited input and adding touch information overwhelms pain processing.
b. Because A-beta fibers have inhibitory connections to pain projection neurons.
c. Because C fibers have touch receptors that are inhibitory.
d. Because C fibers are unmyelinated and slow.

11.
Mechanosensitive touch sensation information from the right side of the body is processed by which side of the primary somatosensory cortex?

a. Left
b. Right
c. Both sides
d. We don’t know which side of the primary somatosensory cortex processes information from which side of the body

12 .
Pain sensation from the right side of the body ascends on which side of the spinal cord?

a. Right side mainly
b. Left side mainly
c. Both sides equally
d. We don’t know where these pathways are located

13.
You have encountered a patient in a clinic reporting widespread loss of **pain and sensation** on her **left side** after a recent fall. Where would her injury most likely be to cause these symptoms?

a. In her right cortex
b. In her left cortex
c. In her right thoracic spine
d. In her left thoracic spine

14 .
Which of the following is true about pain and touch sensation?

a. Pain is just extreme stimulation of the touch sensory system.
b. They are separate sensory systems, but they follow mostly the same pathways from the periphery to the primary sensory cortex.
c. The touch sensory system sends input to the primary sensory cortex while the pain sensory system does not.
d. They are separate sensory systems that follow independent pathways from the periphery to the primary sensory cortex.

15.
Descending inhibition of pain acts primarily on which part of the pain sensory system?

a. The primary pain afferents in the spinal cord
b. The S1 neurons that receive pain information
c. The limbic system
d. The thalamic nuclei

16 .
In S1, the cortical surface area dedicated to receiving sensory information from a particular body part is:

a. proportional to the surface area of the skin on that body part.
b. proportional to the amount of sensory innervation that area receives.
c. similar for all body parts.
d. not organized in any particular way.

9.3 Pain and Itch

17.
Which of the following can influence pain perception?

a. Gender/sex
b. Social factors
c. Psychological factors like attention
d. All of these

18 .
Pain that is physical in origin activates brain regions that are _____ brain regions activated by psychological pain.

a. the same as
b. different from

19.
Which brain system is most responsible for the emotional response to pain?

a. Limbic system
b. Primary somatosensory cortex
c. Thalamus
d. Descending inhibitory system

20 .
Pain:

a. is adaptive.
b. is maladaptive.
c. can be adaptive or maladaptive, depending on duration and context.

21.
Selective serotonin reuptake inhibitors have been shown to reduce chronic pain in some cases. Where could these drugs be acting to have this effect?

a. At the terminals of dorsal raphe serotonergic neurons in the limbic system
b. In the spinal cord terminals of dorsal raphe serotonergic neurons
c. Both A and B
d. Neither A nor B

22 .
Itch:

a. is adaptive.
b. is maladaptive.
c. can be adaptive or maladaptive, depending on duration and context.

9.4 Pain Relief

23.
Pain treatment:

a. can be achieved with a variety of methods, including drugs, surgery, and non-invasive techniques.
b. requires opioids.
c. is pharmacological (drugs) or invasive (involving surgery).
d. is not possible.

2.5.10: Fill in the Blank

9.1 Somatosensory Receptors

1.
Free nerve endings transmit pain signals related to mechanical, thermal, or chemical sources. They are called _____.
2 .
The area of skin in which touch can activate a touch receptor is called that touch receptor's _____.

9.2 Somatosensation in the Central Nervous System

3.
The body surface is represented by different segments of the spinal cord, each of which is called a _____.
4 .
It is believed that the center controlling the descending inhibition of pain is located in the _____ in the midbrain.

9.3 Pain and Itch

5.
_____ pain results from direct injury to nerves in the peripheral or central nervous systems and often involves a burning or electric sensation.

9.4 Pain Relief

6 .
The easiest and most common starting point to treat pain is over-the-counter (OTC) drugs, which mostly work by reducing _____.

Creating movements we *want* to make is a critical part of almost every moment of our lives. At its root, moving how we want is just contraction and relaxation of skeletal muscles. But achieving a smooth, intentional movement requires amazingly sophisticated coordinattion. Consider for a moment the complexity of a gymnastic flip executed by Ms. Simone Biles (see Figure 10.1).

- Before execution, a gymnast needs to visualize her whole planned launch process, including all twists and bends during flight, and the finalizing movements that will stick the landing. She will anticipate how it will feel, and her brain will calculate timing, forces, and angles of movements subconsciously.
- During the exercise, some skeletal muscles will be directly under the gymnast's control. Ms. Biles will quickly engage her muscles to contract and relax to control her movements, executing her plan from start to finish.
- While Ms. Biles consciously directs some of her muscles, most of her movement is actually reflexive. Behind the scenes of conscious awareness, her nervous system will be actively correcting subtle shifts in weight and strain that she may not be aware of and engaging habitual movements in some limbs. This subconscious movement system is essential. First, it lets her focus her attention on the limbs and movements she deems important. Second, it helps her execute those subconscious movements better—if she thinks too much about them, they actually won't happen correctly, resulting in a potentially painful fall.

Ms. Biles does what may feel impossible to many of us, but those movements are possible when the nervous system learns to

support them. It is possible because, at their root, the flips and twists that Ms. Biles executes rely on pieces of the nervous system that are shared across humans. In this chapter, we will be taking a trip through the contributing systems that support all these movement feats, including those we rarely consider because they seem to happen so automatically. We will explore the mechanisms involved when the nervous system implements motor movements by activating specific muscle groups. We will also examine earlier stages in the process such as how the brain modulates and refines movements and how it organizes and plans movements. Along the way, we will consider a variety of diseases that involve dysfunction in motor systems and interventions that may help treat those diseases.

2.5.12: The Physiological Actions Implementing Movement – Contraction of Muscles

Learning Objectives

By the end of this section, you should be able to

- 10.1.1 Explain the components of a muscle from the individual muscle fiber to their combination.
- 10.1.2 Distinguish the roles of actin and myosin, troponin, and tropomyosin, and associating those molecules with the overall construction of the sarcomere along with their roles in establishing a pulling force.
- 10.1.3 Describe the process of skeletal muscle activation into contraction from their initial depolarization till the establishment of the pulling force, with a focus on the energy utilization along with fiber-type specialties.
- 10.1.4 Explain the differential contribution of motor units to the distinction of the two big-picture force generation mechanisms: The activation of each individual muscle fiber and accumulation of more muscle fiber contributions.
- 10.1.5 Differentiate between agonist, antagonist, and synergistic muscles, distinct fiber type contractile properties, and their contributions to movement.
- 10.1.6 Characterize muscle cramps and their sources and illustrates how rigor mortis sets in following death in the context of the molecular components of the muscle.

Disagreement among experts about what constitutes a single muscle leaves a lack of consensus about how many there are. Skeletal muscles can exist in a variety of shapes and sizes, producing diverse quotes of total numbers across the literature. Those advocating higher numbers point to increased movement versatility in select regions where simple opposing pairs can't define the movement (face, tongue). A *rough* approximation would be 640 total muscles arranged in antagonistic pairs with one muscle bending a limb joint and the other involved in its extension. Each muscle is composed of many muscle cells (fibers) capable of contraction with diverse outcomes depending on their attachments. In this section we will examine the structure of muscle fibers and consider the mechanisms that control them.

What constitutes muscle cells and their contractile elements?

To reach our goal here, it is important to envision the whole and the functional system we're discussing. Neural signals need to be sent from their sources in the spinal cord or brainstem out to merge with sets of skeletal muscles where these neurons release neurotransmitter and engage contractions. Neurotransmitter release happens at the terminals of these motoneurons, where it then binds to receptors at distinct locations constituting "the muscle." This binding initiates a cascade of events that leads to muscle contraction, garnering different amounts of force as needed for actions. This phenomenon involves the actions of several players whose names and roles will now be more specifically delineated. Knowing the players will help to understand how the team wins desired actions with intelligent sophistication.

The individual muscle cell is called a muscle fiber, or myofiber. Myofibers arrange themselves in parallel to add cooperative force, or in series (connected end-to-end) to provide length so contraction velocity can build, by accumulating themselves between tendon attachments. Figure 10.2 shows how a muscle mass is composed of multiple muscle fibers (arranged in parallel or series).

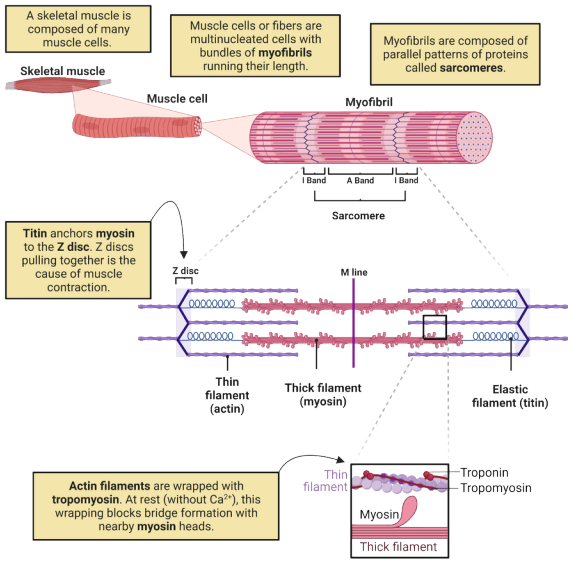

Figure 10.2 Muscle to sarcomere

Individual myofibers can be several centimeters in length and are typically about 80μm in diameter. Each myofiber or muscle fiber contains multiple myofibrils. Myofibrils are elongated rods composed of repeating patterns of proteins. These proteins provide the basis of contraction due to being made up of components that can be induced by the cascade following neurotransmitter receptor activation to pull against each other, shrinking the internal mass, and pulling connected body parts closer together. The more myofibrils packed into a muscle fiber, the more force that muscle fiber can produce. The repeating protein patterns of myofibrils create darker and lighter bands that are visible when looking at muscles. Therefore, skeletal muscles are called "striated."

Within the bundles of myofibrils, the repeating protein patterns represent multiple contractile units called sarcomeres. Several sarcomeres repeat in series along the length of a myofiber. The lower half of Figure 10.2 shows how each sarcomere is bounded on the outside by a Z-disk, into which the tail ends of actin "thin" filaments embed, holding them tightly. Actin are composed of actin protein monomers strung together and wrapped around each other in double helixes. At each full cycle along the helix of each actin filament, there resides a binding site for myosin that is typically covered by tropomyosin, which is a long filamentous peptide chain following the actin helix around each curve.

The actin/tropomyosin filaments make up the "thin filaments" of the sarcomere. Between the protruding strands of actin/tropomyosin, in a separate bundle held in place by the M-line in the middle of the sarcomere and thin strands of titin at either end, there are bunches of outward-facing myosin. These bundles end up with globular heads of myosin bulging out from the bundle at regular small intervals. The remaining portions of myosin are buried in a way that appears like twisted microscopic grape vines (fiber represented by vine, and grapes representing globular heads, middle portion of blowup in Figure 10.2). These myosin bundles extend from the center and comprise "thick" filaments. Finally, along the actin/tropomyosin thin filaments, and at regular intervals near the myosin binding sites, the troponin molecules are found to be attached to both the actin and the tropomyosin (shown in the smaller detail box at the bottom of Figure 10.2).

How does a sarcomere generate contraction?

The basic contraction action of a sarcomere is a repeating cycle in which the myosin heads grab and crawl along the actin/tropomyosin filaments from one binding site to the next, pulling the Z-disks closer together (see Figure 10.3, and watch an animation). This process involves the formation and breakage of cross-bridges between the myosin globular heads and the binding sites along each turn of the actin alpha-helix, initially covered by tropomyosin. To envision how this looks across the sarcomere, imagine the whole thick filament is a caterpillar, its feet lifting from the leaf (actin) and moving forward while others remain planted for stability. While some actin sites are bound by globular myosin heads (caterpillar feet on the leaf), other globular heads are dissociating and thrusting forward to bind again (caterpillar feet lifted off the leaf). This way, the myosin chain pulls actin and its tethered Z-discs inward.

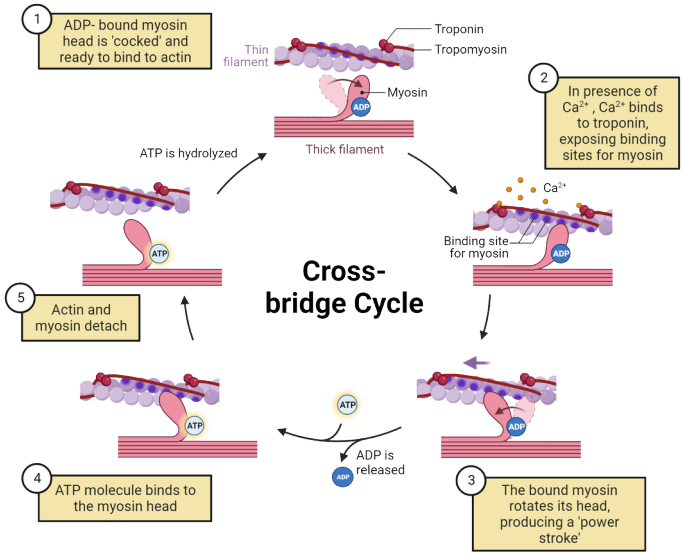

Figure 10.3 Actin myosin contraction cycle

So how is this cycle controlled? Our muscles don't just contract randomly. They contract when our motor neurons tell them to. Calcium is the critical component that controls when this cycle can happen. As described above, myosin grabs on to actin, sticking to binding sites on the actin protein. Without calcium present, those binding sites are blocked by tropomyosin. In response to an upstream action potential in a motor neuron, calcium is released inside the muscle cell. The calcium binds with troponin. Calcium-bound troponin changes shape and acts as a wedge, prying the tropomyosin strand away from the actin strand (Step 2 in Figure 10.3). This shift exposes the myosin binding sites on actin.

Once myosin binds with actin, myosin initiates the "power stroke," changing its shape so as to pull the actin chain toward the center of the sarcomere (Step 3). At the end of the power stroke, an ADP molecule falls off the myosin and an ATP binds to the myosin head instead (Step 4). The ATP binding changes the shape of myosin again, causing it to fall off the actin binding sites (Step 5). When the ATP gets broken back down into ADP + phosphate, the myosin relaxes back to its original position (Step 1). If calcium is present, the cycle can repeat. Though we show this cycle at one specific actin-myosin pair, keep in mind that it occurs throughout the sarcomere, at many sites of potential actin-myosin contact (i.e. the many legs of the caterpillar).

Contractile force entails two distinct processes: shortening and lengthening. This seems counter-intuitive. Isn't "contraction," by definition, "shortening?" Let's clarify by considering the difference between lifting a bowling ball versus catching a bowling ball. The experience of lifting a bowling ball is of course quite different than catching a bowling ball tossed to you. Lifting this ball requires establishing sufficient contractile force to initiate motion upward with muscles in the arms. Catching a bowling ball mostly involves slowing the ball's trajectory or momentum as it moves along rather than immediately reversing its movement. This is where "contractions" differ between shortening (lifting the ball) and lengthening (catching the ball). When the cycling of cross-bridges and power strokes produce sufficient force to counteract a load, muscles can engage shortening contractions and move the limb or body part (we lift the ball). The second category of contraction occurs when contraction force is insufficient to counteract a force, but it can be dampened or slowed down. Often this occurs against the force of gravity, as with the case of catching a bowling ball. The considerable inertia of the heavy bowling ball won't be immediately counteracted by muscle forces in our limbs. Instead, cycling and power strokes produce some counteractive force by attempting to bind and cycle, yet with cross-bridges getting progressively pulled apart like loosening a Velcro seal. These are lengthening contractions. This is analogous to picking up a caterpillar holding on to a leaf, its little legs progressively popping off, slowing your retrieval of the caterpillar. This is important to understand because it describes why some "contractions" seem to be hidden behind the scenes. Like when two muscle-bound competitors are locked in an arm wrestle stalemate, with their gripped hands quivering at the top, one competitor giving a bit (lengthening contraction), with the other gaining a bit (shortening contraction). Similarly, most of our run-of-the-mill movements involve multiple muscles, frequently mixing together shortening and lengthening contractions to achieve our final, desired movement.

From muscle cell action potentials to contractions

Sarcomere contraction relies on a surge of intracellular calcium which is initiated by an action potential that propagates through the muscle fiber. Action potentials of skeletal muscle fibers are initiated by synapsing lower motor neurons (LMNs). LMNs release

acetylcholine (ACh) at neuron-muscle synapses called neuromuscular junctions (Figure 10.4).

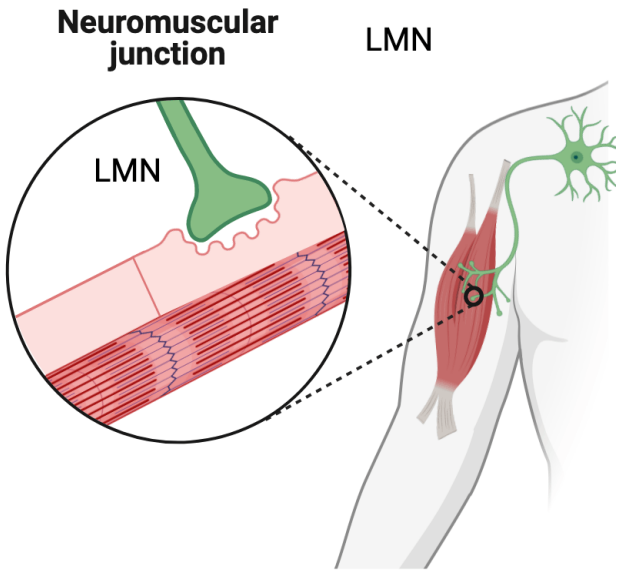

Figure 10.4 Neuromuscular junction Axons of LMNs terminate on muscle fibers in a special synapse called the neuromuscular junction.

The postsynaptic side of these junctions expresses nicotinic ACh receptors, which gate sodium and therefore initiate depolarization when they open. By comparison to CNS neurons which receive thousands of excitatory inputs requiring summation to reach action potential, motoneurons synapse only once with muscle fibers. Thus, both the selection of *that* fiber contraction and some control over the contractile force, derives from the bolus of acetylcholine (ACh) released upon the fiber. Motoneurons must therefore release large amounts of acetylcholine to ensure enough stimulation of the fiber and cause contraction. Most movement events need to be quick and snappy, and cannot wait for prolonged summation to occur, such as escape from predators.

Figure 10.5 shows how initial sodium influx from ACh receptor activation triggers an action potential in the skeletal muscle. Depolarization of the muscle fiber membrane (sarcolemma) leads to muscle action potentials that are perpetuated across the fiber via voltage-gated sodium channels, much like an action potential travels down an axon (see Chapter 2 Neurophysiology). These sodium-based depolarization waves flash across the muscle fiber membrane and cause calcium release from internal stores in the sarcoplasmic reticulum. This calcium initiates contraction by starting the cycle described above.

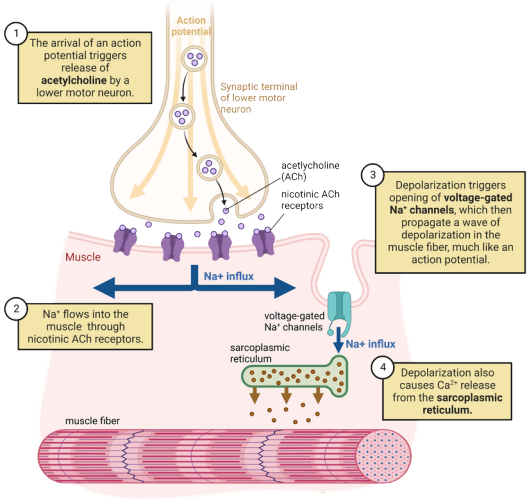

Figure 10.5 Neuromuscular junction mechanism

Differentiating the muscle fiber types

Your author has found himself attempting to quickly make it to a classroom after miscalculating the length of a casual walk. Along the way, his stride speed increases and the fear of being late might cause a burst of effort into a sprint on rare occasions when he pushes the last moment. Different muscle fibers are likely involved between these stages. Specialized myofiber types contain combinations of mainly myosin types along with levels of mitochondria and other components that render distinct properties in energy availability and contraction speed. Most of the time, each motor unit (LMN and connected fibers) connects to similar muscle fiber types so that these can be engaged differentially, though any damage and regrowth might disrupt this pattern over time. Several characteristics differentiate muscle fiber types, applying their characteristics into a rationale for a pattern of recruitment reserving large motor units or specific contraction bursts for last. There are 3 main types of muscle fibers: one slow-twitch (Type I) and two fast-twitch (Type IIA and Type IIX). Several key differences between them are summarized in Table 10.1. Type I and Type IIA are the first recruited types of muscle fibers while Type IIX is reserved for later activation, when greater forces are needed.

Fiber type	Twitch	Recruitment	Capillaries	Energy	Contraction
Type I	Slow twitch	First	More (red)	Blood	Slow
Type IIA	Fast twitch	First	More (red)	Blood, stored energy	Fast
Type IIX	Fast twitch	Last	Fewer (white)	Blood, stored energy	Strong bursts

Table 10.1

Type I (slow) and Type IIA (fast) muscle fibers each receive a much greater supply of blood capillaries, providing more oxygen and other energy-producing supplies to support contraction. These muscle fibers, known as myosin heavy chain, are typically recruited first in general run-of-the-mill movement because the energy stores are unlikely to be depleted. Slow fibers (Type I) contain slightly different myosin heads yielding slower cycling. They contract more slowly and are primarily emphasized for use when speed is not important. Faster Type II fibers contain faster cycling myosin heads and are typically smaller and tend to use a combination of blood supply and glycogen to energize contractions (blood-derived energy staving off fatigue). Both these Type I (slow) and IIA (fast) fibers also contain myoglobin along with iron and take on a red appearance, so they are designated as the red fibers.

Type IIX fibers are designated “white” due to their relative lack of capillary supply. These fibers build up stores of glycogen that are broken down to make ATP and provide rapid bursts of contractile energy. Type IIX fibers are typically recruited last for final bursts of movement, as once their stores of energy are used up, they remain fatigued until energy levels are restored.

Muscle organization and motor units

The axon of any single motor neuron may branch into several terminals with each forming a synapse on a different muscle fiber. Each muscle fiber, on the other hand, is innervated by a single motoneuron axon. Together, a single motoneuron and the several muscle fibers it communicates with constitute a motor unit (Figure 10.6). Thus, a muscle is composed of many motor units, each of which may involve many muscle fibers. More force can be generated by activating more motor units that contract in a similar direction.

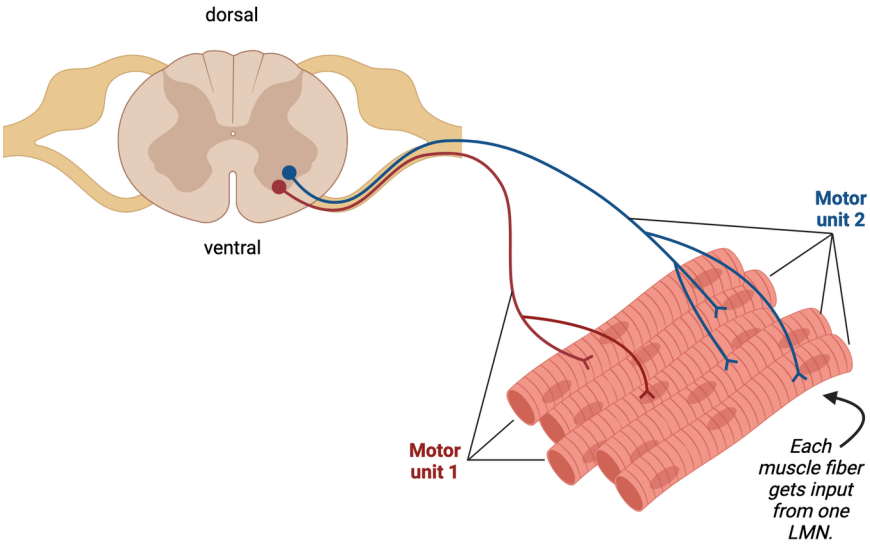

Figure 10.6 Motor unit A motor unit is an alpha motor neuron and all the muscle fibers it synapses on.

To coordinate movement, muscles are activated in pairs of antagonists that pull in opposite directions (flexors or extensors in limbs). Thus, there are ways to coordinate movements by, for example, swinging an arm outward with an extensor and stopping that motion with the opposing flexor. Stiffening any joint requires simultaneously contracting both antagonists surrounding a joint or body part.

Mechanisms of force generation

There are 2 primary ways that we can control how forcefully a muscle contracts (Figure 10.7). The first *simple* mechanism of force generation derives from stimulation of the same motor unit with higher action potential frequency. This causes a higher number of ACh release events at the neuromuscular junction of all that motor unit's muscle fibers. As these ACh release events occur, they cause repeated bursts of sodium influx at the sarcolemma, which then re-initiates calcium bursts and prolongs the capacity of the myosin heads to crawl within each sarcomere involved, recruiting more force.

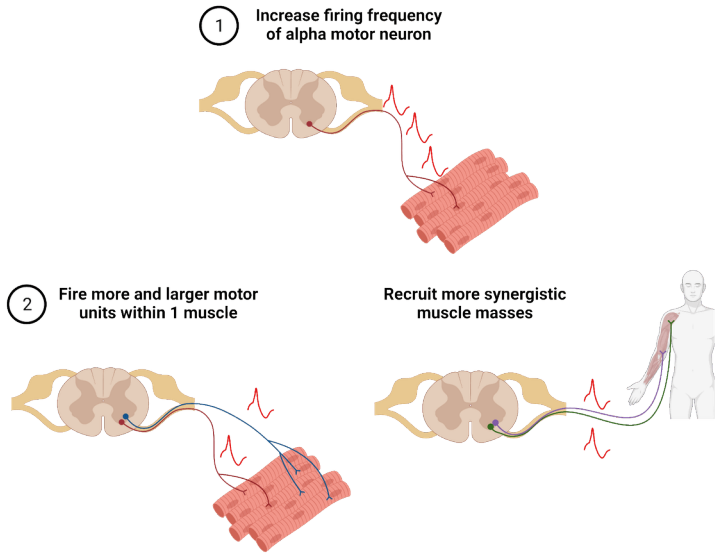

Figure 10.7 Ways to increase muscle contraction strength

However, if only the original muscle fibers synapsed by a single motor unit are used, force recruitment is limited. The second way to increase force is to recruit more synergistic motor units. Motor units whose fibers pull in the same direction are called synergistic motor units. There are two ways that these can be activated, and usually they are activated in sequence. First, muscle

fibers within the same muscle mass are recruited to increase the force that mass engages (e.g., the biceps engage more and more muscle fibers the heavier the barbell while bicep curls). After all the muscle fibers within a single muscle mass are recruited, then synergistic muscle masses are engaged. We may also engage alternative muscle masses that do not pull in *exactly* the same direction because of where tendons attach for different defined muscles, but still contribute some force in our desired direction.

You can use both of these force generation mechanisms in your daily motor movements. Typically, your nervous system activates motor units in a sequential order to support much stronger contractions. The first motor units to be activated are smaller, with fewer connected muscle fibers, and the later recruited fibers will be larger and connected to more muscle fibers (explained later). On top of this sequential activation of motor units, your nervous system can increase the firing frequency of the motor neurons controlling the motor units, causing renewed action potentials and therefore more calcium bursts, thus prolonging the contraction for each fiber. By analogy, force generation through more action potentials would be like a tug-of-war team pulling harder and harder, while the second method of recruiting more motor units would be like adding more larger and stronger members to the team.

Overstretching, cramping, and rigor mortis physiology

For muscles to function optimally, the sarcomeres need to have actin and myosin in optimal positions to be able to bind and slide past each other. If the sarcomere is stretched out too far, the globular heads of myosin won't be able to reach actin filaments. This is overstretching and would make it hard to get a contraction started, though we often don't experience this event because our muscles have natural springiness, so they naturally pull themselves into contraction preparation. The parallel in our example of a caterpillar (myosin) crawling along a leaf (actin) would be if the caterpillar were too far away to reach the leaf. Conversely, if the sarcomere is bunched inward, the actin filaments will crash into each other at the middle and stop the contraction. This represents the limits of pull capacity for the muscle mass. This setup challenges force production at the extremes. These circumstances can be felt by anyone attempting to climb walls or cliffs by grabbing cervices. To hold and lift our own weight, it is typically best to keep limbs slightly bent. A fully stretched arm has a harder time lifting and we might need to swing ourselves out of a joint-locked situation. On the other hand, a fully bent limb offers little movement length or capacity to build up velocity.

Cramps are quick contractions, typically painful, since they continue inwards pull in a manner resistant to relaxation. Cramps can happen when muscles are activated in quick succession without the availability of sufficient energy, or from a position where they can't stretch back out to the ideal position. Cramps can also happen when lactic acid builds up inside muscles. Efforts to metabolize carbohydrates in low oxygen conditions, or when insufficient blood supply exists for all muscles engaged in an exercise, are other causes. Adding more oxygen helps break down the lactic acid, which is why heavy breathing after workouts eventually diminishes cramping.

Interestingly, the stiffness of rigor mortis develops when ATP runs out. As was stated earlier, ATP addition decreases the binding affinity between myosin and actin, allowing dissociation. When ATP runs out (mitochondrial lack of sugar and oxygen), the myosin heads become permanently bound to actin and muscles become stiff. Forensic science calculates the time of death for people in a range of 8-20 hours prior if a body is found already in rigor mortis, though this timeline varies across studies (Anders et al., 2011).

2.5.13: Eliciting Contractions from Lower Levels – Lower Motoneurons and Reflex Arcs

Learning Objectives

By the end of this section, you should be able to

- 10.2.1 Distinguish between upper and lower motoneurons and explain the concept of a motor unit in this context.
- 10.2.2 Enumerate the components of the neuromuscular junction with roles for the basal laminae, junctional folds, acetylcholinesterase, and nicotinic receptors.
- 10.2.3 Explain the basis of classic myasthenia gravis and how it compromises muscle activity.
- 10.2.4 Explain the two processes by which force can be increased based on LMN activity and why the more complex "recruitment of more" follows the size principle to elevate force.
- 10.2.5 Describe special organizations and locations in the spinal cord supporting key LMN distributions in ventral grey in relation to limbs and body parts.
- 10.2.6 Describe what central pattern generation means and how this activity is somewhat like, yet somewhat different from, reflex circuitry.
- 10.2.7 Explain the basis of proprioceptive feedback from spindle fibers and Golgi tendon organs and how those systems integrate into reflex control of movement by exerting lower-level control at the spinal level.

Neuroscientists divide the motor system into lower levels and upper levels for clinical purposes. The implementation of final contractions occurs at lower, output levels, while the organization of what to do when (given current circumstances) occurs at upper CNS levels privy to sensations and goals. Distinct body parts are organized in cortical regions described as primary motor (M1) which sends most of the motor commands into descending axon tracts that eventually inform the posterior spinal and brainstem regions and their reflex-related circuitry how we desire to behave. The M1 area is not the only region capable of engaging major movement decisions. Therefore, all neurons making up regions that typically reside in higher or more rostral locations and coordinate the decisions to move based on decision-making circuitry are called upper motor neurons (UMNs). By contrast, all neurons that reside in more caudal brainstem or spinal regions and *project directly to synapse on muscles* are referred to as lower motor neurons (LMNs). LMNs implement the contractions due to their contact with muscles, and UMNs essentially decide when to engage or which muscles to engage to accomplish an inspired goal.

This section focuses on the LMN system, discussing the mechanisms associated with LMN activation of muscles. LMNs take care of lower implementation. They are defined as all motor neurons extending from the central nervous system (typically the brainstem and spinal cord) and directly connecting with effector muscles. In this section, we will be discussing how LMNs are organized, how their activity drives muscles, and what are the reflexive feedback mechanisms allowing for local control and reflexes. We will discuss the upper levels of control in the following section.

LMN organization

Spinal cord LMNs are responsible for most of our limb and trunk movements. Within the spine, local LMNs reside in the ventral (bottom or stomach-facing) portion of an H-like overall structure comprising the middle portion of the spine. The dorsal (upper or back-facing) portion of spinal grey contains intermediate neurons responsible for relaying sensory information (see Figure 10.8). Importantly, the ventral region of this spinal grey is organized somatotopically in relation to the outer body, so medially located LMNs control medial trunk musculature, and lateral LMNs near limbs control the limb joints progressively (shoulder → elbow → wrist → fingers most lateral).

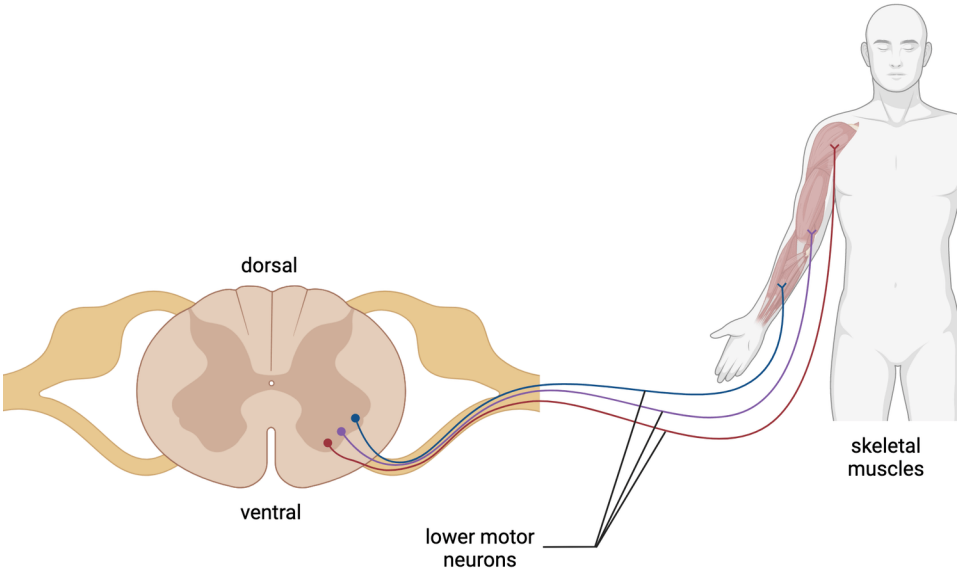

Figure 10.8 LMNs in the spinal cord The lower motor neuron cell bodies are arranged somatotopically in the ventral grey matter of the spinal cord. More medial LMN cell bodies send axons to more medial/proximal muscles.

Moving our heads involves LMNs within various brainstem nuclei, which target our face, eyes, tongue, and other such movements via cranial nerves exiting specific skull foramen (special holes, see Figure 10.9).

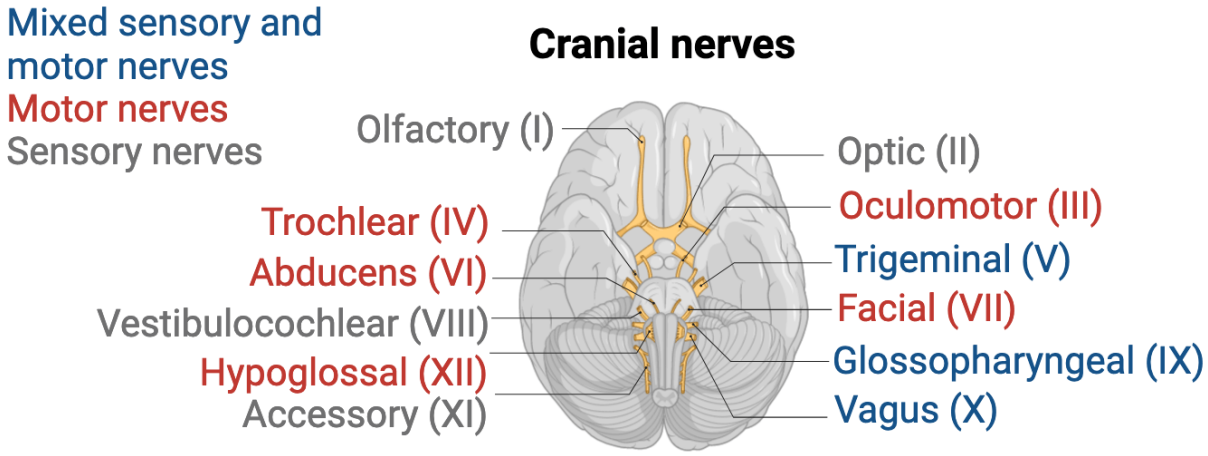

Figure 10.9 Cranial nerves Lower motor neurons (LMN) axons from brainstem nuclei exit from the brain as part of the cranial nerves. Cranial nerves innervate the face, head and neck.

LMNs activate the neuromuscular junction

LMN synapses on muscle fibers occur through neuromuscular junctions (NMJs, Figure 10.5). NMJs from the axon collaterals of a single LMN are activated simultaneously within muscle masses, larger motor units activating more, and smaller less, yielding differential force. Within the NMJ, activated LMN axon terminals release ACh across the synaptic gap and through a leaky surrounding protein matrix encompassing muscle cells called the basal laminae, and onto the postsynaptic surface of a muscle fiber (sarcomere arrangement, see Figure 10.2 and this animation). A motor unit, as was introduced in 10.1 The Physiological Actions Implementing Movement – Contraction of Muscles, is a LMN and all the individual muscle fibers it synapses on. Smaller motor units activate fewer muscle fibers. They get activated in the early movement stages until more force becomes necessary for the current load. Then larger motor units are recruited.

Skeletal muscle ACh receptors, called nicotinic receptors, are ionotropic. When ACh from the LMN presynaptic terminal binds to these nicotinic ACh receptors on muscles, it creates immediate depolarization. Bound and opened nicotinic channels

transmit cations across the sarcolemma and depolarize the muscle fiber, triggering action potentials. These receptor constructs reside on top of waves or ridges in the postsynaptic membrane called junctional folds, placing the receptors near the source of ACh travelling across the synapse. ACh remains only briefly after release from motoneurons. Efficient enzymes called acetylcholinesterase residing in the basal laminae (within the synapse; see Figure 10.5) quickly break it down into choline and the acetyl group, preventing perpetual stimulation disconnected from motoneuron activations (see Chapter 3 Basic Neurochemistry). More force (e.g., greater muscle contraction) can be coaxed from the activated muscle fibers if the LMN is driven to higher action potential frequencies. Resulting increased ACh will maintain and intensify the cycling and power stroking activity within the fibers.

Problems from Myasthenia Gravis

The autoimmune disease myasthenia gravis significantly interferes with ACh effectiveness in generating muscle action potentials. In its classic form, disruptive antibodies are produced that destroy nicotinic receptors by binding-up their protein components. This diminishes the numbers of binding receptors, so the typical release from one LMN action potential becomes inadequate. This loss of ACh effectiveness delays muscle contraction and disrupts the coordination between contractions triggering actions. The end result is slow/jerky movement or sometimes no movement when patients attempt to move. These negative effects of myasthenia gravis highlight the importance of single LMN synapses per each muscle fiber. Each muscle fiber containing only one neuromuscular junction usually maintains control over when muscles contract. Losing this control also means muscles won't always activate properly when needed.

Lower motor neurons as motor units and force selection

A key part of controlling the force of muscle contraction is selecting the number and size of motor units to engage. All LMN axon collaterals from a single LMN, whether large or small, target muscle fibers pulling in essentially the same direction. Larger LMNs exhibit thicker and larger axons which innervate more muscle fibers than smaller ones, thereby generating greater pull. We typically start pushing or lifting with smaller motor units, and engage more, larger ones when more force is necessary. We adjust the force required for a task through trial and error. This helps us avoid crushing eggs unintentionally.

Interestingly, larger LMNs require greater intensities of afferent input to reach action potential threshold than smaller. This is because with greater size comes accumulation of leakiness, a phenomenon known as the size principle. When neurons are depolarized towards their threshold for action potential, specific channels open to allow positive charge in. The larger the neuron, the leakier it gets (depolarization doesn't remain in the neuron but quickly dissipates through expansive channels expressed). If a neuron is leaky, activating the motoneuron resembles blowing up a leaky balloon, requiring faster more powerful breath (i.e., faster more powerful descending UMN, stimuli) (see Chapter 2 Neurophysiology).

This set-up, with larger more leaky and smaller less leaky LMNs, is ideal for recruiting motor units. Descending control, where conscious decisions are engaged, derives from the UMNs (to be discussed in the next section). To activate smaller motor units, only small descending UMN activations are necessary, typically occurring with a new effort of unknown load. However, if the load is larger than anticipated, larger motor units are needed. The system needs to adjust to engage more descending input. This size principle gives us control over recruiting these motor units based on how intensely descending UMN stimulation develops because the bigger LMNs need more excitation from upper levels to fire action potentials. Of course, UMNs can also ramp up the activity of already selected LMNs. This descending control governs both mechanisms of force selection introduced in 10.1 The Physiological Actions Implementing Movement – Contraction of Muscles.

Central pattern generators

Many of the motor, sensory and inter-neurons in the spinal grey are part of central pattern generation . Central pattern generator (CPG) circuits at the spinal cord level coordinate patterns of back-and-forth movements. The circuits supporting these patterns are largely pre-wired to activate locomotion limb flexor and extensor groups, so quadruped animals can maintain patterns of walking → faster walking → trotting → running without lots of descending corticospinal UMN management (Collins and Richmond, 1994). These pattern generators exhibit sophisticated use of inhibitory interneurons, ensuring up and out limb movement is not compromised by muscles pulling the body forward once the limb lands and holds weight. Descending UMNs appear necessary for balance and coordinating changes of movement speed for bipedal species, and largely for quadruped movement speed changes.

In quadrupeds, these CPGs can maintain walking patterns of limb movements with minimal input from the higher cerebrum/brainstem UMNs. For example, spinal transected cats can maintain walking responses across all four limbs on a treadmill without any contributions from the cerebrum (Côté et al., 2003). Two leg walking (i.e., in bipedal species like humans), in contrast, requires additional, significantly greater contributions from balance control systems in the upper motor systems. People with spinal cord injuries, like the late Christopher Reeve, cannot therefore self-generate walking patterns and must use wheelchairs for life. Interestingly, there have been efforts to create external load-bearing and balancing hybrid assistive limb exoskeletons which redirect rehabilitation to the patient's capacity for voluntary motion, and signs point to far greater success potential with these systems than when patients attempt to recover balance on their own, unsupported (Aach et al., 2014). These data suggest that human bipedal walking still benefits from intact spinal CPGs, and evidence also indicates that we utilize CPGs regularly so that we can walk alongside friends and concentrate on our conversations rather than where our feet land (Dimitrijevic et al., 2006; Klarner and Zehr, 2018). Another bit of evidence for CPGs in humans occurs just prior to infants' first walking, when descending control from upper level UMNs is limited, but their back-and-forth "walking" motions nevertheless occur so long as the infant is held. These walking motions when supported are observed far in advance of the infant establishing walking. The balance needed for weight-bearing walking seems to come later and is what is missing after human spines are injured (Minassian et al., 2017).

The feedback proprioceptive senses

Before discussing reflex intricacies, we need to describe the proprioceptive sense mechanisms. These mechanisms are technically sensory, but they are also an integral part of movement control (see Chapter 9 Touch and Pain). Through these sensors we monitor body or limb positions by the degree of muscle stretch (width of smile or extension of arms) and muscle load, or tension, intensity – even the load of our bodies on our legs.

The sensors for muscle *stretch* are called spindle fibers or muscle spindles. They are activated by mechanical pull to signal either whether a stretch has occurred, or at what rate stretch is occurring. The sensors for *muscle tension*, or the loads muscles attempt to counteract, are called Golgi tendon organs. Golgi tendon organs are activated by how much collagen fibers constituting the tendons squeeze down on the terminal sensory endings interwoven among collagen fibers. Their activation therefore reflects the extent of opposing pull between muscle and load. Together, these senses represent proprioception – a self-awareness of where our body is and the forces necessary to get it there.

The Disembodied Lady

To grasp how much we use proprioception, consider the story by Oliver Sacks in “The Man Who Mistook His Wife for a Hat and other Clinical Tales” (1987). In the essay *The Disembodied Lady* within this book, Sacks reports the horrible circumstances of a life limited due to damage in proprioception-processing regions. The woman he described felt that she was living in an essentially dead body. For example, she had to guide her limbs into place with visual confirmation while dancing because she could not *feel* her body movements as intentional. Imagine anyone who appreciates the elegance of ballet having that feeling of movement “rightness” snatched away! The integration between contractions engaged and the feeling that contractions are moving us where we intended, provided by proprioception, is critical in supporting the implicit feeling in which we’re doing what we intended to do, and are doing it right. As we describe these mechanisms of proprioception, keep in mind some sensory information is utilized only within lower levels to support unconscious reflex adjustments, while other information goes to upper levels for conscious (explicit) realization to produce the “feeling” lost by this disembodied lady.

The Muscle Spindles and related reflexes

Muscle spindles are also called spindle fibers, or generally, stretch receptors (see Figure 10.10). To appreciate the function of these receptors, think about kicking a soccer ball at different speeds. Kicking the ball hard requires some momentum in our leg, so we should be able to initially feel our leg further back in space before initiating this swing. The sense of our properly positioned leg comes from stretch signals originating at our leg extensors and hip flexors. The sensory information from muscle spindles let us focus our eyes on finding the goal or teammates rather than looking at our legs during the match.

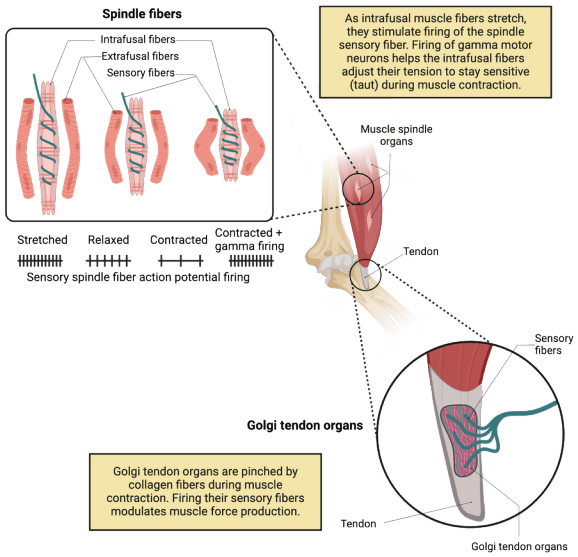

Figure 10.10 The muscle movement sensors

Proprioception via muscle spindles relies on intrafusal muscle fibers, which are different than the force producing and contracting muscle fibers (discussed in the previous section about contraction strategy) that we can now call extrafusal fibers by comparison. Both intrafusal and extrafusal fibers extend in parallel from one tendon to the other. However, they each have different functions and connect to unique classes of LMNs. Extrafusal fibers engage movement/contraction—they are the muscle fibers that generate force. Intrafusal fibers, in contrast, host spindle fiber stretch receptor mechanisms.

Spindles, which include the specialized sensory fibers wrapping around the middle of intrafusal fibers, are key to sensing stretch. When intrafusal fibers are pulled lengthwise, mechanical receptors open within spindles to elicit depolarization, activating their attached sensory fibers (Hunt, 1990).

Stretch response-based reflexes are plentiful within the spinal cord architecture. When a larger muscle is stretched rapidly and unexpectedly, a reflex mechanism involving feedback from the spinal cord snaps the limb back into place. The knee-jerk reflex is prominent among such stretch reflexes (see Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy, shown in Figure 10.11). Many of you have probably experienced your doctor producing this during routine check-ups. To elicit this reflex, a clinician hits just below your kneecap with a rubber hammer, impacting the tendon of your leg extender muscle, causing an unexpected stretch. This extensor stretch excites the spindle sensory fiber, which synapses on and excites alpha motor neurons in the spinal cord, which in turn activates leg extensor contractions. Your leg kicks outward. Doctor: Beware!

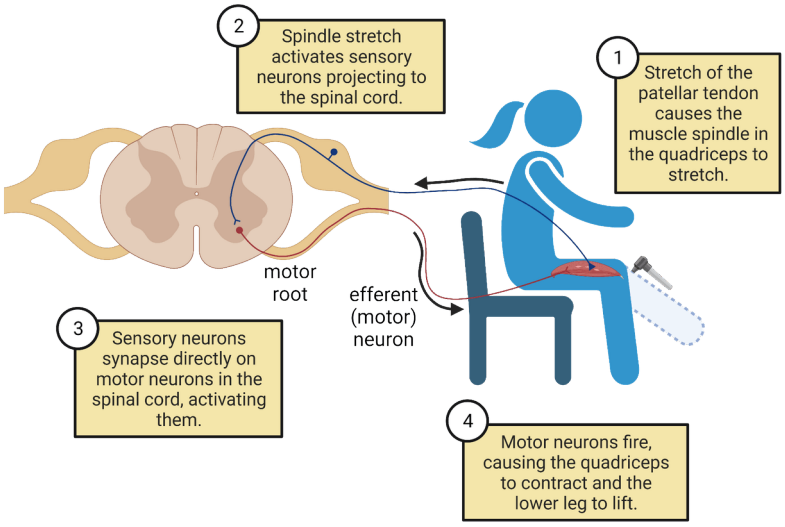

Figure 10.11 Knee-jerk reflex

You might wonder why we need this reflex. We don't usually hit ourselves in the knee. But imagine yourself on a lurching boat. Your legs attempt to keep you upright, but you can't keep up with the timing of the waves and create anticipatory movements. Luckily, the knee-jerk reflex responds to waves which might make you fall backward, tightening the extensor muscle and pulling your body forward rather automatically. If you spend time on ships where your muscles do this regularly, you develop *sea legs* (muscular thighs), unaware of the extra exercise while just standing there.

Though reflexes are somewhat self-contained at the spinal cord level, they also rely on upper motor system input for regulation of their strength. This dependence is quite evident when descending UMN control is absent, as in "spinal" injuries severing the descending systems at the brainstem level. Patients with such injuries show large increases in the intensity of reflexes. This hyperreflexia indicates that descending control interacts intimately with reflex circuitry, usually to keep the degree of reflex responses circumscribed to desired levels but also because UMNs often activate general limb motion through synapsing on spinal reflex circuitry (Frigon and Rossignol, 2008; Adams and Hicks, 2005).

Gamma versus alpha motoneuron system

We have described the extrafusal fibers as contracting to generate force/movement, responding to ACh from LMNs to initiate this force when needed to move our bodies. The LMNs activating those extrafusal fibers are called alpha motoneurons. Separate from the alpha motor neuron system is the gamma motor neuron system. The intrafusal fibers are innervated by an LMN population called gamma motoneurons, whose job is to tighten the intrafusal fibers to ensure the spindles remain sensitive. Mechanoreceptors in spindles only open and produce a signal when the spindles are stretched tight, so it's important for mechanisms to maintain tension on the intrafusal fibers. If they slacken, no signal can be generated. To understand this, imagine that a rubber band is representing the spindle fiber. You've made evenly spaced half-centimeter-apart marks along its length, representing the wrapping curls. If you stretch the rubber band, the marks separate. This represents the action causing a signal to be generated by the spindle fiber. Now allow the band to slacken to shorter than its unstretched length. At this point, the marks don't separate and won't until the band is extended to its original pre-stretched length. Mark separation cannot occur again until tightness is restored, visually representing what gamma motoneurons do to intensify stretch perception. They keep our spindle fibers tight and sensitive when this sensitivity is needed.

Figure 10.10 demonstrates how gamma motor neuron firing maintains spindle sensitivity as fibers around them contract. A contraction of the main muscle mass would naturally cause the spindle fibers to go slack and stop sending signals. This loss of tension is rectified by gamma stimulation of contraction and tightening of the intrafusal fibers. The ability to maintain sensitivity to stretch despite muscle contraction is, therefore, derived from *coactivation* of the alpha and gamma systems at unique moments of need. Interestingly, we don't always co-activate alpha and gamma systems. Quick, thrusting movements like waving away a horsefly or throwing a punch are termed ballistic and differ from our more controlled movements in that the gamma motor system does not co-activate with the alpha motoneurons. Instead, the alpha motoneurons initiate a force vector and simply let it fly without attempting to sense the ongoing movement or slow down the trajectory. The important take-home is gamma motoneuron activity increases sensitivity of stretch perception. It is not involved in producing pulling force to move our bodies.

The Golgi Tendon Organs and related reflexes

As its name implies, the Golgi tendon organ receptor for tension or force produced by muscle contraction is buried within the tendons at either end of skeletal muscles. These receptors sense the tension or force produced by skeletal muscles when contractions pull hard, or the lack of force when pull is weak.

There are Golgi tendon organs in every skeletal muscle tendon. Some muscle tension is more subtle and constant than we might imagine. When we lift a barbell, the force generated is proportional to the weights and effects of gravity on them. Not as intuitive but no less imaginable: holding our body up creates tension in the muscles of our legs.

Instead of a stretch opening mechanical ion channels to cause depolarization, in this receptor, a squeeze induces depolarization. Each tendon is made up of multiple collagen fibers weaving into and through each other. The resulting strong, combined tendon fiber withstands the pull forces placed upon it. Rather than wrapping around a single fiber like spindle fibers, Golgi tendon organs sensory endings weave within the matrix of the tendon’s collagen fibers. Just like fingers are squeezed if inserted between the strands of rope twine pulled tight, these Golgi tendon organ end fibers are squeezed by the force produced by the contraction of the muscle fiber, eliciting firing (Stuart et al., 1972). The experience of dancing with others involves holding hands, lifting, and swinging in ways that we’d rather not be interpreted as “too tight,” “too sudden,” or “too fast.” Being subtle with our touch can also avoid accusations of squeezing parts that perhaps should not be squeezed out of context. Feedback from Golgi tendon organs to our lower motor neurons keeps it soft, appropriate, and “let’s just glide this way.”

Collaboration between grip, touch and stretch

Though we considered spindle and Golgi tendon organs separately above, our movements are constantly informed by their integrated proprioceptive feedback. Proprioceptive guidance of our movements can also be supplemented by input from other sensations, such as our touch receptors (see Chapter 9 Touch and Pain). To appreciate how touch and proprioception come together to inform complex movement, consider how monkeys swing through trees. This activity also involves considerable descending control from UMNs, but for now we can envision what occurs within our current focus on the lower level. Monkeys swing through trees all the time; it's simply part of daily life. But they require sophistication. To succeed, the monkey needs to hold one branch until it has sufficient grip to switch its body weight to the next branch. Then, it needs to release the previous branch in time with the swing, so it doesn't get stuck holding two branches (awkward). The primate needs a *pattern* of swing-grab-tighten-hold-let-go. Let's look at all the sensory components needing to be coordinated (Zimny et al., 1989; Lephart et al., 1998; Gilman, 2002; Lephart and Jari, 2002):

- Getting a hand or foot (remember monkeys have hand-like dexterity in both their feet and hands) in proximity to a branch requires hand-eye coordination combining internal representation with stretch proprioception: spindle fibers.
- Initiation of grasping requires recognition of the touch pressure of the new branch in the palm—these receptors are part of your somatosensory system.
- Grasping requires activation of hand-finger muscles via UMNs, and the needed force of the grasp must be calculated via with the monkey's knowledge of the grip necessary to hold its body weight—Golgi tendon organs in the hand/fingers and somatosensory touch receptors in the skin of the hand/fingers.
- Once grip is established, this perception needs to be coordinated with release of the previous branch, via interaction between ascending proprioception and touch from Golgi tendon organs and somatosensory touch receptors; also, via ascending sensory systems providing conscious realization, which feeds back through various UMN systems to the hand and fingers of the previous limb for release or diminishment of force from the grip.

Ideally, these stunningly coordinated events are automated into a motor program habit to allow them to occur in smooth progression. The monkey can attend to the bigger picture towards good (food, conspecifics) and away from bad (predators, angry alpha males). Such a trajectory requires integration of subtle shoulder motions in the swing with visual appreciation of branch options along with following the optic flow to gauge speed. This is a remarkable demonstration of systems coordination!

2.5.14: Our Brain Gets Involved – Responsibilities of Upper Motor Systems

Learning Objectives

By the end of this section, you should be able to

- 10.3.1 Compile a descriptive story regarding how the following UMN brain structures collaborate with distinct contributions to movement formulation and engagement: Prefrontal and premotor cortices; Cerebellum; Basal ganglia; and Primary Motor cortex (M1)
- 10.3.2 Enumerate the regions of control within the homunculus of M1 anatomically along the precentral gyrus.
- 10.3.3 Differentiate the complimentary contributions to background motor control from the basal ganglia and cerebellum in terms of muscle contribution selection and the smooth stopping and starting.
- 10.3.4 Understand the source, related circuitry, and outward expressions of the following disease states: Cerebellar Ataxia; Huntington's disease; and Parkinson's disease.
- 10.3.5 Describe how final movement selections are made in M1 according to the findings of Apostolos Georgopoulos and how that translates into a sort of democracy of movement trajectory determination.

In this section, we will explore the contributions of UMN systems to voluntary movements. Progressively, we will discuss ascending signals providing critical decision-making information to UMN areas, and descending implementation signals to the lower areas (brainstem and spinal cord). We'll address three major cortical areas:

1. The prefrontal cortices, the most anterior of movement-related cortices where major executive decisions are made.
2. The collection of regions referred to as the premotor cortices (dorsal, ventral, cingulate, supplementary). These coordinate which muscles should be activated when new game plans are formulated, and receive feeds from posterior sensory cortices, the basal ganglia, and the cerebellum through the thalamic way station.
3. Finally, we will discuss the primary motor cortex, or M1. We will find that this area continues to compile inputs and formulate final detailed movement decisions prior to sending commands to the LMNs in the brainstem and spinal cord.

Our lower motor systems clearly need guidance if we are ever going to move how we want. In this section, we will learn how the upper motor structures are poised to deliberate, compose, compile, and then direct the lower motor neurons.

The Prefrontal Cortex – Integrating our wants and needs with circumstances

Within the most anterior portions of the cerebral cortex behind our foreheads and over the orbits of our eyes, prefrontal cortices begin the earliest portions of conscious decision-making and are included as motor regions for this reason (see Figure 10.12). Willed movements depend on both decisions and integration of emotions and desires within internal representations concerning our circumstances in the world. We need to understand problems we face prior to acting and speaking in response to them, lest our actions be thoughtless or wildly inappropriate. For example, prefrontal lobotomy patients are unable to plan for their futures, and fail to self-monitor as actions occur (Milner & Petrides, 1984; Malloy et al., 1993; Chirchiglia et al., 2019). This clearly defines these cortical regions as the locus of deciding what to do. As indicated in Figure 10.12, this area receives necessary decision-making information from many other areas. After processing, it sends this information to multiple regions, providing both the feeling of the decision and the action chosen.

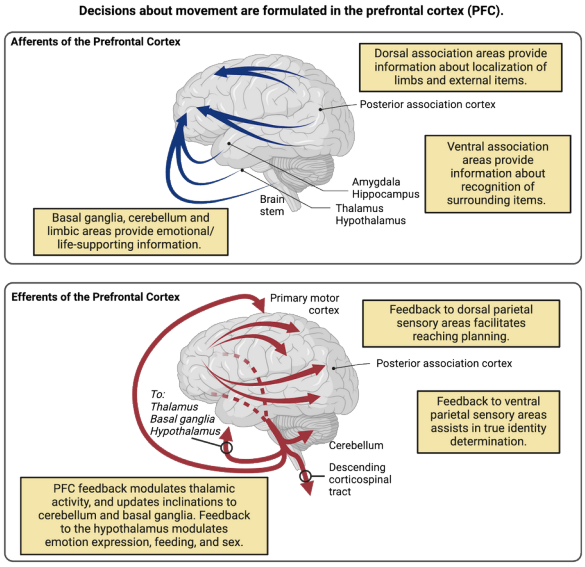

Figure 10.12 Image credit: Image inspired by Fuster, J. 2015. The Prefrontal Cortex. 5th Ed. eBook ISBN: 9780124080607

Premotor cortices

Once an executive decision about a desired movement has been made in the PFC, the conscious compilation of movements into useful patterns occurs in the premotor cortices. These cortices reside in the lateral and dorsal regions of the frontal lobe, behind the prefrontal areas. This general region compiles movements by combining multiple muscle sets across space (different simultaneous contractions combining, adjusting movement trajectory) and time (different movements in sequence). See Figure 10.13 for an example of these functions, as gymnast Simone Biles plans a complex flip. Her premotor cortex will be essential for planning force and distance while her supplementary motor area stitches together the order of movements she will need.

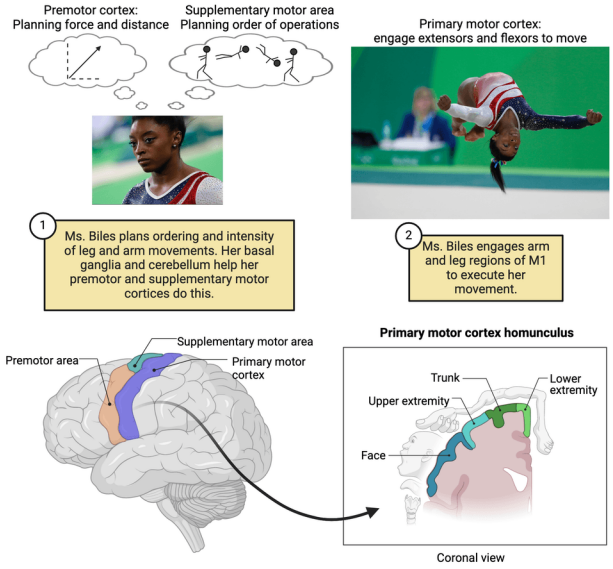

Figure 10.13 Premotor versus motor processing Image credit: Thinking Simone Biles: By Agência Brasil Fotografias - EUA levam ouro na ginástica artística feminina; Brasil fica em 8° lugar, CC BY 2.0, https://commons.wikimedia.org/w/inde...curid=50584958; Flipping Simone Biles: By Agência Brasil Fotografias - EUA levam ouro na ginástica artística feminina; Brasil fica em 8° lugar, CC BY 2.0, https://commons.wikimedia.org/w/inde...curid=50584654

Of course, Simone Biles has done these flips many times. Her repeated practice has made much of her motor planning subconscious. This process of honing motor movements into habitual, subconscious patterns relies strongly on interactions of premotor cortices with other cortical structures such as the striatum (basal ganglia), and cerebellum. These two areas become involved more heavily during acquisition (where movement skills are packaged), consolidation (where movement skills are honed

into quickly accessible repertoire habits or motor programs), and retention (where established repertoire movements are stored so they can be accessed quickly in response to key circumstances). Both primates and rats suffer deficits in learning formal, visually directed motor tasks after the removal of premotor cortices – further evidence of this region's critical role in retaining learned skill and movement adaptation for future endeavors.

The premotor areas' primary output is regulation of M1 neurons, which connect extensively to LMNs. For many years, the premotor cortices were believed to influence motor movement exclusively via their regulation of the primary motor cortex. However, more recent evidence shows stimulation of the premotor cortices yielding combinations of motor responses in harmony across both sides of the body. Thus premotor cortex engages built-in and learned complex combinations of actions, within an organism's more sophisticated repertoire (Geyer et al., 2000). Premotor cortices send descending axons into the spinal cord, meaning that M1 is not the only direct regulator of LMNs. This is important to keep in mind.

The basal ganglia

This cluster of subcortical nuclei includes the main input regions, caudate and putamen nuclei, with circuit components extending into the external and internal globus pallidus, subthalamic nucleus, and substantia nigra reticulata. Importantly, in most animal species, the caudate and putamen nuclei are not distinct. Therefore, they have been largely treated as a similar pair and frequently referred to together as the striatum. There appear to be several parallel "loops" traversing the basal ganglia, beginning with afferents from various areas of the cortex entering and stimulating the main input cells of the striatum. The final output nuclei of the motor loops of the basal ganglia send inhibitory inputs into the movement area of the thalamus, the ventral anterior/ventrolateral (VA/VL) complex (ventral anterior and ventrolateral thalamic nuclei).

Here, we will focus on the role of the basal ganglia in the conscious support of body movement. Recall that conscious actions are guided by plans formulated and relayed by the frontal cortex. Therefore, structures involved in the motoric basal ganglia loops start with afferents from most of the cortex, including sensory and motor areas converging on neurons throughout the caudate and putamen (as stated, usually understood as a group). The subsequent pathways through the basal ganglia can be divided into a direct pathway and an indirect pathway, both of which end up affecting firing of neurons in the VA/VL thalamic complex. The VA/VL complex represents a distinct waystation that specifically targets movement control areas in the cortex, primarily premotor areas. The net effect of activity in the direct pathway is to promote VA/VL firing and therefore planned movement. The net effect of the indirect pathway is to inhibit VA/VL firing and thereby suppress unwanted movement (Figure 10.14). Balance of activity in each of these pathways helps us move how we want, while preventing undesired movements. We will see later how specific diseases impacting each pathway can lead to different symptoms.

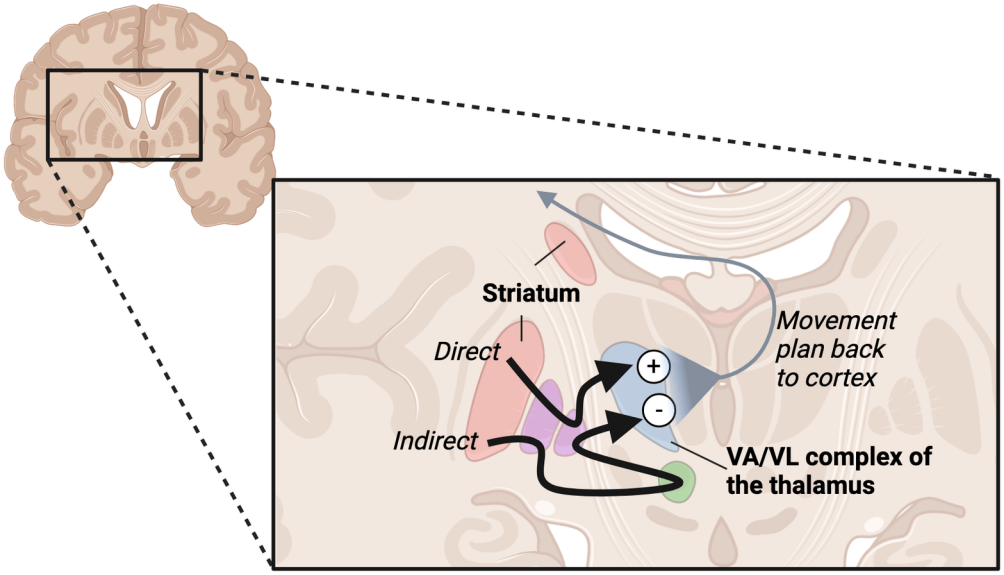

Figure 10.14 Direct vs indirect motor pathways The direct pathway of the basal ganglia promotes planned movements, while the indirect pathway inhibits unwanted movements. **Purple** = GPe/GPi and **Green** = subthalamic nucleus.

Both the indirect and direct pathway use disinhibition as an important part of how their circuit activity is controlled. To better understand disinhibition, we will look more closely at the direct pathway (see Figure 10.15).

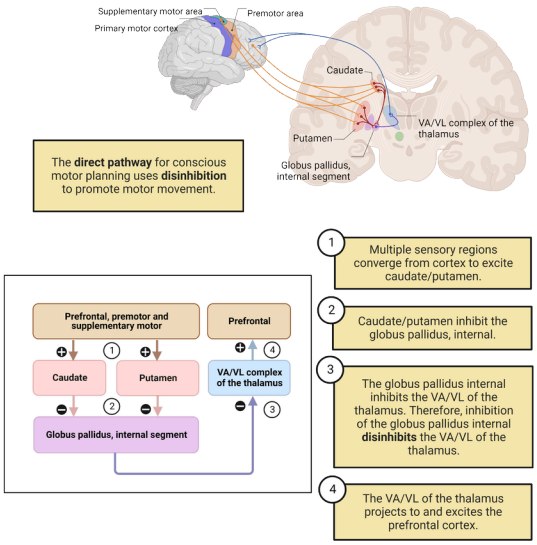

Figure 10.15 Basal ganglia circuits

In the direct pathway, the excitatory input from the frontal cortex areas synapses on inhibitory efferent neurons within the striatum. Those inhibitory striatal neurons then send afferents to the globus pallidus internal (GPi). These GPi neurons are also inhibitory and connect to the VA/VL complex of the thalamus via their own inhibitory efferent neurons. In Figure 10.15, a simplified conscious motor planning diagram for the direct pathway emphasizes the prefrontal cortex because it is where conscious decisions tend to occur, confirming your intended actions and goals along the way. Overall, this inhibition of GPi output neurons results in *disinhibition* of the movement-related thalamic nuclei in the VA/VL complex. The thalamic cells send excitatory outputs towards the premotor/supplementary motor cortices for body movement, or to the brainstem centers for eye and head movement (Groenewegen, 2003). Planned movement is thereby promoted.

The indirect pathway uses similar processes but has more complex circuitry, involving additional brain nuclei and more inhibitory/disinhibitory connections than in the direct pathway. The end result of exciting the indirect pathway is inhibition of the VA/VL and prevention of overactivation of cortical motor areas or the diminishment of *unwanted* movements. One structure within the indirect pathway, the subthalamic nucleus, adds an excitation to the equation which increases how much suppression takes place. Malfunctioning here can lead to ballistic thrusting movements and is often blamed for the inappropriate tremors occurring in diseases of the basal ganglia.

Establishing habits and motor sequences

While we've described conscious involvement, the basal ganglia does also maintain heavy involvement in subconscious skill learning and movement control. Sometimes, we have an explicit or conscious desire to repeatedly produce a specific movement sequence that is learned and established via consolidation as an accessible circuit coordinating multiple muscles in a sequence or ensemble. A motor sequence represents a timed pattern of muscle activation sequentially, like finger movements on a piano in a Beethoven concerto. A muscle ensemble represents a group of muscles activated simultaneously to either create a specific movement trajectory or ensure other parts of the body remain stiff while limbs maneuver, like a wrestler using arms, legs, and back contractions to pin an opponent. The basal ganglia are essential for using motor sequences and muscle ensembles in habitual or learned movements. Specifically, the basal ganglia help to select cooperative muscle ensembles and inhibit unhelpful muscles when executing a learned motor skill.

To understand the role of motor system learning, imagine how we might learn to draw cartoon characters like Snoopy or Garfield. Our first tries are often embarrassing. To create these drawings free-handed, we must coordinate the actions of many muscles in our arms and hand. When should we select "this" muscle, or "that," or combinations of both? The basal ganglia circuitry focuses on proper selection of either individual muscles or groups that *can* produce the desired line in the right direction (drawing Snoopy's rounded snout, or Garfield's stripes or whiskers; see Zham et al., 2017). If the wrong muscles are selected, or the groups of muscles compete rather than cooperate, the drawing will look shaky and wobbly, and we might be likely to discard it rather than showing our friends. After learning to select the right muscle groups for each part, we can proudly show our friends the results. The basal ganglia can *select* which muscle groups to activate in sequence, so muscle ensembles combine with motor sequences. The package becomes a learned habit, re-played as circumstances demand (piano playing, wrestling).

Some disease states may result from inappropriate activation of motor sequences in basal ganglia circuitry. For example, some researchers suggest that Tourette's syndrome sudden-onset expressions ("tics" or bursts of uncontrolled movement), and dystonia (writhing movements and awkward postures), stem from over-reactive sensitivities at the level of the caudate and putamen, making "chunks" of unintended movements essentially habitual (Mink, 2018; Graybiel and Mink, 2009; Albin and Mink, 2006). The circuitries controlling habitual learned movements are substantially more complex than the conscious motor circuits, involving more sub-structures within the basal ganglia. While we will not describe those complexities here, your author hopes that you will pursue more advanced classes where these circuits are covered, as they are exciting, and hotly debated.

Disorders of the basal ganglia

We shall now describe two devastating diseases, Huntington's and Parkinson's, to emphasize functions that rely on the basal ganglia. Some readers may know people who suffer from various stages of movement control deterioration in these disorders. Neither Huntington's nor Parkinson's patients can engage proper motor sequences on demand while suffering their deficits (Moisello et al., 2011). Both diseases involve basal ganglia dysfunction, but result in different symptoms due to loss of different parts of the basal ganglia circuitry.

Patients with Parkinson's disease experience severe, progressive loss of motor control. This includes (1) shakes or tremors; (2) "cogwheel" rigidity, a special kind labeled to emphasize the interspersion of stiffness with short releases, much like clock minute hands clicking into place; and (3) postural instability appearing to derive mostly from insensitivity to vestibular and muscular cues (Sveinbjornsdottir, 2016). While the tremors appear outwardly like other basal ganglia diseases such as Huntington's, they often manifest more at rest when no effort to engage movement exists (resting tremor), compared to action tremor associated with cerebellar ataxia, discussed later.

Parkinson's disease is caused by cell death of the dopaminergic neurons originating in the midbrain substantia nigra pars compacta, projecting into the caudate and putamen (Figure 10.16; Fahn 2008).

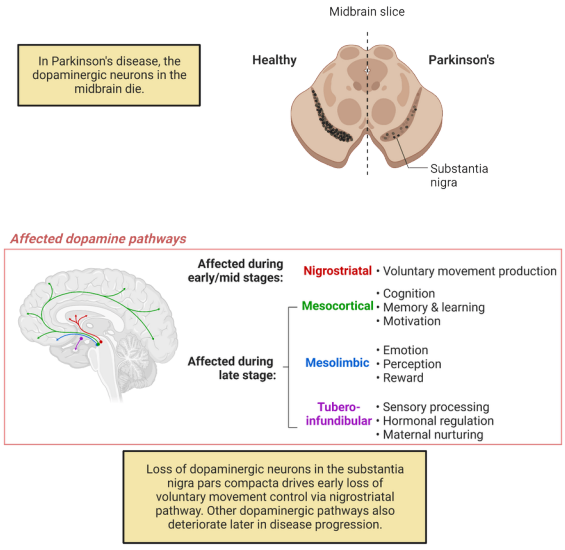

Figure 10.16 Parkinson's disease anatomical pathology

Dopamine contributions to basal ganglia function are complex. As is usually the case with a modulatory transmitter, it largely adjusts the way glutamatergic excitation engages postsynaptic cells. In this case, the postsynaptic cells are inhibitory efferent neurons in the striatum (Surmeier, 2011). The interactions of dopamine with the striatum neurons are complex but their net effect is to stimulate the parts of the caudate and putamen that promote movement behavior, i.e., the direct pathway striatum neurons (follow the circuit diagram in Figure 10.17; Wall et al., 2013, Surmeier, 2011). Its loss in Parkinson's disease makes movement much more difficult.

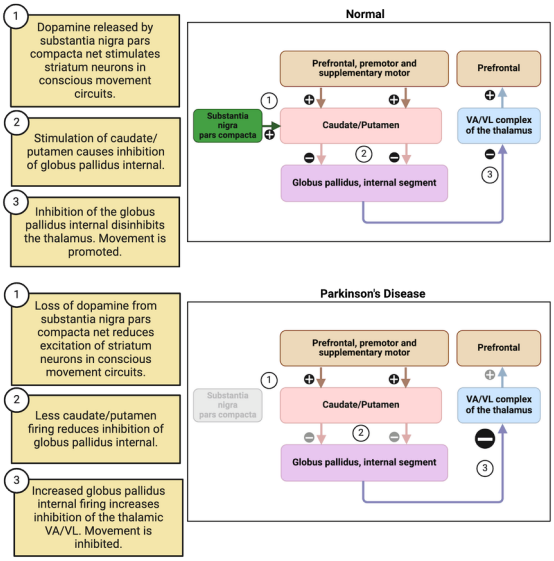

Figure 10.17 Parkinsonian state of basal ganglia

One major treatment for Parkinson's patients is Levodopa (L-DOPA). It is a precursor molecule of dopamine derived from the amino acid tyrosine and is used by the enzymes within dopaminergic neurons to produce dopamine (see Figure 10.18 and Chapter 3 Basic Neurochemistry).

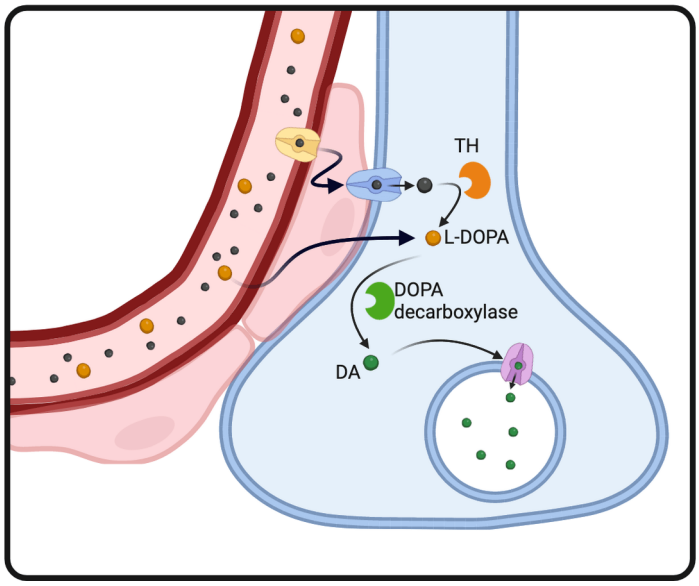

Figure 10.18 L-DOPA and Parkinson's disease treatment Reminder: L-DOPA is a precursor in dopamine synthesis. L-DOPA is also BBB permeable, so L-DOPA in the blood can get into the dopaminergic neuron terminals and boost dopamine synthesis.

When this drug is administered, there is typically an initial surge of dopamine, yielding improved movement. However, sometimes there's a tendency to overdo. This is seen as impulsivity or a tendency to take more risks behaviorally, but that tapers off as the acute effects diminish (Voon et al., 2017). The greater propensity for movement is typically referred to as an "up, on, or acute" state by comparison to the "down, off, or long-term state" when the L-DOPA wears off (Albin & Leventhal, 2017).

The inconsistency of L-DOPA effects over time is one reason alternative treatments, like stem cell transplantation, are sought for Parkinson's, which may provide more consistent dopamine presence (Sandstrom et al., 2018). Dopaminergic replacement cell populations derived from stem cells are typically placed into patients' putamen, because this structure typically receives the highest dopaminergic input, and is most closely associated with movement control (Freed et al., 2011). Also, growth of new axons is considerably challenged across long distances in the adult brain, though strategies for guiding axon growth from the more appropriate substantia nigra pars compacta are being developed (e.g., Zang et al., 2013). Other treatments including a thalamotomy are more radical. In thalamotomy, distinct input regions of the thalamus are targeted for destruction, eliminating

the supportive control provided by the compromised basal ganglia. While actors like Michael J. Fox opted for this treatment due to its general preservation of facial expression control, it is not an ultimate cure as the movements produced are often jerky and challenged. Restoring more natural or appropriate basal ganglia activity would be preferable to eliminating its influence, but this remains a challenge to achieve.

Deep brain stimulation is another potential treatment for Parkinson's disease. In this treatment, electrodes are placed strategically into either the subthalamic nucleus, the internal globus pallidus (GPi) or select regions within the VA/VL thalamus that override the internal signaling strategy provided by the basal ganglia. Deep brain stimulation is particularly helpful in treating the resting tremors that are common in those with Parkinson's disease. The resting tremors in Parkinson's disease arise due to complex dysregulation of input to the GPi/VA/VL. Proper placement and high frequency stimulation of electrodes in these areas, supported by power coming from a battery that is typically placed under the skin around the shoulder, can significantly reduce these tremors (Figure 10.19).

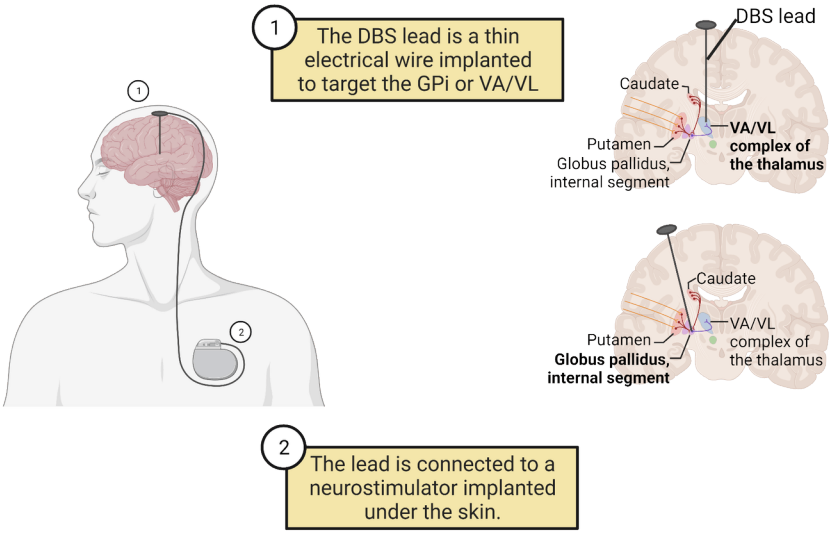

Figure 10.19 Deep brain stimulation and Parkinson's disease

Huntington's disease (HD) arises from a dominant genetic mutation on the *huntingtin* gene within the autosomal portion of chromosome four. Though the genetic mutation is present from conception, the symptoms develop over a lifetime (Walker, 2007). Being autosomal dominant means that a person only requires one copy of the huntingtin gene to develop HD and a parent with HD has a 50% chance of passing on their mutated gene to their offspring. In HD, cognitive difficulties often arise first in the chain of symptoms since the basal ganglia are involved in strategic thinking and developing capacity to adapt thinking to new circumstances, given its interaction with prefrontal and premotor cortices (Novak & Tabrizi, 2011). Typically, movement problems arising in later adulthood, usually around 50-60 years of age, elicit more profound diagnostic concerns.

HD-related movement problems include a sort of undulation of limb and facial movements as if these cannot be suppressed. Limb movements appear dance-like and are referred to as chorea, though they are far from purposefully choreographed or intended (Thompson et al., 1988). At later stages, body movements stiffen, challenging the coordination of swallowing-related pharynx and esophageal muscles (dysphagia). This leads to problems of aspiration and choking (Heemskerk & Roos, 2011).

HD symptoms occur because of the progressive death of striatal neuron cells. The loss of striatal neurons destroys basal ganglia function. The neurons that perish early and more prominently represent those striatal neurons within the indirect pathway, the pathway that primarily suppresses unwanted movement. Progressive deterioration of indirect basal ganglia pathway leaves the VA/VL of the thalamus increasingly disinhibited and yields increased and uncontrolled muscle engagement until the antagonists become overstimulated, stiffening limbs by simultaneous activation (Joel, 2001; Nair et al., 2021). This overstimulation is evidenced as increasingly intense chorea and slowed movement (bradykinesia). Harkening back to drawing Snoopy, consider either unsuppressed wild movements of muscles, or muscles getting locked into tug-of-war battles rather than smoothly guiding the pen. Snoopy's snout would either look too short, or overly long.

There are no directly targeted cures for Huntington's disease right now. The absence of a cure has made diagnosis and genetic testing for Huntington's disease ethically and emotionally complicated. Without clear treatments available, a child with a parent showing symptoms of Huntington's has a dilemma. They have a 50% chance of carrying the mutated gene. If they are tested and

have the Huntington's mutation, there is little they can do, so many patients may decide they don't even want to know. Hopefully that dilemma will be resolved in the future, as there are several treatments being actively worked out. Given the disease derives from a distinct mutation in the huntingtin gene, involving an inappropriate expansion of the genetic code, there have been some ideas about either suppressing mutated genes or targeting the mutation with gene therapy for heterozygotes. Transplantation of stem cells into Huntington's patients has also been attempted with varied success (Rosser & Bachoud-Levi, 2012). Currently, however, standard of care is pharmacological treatments, such as tetrabenazine, to reduce symptoms. Tetrabenazine is a vesicular dopamine transporter blocker that prevents the filling of dopaminergic synaptic vesicles (Bonelli, & Wenning, 2006). These drugs suppress chorea because they tend to dampen the movement initiation of the basal ganglia-based motor driving mechanisms. Dopamine net diminishes the activity in the indirect pathway, thereby promoting direct pathway initiation of planned movements. However, these drugs also tend to spread and have high cognitive side effect potential such as depression or other tensions (Paleacu, 2007). Much work is needed to improve treatment of Huntington's disease.

The cerebellum

The cerebellum sits behind and below the cerebrum, atop the brainstem. Its folia look like two lateral bunches of curled-up spaghetti. Its main function is to smooth-out our behavioral efforts. It does this by either pre-processing movement intentions building in the premotor cortical areas, or via upper-level imagined anticipation. For example, if you contemplated a large rock in front of you in the middle of a creek, and whether you *might* be able to land on it to cross the creek. Alternatively, to improve attempted actions, we process the differences between *intended* and *actual movements*, and adjusting signal durations/intensities until proprioception from afferent spinocerebellar tracts says we "nailed it" (Stecina, et al., 2013; Therrien & Bastian, 2019). You might compliment someone with "you have an efficient cerebellum" as a *neuroscientist exclusive* way of implying they move with sophistication.

How the basal ganglia and cerebellum divide their supportive roles in movement has intrigued neuroscientists for years. The functions of the two different regions are difficult to disentangle (Proville, et al., 2014). To simplify, coordinating necessary muscle *selection* seems to be the specialization of the basal ganglia, while coordinating contraction *timing and degree* requires the cerebellum. Analogous smooth and elegant line production while drawing Snoopy requires sophisticated starting and stopping, and smooth transitions of pen direction, to avoid jerky images (see Fujisawa & Okayama, 2015). Another way to think about it is that the basal ganglia "chunk" flexors here and extensors there, while the cerebellum smooths out their actions. Such responsibilities are emphasized more strongly in either structure, though in any one effort we *will* utilize both structures.

The cerebellum provides its smoothing functions (while you are drawing Snoopy or doing any number of other tasks) through extensive error correction. A motor error occurs when the way we actually move does not match where we intended to move. Detecting errors therefore requires at least 2 streams of information: one about action and the other about intention. Intention comes to the cerebellum from the brain via projections from the pontine nuclei in the brainstem, or from spinal cord regions where descending UMN tracts depict what we *intend* to do (either consciously or implicitly) to *anticipate* goals which also ascend the spine into the cerebellum. The cerebellar input about movement derives from proprioception feedback (largely muscle stretch), which depicts *moves that happened,* ascending from the spinal cord via spinocerebellar tracts (or trigeminal that monitors head/face movement). Progressively, the cerebellum compares these two components and adjusts the prompting UMN signals until we nail it (*intended = actual*).

The role of the cerebellum in providing smooth integration of motor effort timing and intensity can be appreciated when it is impaired, as happens in cerebellar ataxia or when someone consumes alcohol (Sokolov et al., 2017; Spencer et al., 2005; Bareš et al., 2009). Cerebellar damage (cerebellar ataxia) causes dysmetria, where one exhibits a "drunken gait" because foot placement can't be error-corrected or smoothed, and intention tremor where movements overshoot stopping points and oscillate around target destinations (Schwartze et al., 2016). It is important not to conflate alcohol effects with cerebellar damage. Drunkenness derives from the way alcohol enhances the effects of GABA across wide regions of both motor control and decision-making circuits. Cerebellar damage specifically eliminates the controlled-targeted landing of limbs to the right place. Cerebellar ataxia is analogous to rendering smooth limousine driving into two choices: full throttle or slamming on breaks. Yet visually, walking while drunk and walking with cerebellar ataxia appear outwardly similar. The cerebellum constantly contributes to posture alignment behind the scenes (subconsciously) so removing these contributions causes loose and wavy lack of balance. People can experience ataxic gait for multiple reasons. Any ataxic walking (caused by cerebellar damage or any other source) looks like feet land where they do by accident, rather than on purpose. Cerebellar ataxic gait occurs because the cerebellum can't correct the extent of movements properly, emphasizing approximations (see this video on Ataxia).

Corrective actions incorporated with ongoing movement, not after we perceive movement

Just like the basal ganglia, the cerebellum supports movement control by tweaking the thalamic VA/VL complex, though synapsing through distinct circuits. The cerebellum is inspired into action in relation to initial learning, and later provides anticipatory adjustment signals that integrate into ongoing movement but are sent prior to or in conjunction with the UMN signals that descend to initiate LMN actions. Most cerebellum contributions are made subconsciously and become integrated into movements we *subsequently* produce (the lack of sufficient adjustment is shown when errors occur, such as ataxia). Success in generating desired smooth movements, ending without jerky shakes, requires error corrections to be incorporated before movement begins. If we had to wait for proprioceptive feedback before correcting, there would always be a "jerk-back" effect due to delays inherent in sensory systems. This can result from conscious movement monitoring. Conscious proprioception (cortical) is slower than ongoing movements, so modifications come post-movement, making it jerky and uncoordinated. Damaged cerebellum patients are limited to this, so when their conscious stream is distracted, they produce more movement errors because their cortex cannot multitask well (Brunamonti, et al., 2014). Thus, a well-primed (skill consolidated) healthy cerebellum recognizes the need, then delivers its adjustments along with *subsequent* UMN-driven movement efforts rather than correcting errors after the fact. It learns while we do behind the scenes to determine how much boosting or tapering is necessary, and subsequently contributes these adjustments to future movements. Imagine these contributions behind the scenes of established Olympic floor moves, or the slight-of-hand demonstrated by a seasoned magician (Dahms et al., 2020).

Practicing and imagining success

It's important for new behavior to start off slowly, allowing sufficient time for proprioceptive sensory feedback to reach the CNS and become conscious perception. We do this all the time when we are learning how to move in specific ways. For example, choreographed fight moves à la Jackie Chan are typically rehearsed slowly before filming so actors can anticipate blows and pull back to "act" hit. By going slowly, we have time to consciously perceive motor errors and use our cerebellar processes to correct them. Through this slow practice, the cerebellum helps us learn how to execute movements faster and faster, with less conscious perception of proprioception needed to keep our bodies on track. Notably, even imagined movements can play a role in this learning—a mental rehearsal without physical engagement (Decety & Ingvar, 1990, Jackson et al., 2003). Actors, dancers, skaters, and sports professionals do this *all the time*. The performance improvements from imagined practice are real, not illusory, as they entrain the cerebellar circuitry support of cerebral movement control via the same circuitry that adapts to actual movement.

Primary motor cortex

The primary motor cortex (M1) region receives our "upper-level" synaptic progression last. This progression collects and coordinates movement intentions before sending those UMN compilations down to the brainstem and spinal cord for movement generation by the LMNs. M1 is also the first cortical area with full lateralization of limb and face movement control: M1 neurons on the right side of the brain all target LMNs for the left limbs and facial area, while M1 neurons on the left side of the brain all target LMNs for the right limbs and facial areas. This lateralization contrasts with the premotor regions we discussed so far, which engage bilateral control. M1 lateralization is restricted to limbs and facial lateral areas, not the trunk, which is generally ipsilaterally controlled.

Primary Precentral Gyrus Organization

The posterior frontal cortex has a major crease, the central sulcus, dividing the precentral (green in Figure 10.20) and postcentral gyri.

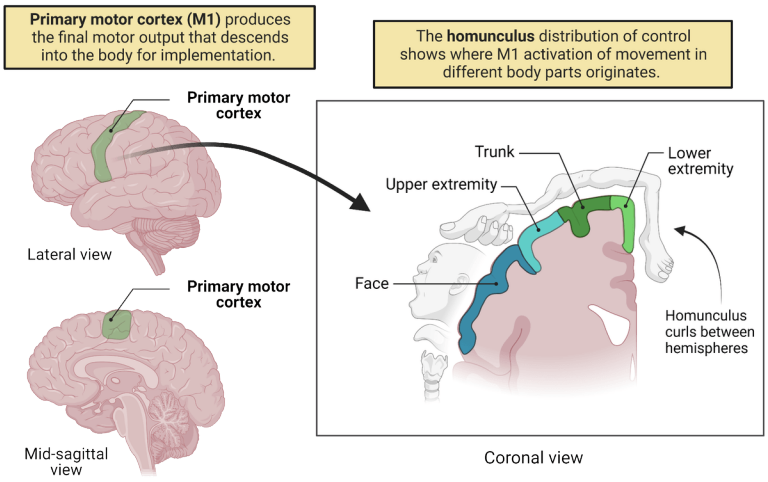

Figure 10.20 Primary motor cortex

This strip, from between the hemispheres out laterally, ending just above the lateral fissure (defining the top of the temporal lobe), contains the primary drivers of voluntarily organized/coordinated movement known collectively as the primary motor cortex. The neurons of the primary motor cortex are arranged in a homunculus. This arrangement is essentially a map of a little person lying across the precentral gyrus, so toe control is buried between the hemispheres. This map was famously created by neurosurgeon Wilder Penfield, who assessed movements when brain regions were stimulated during surgeries correcting epilepsy and made direct recordings during movements (Penfield and Rasmussen, 1950). The idea of a homunculus depicts the "person" as a distorted image made up of enlarged areas where more neuronal space engages with specific moveable body parts. The complexity or subtlety of movement of any body part tends to engage larger numbers of neurons as this attribute goes up, so the eventual map of a person has a large tongue, huge lips, prominent face around the forehead, huge hands and feet, with a smaller torso, limbs, and joints, according to the degree of movement sophistication possible. The motor homunculus is to movement sophistication as the somatosensory homunculus is to somatosensory density (see Chapter 9 Touch and Pain).

Descending motor projections

The primary motor cortex neurons send their axons out to the brainstem and spinal cord via three tracts (see Figure 10.21).

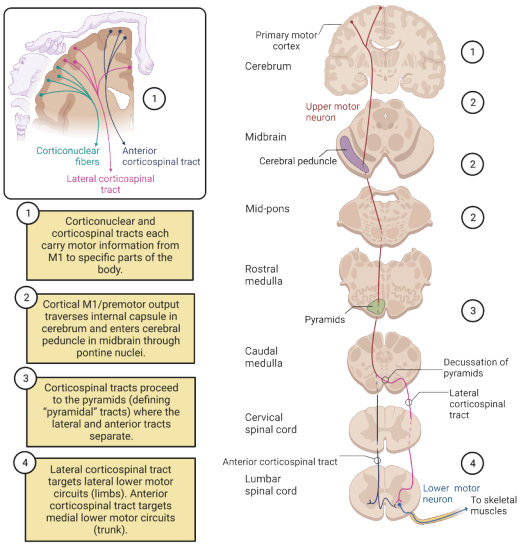

Figure 10.21 Corticospinal motor pathways for the body

- The corticobulbar (or corticonuclear) tract, carries descending efferents from the cortex, synapsing on brainstem nuclei serving regions of the jaw, face, ear mechanisms, for gagging or swallowing, or crinkling our noses. Corticobulbar tracts largely provide bilateral support, where each side directly serves ipsilaterally, and crosses over at the level of various nuclei to the contralateral side. The exception to this rule would be the descending tracts subserving the facial nucleus, specifically the lower part of the face, which is exclusively contralateral (Patestas & Gartner, 2016). We're overlooking autonomic patterning aspects of this projection to focus on controlled movement.
- The lateral corticospinal tract is the major descending tract for body limbs. It crosses almost entirely to the other side of the body to control the contralateral (opposite side from originating hemisphere) limbs, mostly the arm/hand/fingers and leg/foot/toes.
- The anterior corticospinal tract is a smaller but important tract responsible for controlling trunk muscles and more medial aspects. While some of this tract decussates (crosses over) at the level of the spinal cord in the ventral white matter as shown in Figure 10.21, a majority subserves the ipsilateral side.

The upper part of our body (head) is largely controlled via cranial nerves derived from the brainstem and therefore the corticobulbar tract. The two corticospinal tracts descend to different levels of the spinal cord. Within the spinal cord, these tracts interact with LMNs and the circuitry making up the reflex architecture (also used to engage the knee-jerk, or withdrawal reflexes, utilizing local spinal circuitry described above) to control the lower parts of our bodies such as limbs and trunk.

Why do some descending UMNs control need to cross over to operate the opposite side of the body? One simple explanation may be that visual information passing through lenses of your eyes is flipped (see Chapter 6 Vision). Events occurring to our left pass to the right sides of our retinae. The right sides of each retina connect with the right hemisphere, while the left connects with the left. However, the information they process is relevant to the opposite sides of our bodies. This probably created pressure for natural selection to derive a map of limb control so each hemisphere could control the opposite side.

People behind the science: Vector Trajectories

Apostolos Georgopoulos MD, Ph.D. currently heads a Brain Center at The University of Minnesota where he is Regents Professor of Neuroscience. His work brought important insights to the way motor cortex activates limb movement. To appreciate his findings, it's important to understand the concept of a vector, a force directing movement encompassing both *speed and direction*.

When we kick a ball softly, its path forms a vector with little *speed*. Kicking the ball harder in the same *direction* maintains this vector with greater *speed*. A different *direction* would elicit a different vector. Similarly with moving our arms. The generation of force accumulation to drive movement intensity at the LMN level was discussed above in 10.1 The Physiological Actions Implementing Movement – Contraction of Muscles.

The key to Georgopoulos' findings is, across the population of M1 neurons, each neuron's activity seems to be associated with a vector of limb movement. Or, as each M1 motoneuron fires action potentials, their frequencies intensify in relation to the limb movement's direction and trajectory range (Georgopoulos et al., 1983).

To determine this, Dr. Georgopoulos and his team recorded from hundreds of individual M1 neurons within the brains of monkeys while the monkeys moved a specialized apparatus (Georgopoulos et al., 1992). It was set up like a large lever-shift which picked up movement direction, and could be adjusted to provide back-pressure along certain trajectories.

Think of this as a large old-school Atari-like joystick, shifting rather than simply angling in different directions. When the animal pushed the lever in one direction, a distinct neuron population appearing to "prefer" that direction elicited strong bursts of activity, while other populations "preferring" other directions diminished responses. If the vector of an M1 neuron's preference required extra force, that MI neuron increased its firing rate (Georgopoulos et al., 1982). The key to the developing hypothesis was at each motion of the arm, larger populations of neurons contributed their "vote" for arm vectors into the descending feed. At each moment key populations "won" the vote to over-ride alternative movement preferences. Brain democracy!

At first, these experiments were performed with only two-dimensional movement directions across a flat surface (1983). Eventually, more exciting results were obtained from monkey arm movement tracked three-dimensionally. Based on the same premise, a more complex division of "preferences" yielded similar results (Georgopoulos et al., 1988). It is fascinating to consider the wider implications of this. Guiding one's arm or hand towards a target follows calculations of vector trajectories in regions like the posterior parietal cortex and the cerebellum, to be sent forward toward the premotor cortex.

It's now clearer how this guidance appears to help reinforce individual neurons contributing "votes" or preference activations in concert with needed directions through increasingly selective intensities of stimulation of select M1 cortical neurons (e.g., Georgopoulos et al., 1992; Taira et al., 1990). Since these preference activations persist across a population, this also seems to provide greater stability in the capacity to elicit distinct movements, diminishing the probability of select damage eliminating specific movement trajectory capacities. This would be incredibly helpful in restoring post-stroke movement, for example. To draw Snoopy, many hand muscles need to be selected individually or simultaneously and this neuronal "voting" is also supported by basal ganglia contributions along the way when we draw him again, and again (necessary for moving pictures).

Moving Beyond Vector Trajectories into Controlling Robot Arms

In the previous section, we discussed how the pioneering work of Georgopoulos pointed towards this key cortical element of "voting populations." More recently, new and fascinating cutting-edge things have been happening to build off his work. By studying consensus of neuronal activities and how they link to vector trajectories, researchers have begun to be able to predict where limbs might go based on neuronal activity! Once you can predict what neuronal activity does, it becomes possible to tap in to those neurons to recreate movements. This basic idea is what underpins many modern efforts to link robot prosthetics to the human brain.

Many forms of brain or spinal cord damage can render a person unable to move any limbs despite owning an active and intact brain (quadriplegic). Neuroscientists such as Andrew Schwartz and others have been working to turn that remaining ability to direct movements in the brain into real movements of robotic prosthetic devices. This work is all based in the original concepts derived from Georgopoulos and has now yielded robotic arms that can respond to recordings from a patient's brain and engage complex arm and hand type movements to select, grasp, and move objects! The details of how two human subjects with quadriplegia were implanted with specialized electrodes over the arm-related region of their M1 homunculi and subsequently gained considerable control over an attached robot arm are originally described in Lancet (Collinger et al., 2013). Since this initial proof-of-principle, improvements have been made. For example, a patient in 2015 received a version of this system that was not just unidirectional—taking motor commands and linking them to the prosthetic. This newer version also incorporated input from sensory information. Remember back to our example of a monkey swinging through the trees. To swing, grasp and release well, the monkey integrated several sources of touch information. Grasping without feeling the grasp would make branch swinging a far greater challenge for the monkey. The same applies to patients with prosthetic limbs. Adding touch feedback greatly improved the ability of the patient to use their limb. These devices, adjusted for circumstances, are moving outside of a theoretical possibility into a distinct therapeutic option reality! If movement practice feedback could also be incorporated, it is conceivable that practiced learning could get such patients back to cooking in the kitchen!

A Special inspiration from your author

It has been a pleasure sharing a neuroscientist's view of movement with you all. All the complexity ensures our capacity to *do what we want to do*. Considerable control has evolved at both lower implementation levels and higher formulation levels. Collaborations between brain, spine, and muscles above help us repeatedly *do what we want* without having to re-invent every motion from scratch. Background processing and delegation promotes the feeling of quick shifts from thinking to doing. Now you should have a better sense of the complexity. On several occasions, this chapter has used expressions like 'apparently,' 'it seems like,' or 'seems to.' Such expressions demonstrate there's a lot neuroscientists still need to learn about body movement mechanisms. The author hopes that future neuroscientists or readers with related intentions may see clarifying this as a challenge. Also, this author wishes to thank the editor Dr. Elizabeth Kirby, his father (Dr. Harald M. Sandstrom), his brother (Jonathan R. Sandstrom), and his colleague Dr. Gary L. Dunbar for their extraordinary editorial support that substantially improved this chapter's clarity and focus.

View this Interactive Content online

Effector skeletal muscles move limbs and body parts in desired directions by pulling in a coordinated manner, typically in conjunction with antagonistic partners pulling in opposite directions. To accomplish the pulling, motor neurons synapsing at neuromuscular junctions initiate contractions. Depolarization derived from ACh opening nicotinic ionotropic receptors filters through the muscle fiber from the sarcolemma into the inner core where myofibrils reside, releasing calcium from storage in the sarcoplasmic reticulum. This calcium initiates and maintains a contractile machinery where myosin heads extending from thick filaments pull actin chains inward by forming cross-links and cocking inward, then releasing and re-binding with power strokes until the calcium dissipates. This activity represents a multiple-molecule-coordinated event occurring at different speeds and efficiencies depending on the arrangement of muscle fiber connections to the tendons, and on the efficiency of myosin head cross-bridge cycling. The pulling can either move a limb or slow externally forced movement by eliciting force attempting to counteract loads (e.g., shortening or lengthening contractions). This gets more complex when different antagonist muscles play tug-of-war across joints to produce desired movement speeds, as the same systems are in play. Force increase can be elicited by higher frequency activation of select populations of muscle fibers, or increasingly recruiting larger populations of muscle fibers to pull in synergistic (same) or close to the same directions. Muscles simultaneously pulling in distinct directions tend to produce intermediate movement trajectories between the pull directions. Blood-rich fibers are commonly recruited first. They are more resistant to fatigue. Those utilizing stored glycogen alone for their energy (ATP) source are recruited for final thrusts.

10.2 Eliciting Contractions from Lower Levels – Lower Motoneurons and Reflex Arcs

Distinguishing between upper and lower motoneurons (UMNs, LMNs) is important to divide the overall action of motor control into the conscious selection and patterning activity (upper) versus the implementation and minor adjustments to maintain bodily status quo (lower). We described how LMNs extend into the periphery to synapse with muscle fibers, and how larger LMNs synapse with more fibers than smaller, thus forming the larger and smaller motor units. Motor units activate connected muscles through neuromuscular junctions relatively simultaneously. Fibers synapsed upon typically pull in the same direction.

LMNs are activated from their central nervous system residence either at the brainstem or spinal cord, either via descending UMNs in the context of conscious intended actions or via reflex arcs creating quick local lower corrective actions while monitoring circumstances with sensory feedback. Within the spinal cord, LMNs are arranged at the ventral spinal grey in a pattern where medial LMNs connect to medial body parts. The more lateral the LMN residence, the more lateral the activated body part (e.g., finger movement most lateral in the cervical cord). Also within the spinal cord: reflex arc circuitry and circuitry supporting central pattern generation coordinate simple levels of locomotion.

Spindle fibers and Golgi tendon organs are the two main sensory feedback systems for muscles. They cover stretch and muscle tension, respectively. Muscle spindles detect stretch via the longitudinal pull on intrafusal muscle fibers, which can be tightened by the gamma motoneuron system to maintain sensitivity at critical moments. Golgi tendon organs detect tension when muscles pull against a load, producing inward pressure by the collagen fibers constituting tendons. They can help ensure a soft touch when

needed. Proprioceptive sensory systems also extend into skin vibration and stretch sensations contributing to more complex actions at the lower level.

10.3 Our Brain Gets Involved – Responsibilities of Upper Motor Systems

Upper system control, via upper motoneuron sources, combines the efforts of the prefrontal cortices, the basal ganglia, the cerebellum, the premotor cortices, and the primary motor cortices. Initial maneuvers based on our needs are formulated within the prefrontal cortices. Inappropriate or inconsiderate behaviors may stem from damage within prefrontal cortex in general, or more specifics may be distorted as plans get further formulated in premotor cortices. After a big picture “what do we want” is formulated, movements to accomplish this grow in increasingly specific ways, like deciding which limbs, directions, and sequences of movement will accomplish our objectives. We build repertoires within the basal ganglia. The premotor cortices dip into the underlying striatum to engage circuits compiling and connecting movement repertoires in conjunction with the correct groups of muscles (ensembles) for the task.

As the details of movement plans are “fleshed out,” the basal ganglia loop feeds modulatory control back into the premotor cortices, and the cerebellum becomes involved by increasingly anticipating/appreciating how the intensity of movements needs to be tailored for smoothness. The cerebellum orders and manages this effort, paying attention to limb location and possible adjustment. The compiled patterning, including smoothing from the cerebellum, is fed forward into the primary motor cortex, encouraging proper sets of UMNs to activate and promote preferred movements with the proper emphasis (likely continuously reinforced by the cerebellum).

M1 primary motor cortex neurons descend into the brainstem and spinal cord to elicit movements of either the head/viscera or the body/limbs. Thus, the planned movements are fed forward toward areas closer to their physical enactment. If these signals are blocked, weakness and spasticity result because this releases lower motoneurons from control of activation and reflex circuitry through which many descending upper motoneuron signals actuate control.

2.5.16: Key Terms

10.1 The Physiological Actions Implementing Movement – Contraction of Muscles

actin, cramps, cross-bridges, lengthening contraction, lower motoneurons (LMNs), motor unit, myofiber (muscle fiber), myofibril, myosin, neuromuscular junction, overstretching, power stroke, sarcolemma, sarcomere, sarcoplasmic reticulum, shortening contraction, tropomyosin, troponin

10.2 Eliciting Contractions from Lower Levels – Lower Motoneurons and Reflex Arcs

acetylcholinesterase, alpha motoneurons, ballistic, central pattern generators (& generation), collagen fibers (tendon components), extrafusal muscle fibers, gamma motoneurons, Golgi tendon organs, hyperreflexia, intrafusal muscle fibers, junctional folds, knee-jerk reflex, lower motor neurons (LMNs), muscle spindles (spindle fibers), Myasthenia Gravis, nicotinic receptors, proprioception, reflexes, size principle, somatotopically, upper motor neurons (UMNs)

10.3 Our Brain Gets Involved – Responsibilities of Upper Motor Systems

acquisition, action tremor, anterior corticospinal tract, basal ganglia, bradykinesia, caudate, central sulcus, cerebellar ataxia, cerebellum, chorea, cogwheel rigidity, consolidation, corticobulbar (corticonuclear) tract, dysmetria, dysphagia, dystonia, globus pallidus (internal/external), homunculus, intention tremor, lateral corticospinal tract, Levodopa (L-DOPA), muscle ensemble, motor sequence, prefrontal cortices (cortex), premotor cortices (cortex), primary motor cortex (M1), putamen, resting tremor, retention, spinocerebellar tracts, substantia nigra pars compacta, Tourette's syndrome, ventral anterior/ventrolateral (VA/VL) complex

2.5.18: Multiple Choice

10.1 The Physiological Actions Implementing Movement – Contraction of Muscles

1.
A skeletal muscle is composed of many multi-nucleated _____ which each contain bundles of _____, where contractile proteins are organized into _____.

a. sarcomeres / myofibrils / muscle cells (fibers)
b. muscle cells (fibers) / sarcomeres / myofibrils
c. myofibrils / muscle cells (fibers) / sarcomeres
d. muscle cells (fibers) / myofibrils / sarcomeres

2 .
The thin filament base attachment points that also demarcate the borders of each sarcomere in a myofibril are called:

a. M-lines.
b. Z-discs.
c. A-bands.
d. I-bands.

3.
Which contraction-associated protein is considered a “thick filament” and contains the globular heads within a myofibril?

a. actin
b. myosin
c. troponin
d. tropomyosin

4 .
Which contraction-associated protein initially covers binding sites expressed by the thin filaments that the globular heads of thick filaments bind to, and is *moved away* by another protein to initiate contraction?

a. actin
b. myosin
c. troponin
d. tropomyosin

5.
Which contraction-associated protein starts the cross-bridge cycle with its globular heads bound with adenosine diphosphate (ADP)?

a. actin
b. myosin
c. troponin
d. tropomyosin

6 .
Which ion is primarily involved in the initiation of massive muscle *depolarization* called a muscle action potential following the opening voltage-gated channels?

a. calcium
b. sodium
c. potassium
d. chloride

7.
Which of the below neuron types would synapse directly onto a muscle cell/fiber?

a. lower motoneuron
b. upper motoneuron
c. pyramidal cell in motor cortex
d. interneuron in spinal cord

10.2 Eliciting Contractions from Lower Levels – Lower Motoneurons and Reflex Arcs

8 .
A motor unit consists of:

a. a muscle cell/fiber.
b. a motoneuron and all the muscle cells/fibers with which it synapses.
c. an anatomically defined muscle bundle such as the triceps muscle.
d. all motoneurons that connect to muscle cells/fibers pulling a limb in the same direction.

9.
Neurons that make up the hypoglossal cranial nerve (#12), and a motoneuron from the ventrolateral spine, are both ***lower*** motoneurons because (by definition) they:

a. are involved in motor control.
b. reside in motoric-associated regions of the nervous system.
c. project directly to muscles.
d. release acetylcholine as their neurotransmitter.

10 .
The enzyme that breaks down acetylcholine into choline and an acetyl group after release from motoneurons is called:

a. nicotinamide.
b. choline acetyltransferase.
c. adrenaline.
d. acetylcholinesterase.

11.
A disease that results from diminished expression of nicotinic receptors on motor end plates and corresponding jerky/slowed movement is called:

a. myasthenia gravis.
b. amyotrophic lateral sclerosis.
c. hyperadrenalism.
d. depressive neurosis.

12 .
Which type of sensory system is NOT involved in “proprioception?”

a. Golgi tendon organs
b. nociceptors
c. spindle fibers
d. intrafusal muscle fibers

13.
The _____ are sensitive to longitudinal pull or stretch of muscles and work by wrapping around differentially expanded _____ muscle cells/fibers which maintain different sensitivities to stretch within muscle masses.

a. spindle fibers / intrafusal
b. Golgi tendon organs / dead

c. dorsal root ganglion neurons / extrafusal
d. spindle fibers / extrafusal

14 .
Golgi tendon organs extend sinuous sensory fibers that intermingle with the _____ fibers making up muscle tendons. Thus, when muscles engage increasing _____, these sensory devices inform us of this (which can be considerably useful to unconscious appreciation of which limb currently holds our body weight during walking).

a. glycogen / force
b. collagen / stretch
c. collagen / force
d. keratin / stretch

15.
One sort of task described in your textbook that involves a complex dynamic coordination between skin touch receptors, Golgi tendon organs, and both upper and lower motoneurons would be:

a. monkeys scratching their heads.
b. monkeys swishing their tails around.
c. monkeys swinging through the trees from branch to branch.
d. monkeys eating a banana.

10.3 Our Brain Gets Involved – Responsibilities of Upper Motor Systems

16 .
Ascending targets of both the basal ganglia modifications and the cerebellar modifications (modified within the ventral anterior and ventral lateral thalamus), generate thalamocortical projections targeting the _____ cortices where preconscious habitual or practiced modifications and adjustments are added more specifically to our movement repertoires via _____ cortices.

a. premotor / supplementary
b. supplementary / occipital
c. posterior parietal / temporal
d. cingulate / premotor

17.
Which brain structure is NOT a part of the basal ganglia?

a. caudate nucleus
b. internal globus pallidus
c. red nucleus
d. all of the above

18 .
The basal ganglia specializes in combining proper muscle selection over time so that a motor sequence reproduces the same desired motion pattern every time it is elicited from our repertoire (like being able to draw Snoopy). When this skill becomes so established it requires little trial-and-error it is referred to as a:

a. reflex.
b. posture.
c. rebound.
d. habit.

19.
Which of the below brain diseases manifests “cogwheel rigidity” as a major part of its outward behavioral expression?

a. Huntington’s disease
b. Parkinson’s disease
c. cerebellar ataxia
d. Tourette’s syndrome

20 .
Dopamine is a(n) _____ neurotransmitter that _____.

a. ionotropic / excites neurons that it influences like all excitatory neurotransmitters
b. modulatory / acts as movement juice and biases all movement neuronal systems towards activation of movement
c. modulatory / largely adjusts the way neurons within the caudate and putamen targets respond to more rapid ionotropic stimulation
d. ionotropic / inhibits neurons that it influences like all inhibitory neurotransmitters

21.
The Parkinson's disease treatment called *deep brain stimulation* targets either the _____ or select regions within the _____ or _____ thalamus for continuous rapid electrical stimulation in a manner that reversibly diminishes the distorted contributions of these structures to the symptoms of Parkinson's disease.

a. caudate / ventral posterolateral / ventral posteromedial
b. globus pallidus external / ventral anterior / ventrolateral
c. internal globus pallidus / ventral posterolateral / ventral posteromedial
d. internal globus pallidus / ventral anterior / ventrolateral

22 .
Which of the below behavioral symptoms is generally NOT among those expressed after cerebellar damage?

a. ataxia
b. drunken gait
c. resting tremor
d. intention tremor

23.
Which descending axonal fiber tract derived from the motor cortices among those depicted below is responsible for activating brainstem areas such as those responsible for movement-associated cranial nerves?

a. lateral corticospinal
b. anterior corticospinal
c. corticonuclear
d. corticothalamic

24 .
Which descending axonal fiber tract derived from the motor cortices among those depicted below is responsible for activating mostly trunk movement areas of the spinal cord responsible for such things as posture, or performing a belly-dance?

a. lateral corticospinal
b. anterior corticospinal
c. corticonuclear
d. corticothalamic

2.5.19: Fill in the Blank

10.1 The Physiological Actions Implementing Movement – Contraction of Muscles

1.
When the myosin globular head is attached to the thin filament binding site and proceeds to angle itself toward the center of the sarcomere to pull the thin filament inward while bound by Adenosine Diphosphate (ADP), this is called a _____.

10.2 Eliciting Contractions from Lower Levels – Lower Motoneurons and Reflex Arcs

2 .
Lower motoneurons within the spinal cord responsible for controlling finger movements are located within the ventral grey more _____ than motoneurons responsible for controlling shoulder movements.
3.
The type of sensation in which information about the stretch, amount of force used, or general location of limbs based on the extension of muscles are all processed is generally called _____.

10.3 Our Brain Gets Involved – Responsibilities of Upper Motor Systems

4 .
A timed pattern of sequential muscle activations such as what happens when we type out “a timed pattern of muscle activations,” on a keyboard is known as a _____.
5.
The precursor molecule representing partial production of dopamine as it is derived from the amino acid tyrosine, which is given to Parkinson’s patients because, unlike dopamine, it can cross the blood-brain barrier, is called _____.
6 .
The primary motor cortex (M1) strip in the precentral gyrus (frontal lobe) of our brains contains a map of movable body parts where the size of each part increases according to the sophistication or subtlety of movement said part can accomplish. This size-modified body part map is called the motor _____.

2.5.20: Touch

Touch

Learning Objectives

1. Describe the role of social and affective touch in development and bonding.

2. Describe how the somatosensory system allows for the sensing of touch, temperature, and position in space.

3. Describe the process of transduction in the senses of touch and proprioception.

4. Explain how expectations and context affect pain and touch experiences.
