Fourth, genetic information is transmitted across generations by genetic transmission (heredity). By contrast, learned information, in a few species including us, can also be transmitted across generations--not by genetic transmission, but instead by what is known as cultural transmission (tradition, imitation of the old by the younger members of the social group, books, teaching and learning, storytelling, and so forth). Cultural transmission occurs in relatively few species. We can do it; chimpanzees can do it to a limited degree; Japanese macaque (ma-cack) monkeys can do it to a limited degree. For example, one clever macaque female invented an efficient way to clean sand from wheat grains; other macaques in the group watched and learned, and the learned behavior spread throughout the group and then across generations--cultural transmission (Schofield, et al., 2018). However, rats, and most other species, can't do cultural transmission, and certainly no other species comes close to using cultural transmission to the extent that humans do.

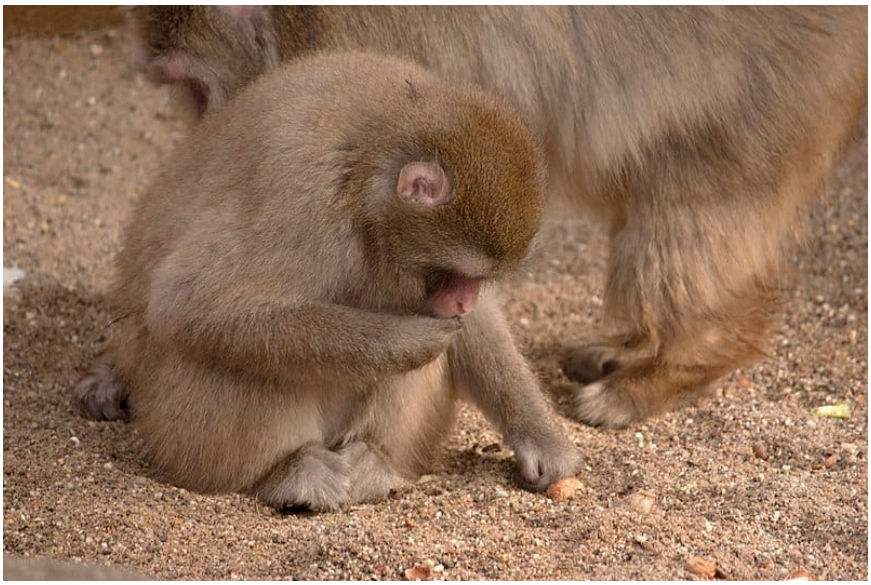

Figure 4.2.23.4: Macaque monkey feeding. Learned behaviors can be transmitted across generations by cultural transmission by humans and a limited number of other species including macaques (Image from Wikimedia Commons; File:Artis Dining Japanese macaque (6807832054).jpg; https://commons.wikimedia.org/wiki/F...8807832054).jpg; By Kitty Terwolbeck; licensed under the Creative Commons Attribution 2.0 Generic license).

Cultural transmission takes a special kind of brain but most species don't have the kind of brain circuit organization required for cultural transmission (the transmission of learned information from generation to generation). Language in humans, of course, plays a crucial role in human cultural transmission, but so do technological and social inventions such as writing, the printing press, film, video, formal education, research institutions, computers, and the internet. All have magnified human cultural transmission and played an enormous role in recent human adaptation (Koenigshofer, 2011). Just as swimming can be considered a defining adaptation of fish, cultural transmission is an adaptive specialty of humans.

	Period of Acquisition	Laws of Acquisition	Mechanisms of Encoding/Storage	Transmission Mechanism
Genetic information	acquired over generations (slow information acquisition process), producing species-wide, innate adaptations	acquired by the laws of evolution, primarily by natural selection, over the evolutionary history of the species	encoded and stored in a molecular code in DNA in the genes and chromosomes of the nucleus of cells	transmitted across generations by genetic transmission (heredity, inheritance)
Learned information	acquired during an individual's lifetime (fast information acquisition process) producing rapid and individualized adaptation	acquired by the laws of learning such as the law of effect and association by occurrence of events close in time	encoded and stored in changes in neural circuits probably involving changes in synaptic connections between neurons	transmitted across generations by cultural transmission

Table 10.1.1. Comparisons between genetic and learned information organizing behavior into adaptive patterns. Adaptations, including behavioral adaptations, are not random, but highly structured. This structure requires information. Two sources of information organize behavioral adaptations--genetics and learning, nature and nurture, in interaction (table and caption by

Kenneth A. Koenigshofer, PhD; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

Types of Biological Adaptation

At this point it is useful to note that biological adaptations can be loosely categorized into three (overlapping) general types:

1. Anatomical adaptations (structural features of the organism such as having fur, or wings, or fins, or hands, or bones, or a liver, or a large brain with a well developed cerebral cortex). These are organized by genetic information and change (evolve) only relatively slowly (although small changes, for example, in beak size and thickness of finches in the Galapagos, can occur much more rapidly; Grant & Grant, 1993).
2. Physiological adaptations (internal dynamic processes of the organism such as photosynthesis in plants, digestive processes in animals, the immune system's operations, shivering in response to cold, sweating in response to excess heat, the circulatory system's operations, etc.). These are organized by genetic information and change (evolve) only relatively slowly, although the immune system shows significant plasticity during the individual lifetime to deal with newly encountered pathogens.
3. Behavioral adaptations(the goal-directed movements of the organism and the mental processes such as thoughts, plans, emotions, perceptions, reasoning processes, imagination, etc. that underlie and control these movements). As implied above, behavioral adaptations can be organized by genetic information (genetically preprogrammed, "instinct" and reflexes; flying in flies; swimming in fish; feeding in frogs; sex drive in humans) or by learned information (acquired during the lifetime of the animal), or by a combination of both of these sources. It is important to be aware that *the abilities for learning* in any species are themselves genetically evolved. Species that can learn can do so only because learning, and the properties of the nervous system that make learning possible, evolved in those species, including humans, as a result of natural selection.

Figure 4.2.23.5: Human sex drive is inborn. It can be thought of as a psychological adaptation involving intense emotions leading to reproductive behavior within the context of a pair-bond, increasing likelihood of surviving offspring. Learned cultural practices influence courtship practices and the expression of innate sex drive. (Image from Wikipedia Commons; File:Family love wiki008.jpg; https://commons.wikimedia.org/wiki/F...ve_wiki008.jpg; By Shagil Kannur; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

Behavioral adaptations can be categorized, at least conceptually, into 2 major types based on the source of the information that controls them: 1) learned adaptive patterns of behavior, often called "adaptive adjustments" by biologists (organized primarily by learned information, that is, information acquired during the lifetime of the individual animal, such as agricultural practices in humans) and 2) genetic or innate behavioral adaptations (organized by hereditary information, information stored in DNA, acquired over the evolutionary history of the species). However, many behavioral adaptations (perhaps most, in the more complex animal species especially) are a combination of both sources of information. Learning always involves genetic information to some degree because even "general" forms of learning such as conditioning incorporate and interact with information acquired by genetic evolution. Ability to learn is genetically evolved and learning processes follow laws of learning evolved by natural selection. Even conditioning mechanisms incorporate genetically encoded information that guides learning (Chiappe &

McDonald, 2005; Gallistel, 1992, 2000; Koenigshofer, 2017).

Some authors refer to learned behaviors as "adjustments," rather than "adaptations." However, here we sometimes may use "learned behavioral adaptations" to emphasize that learning capacities themselves are genetically evolved, and that, generally (in healthy animals), learning and learned behaviors typically contribute to improved adaptation because of the evolved adaptive organization of pleasure and pain circuitry in the brain. For example, reward mechanisms in the brain that reinforce learned voluntary behaviors involve genetically evolved reward circuits, and punishments that inhibit voluntary behaviors involve activation of genetically evolved pain and fear circuits (reduced activity in reward circuits can also be "punishing"). In addition, behavioral change in general is a consequence of other evolved properties of brains at the synaptic level (see Section 10.4). The behavioral guidance provided by these circuits improves adaptation, increasing biological fitness (chances of survival and reproduction).

The behaviors of various animal species can be thought of as falling on a **nature-nurture continuum**, with some behaviors in some species (flies, roaches) being almost completely at the nature (innate) end of the continuum (i.e. behavior determined by genes and genetic evolution), while at the other end, the nurture end of the continuum, are behaviors which are dependent primarily on information acquired during the lifetime of the individual (i.e. learned information), such as termite fishing by a chimpanzee, or in the case of humans, how to make a flint spearhead, how to make a light bulb, do calculus, dig a well, or engage in modern agricultural practices (Koenigshofer, 2011, 2016). See figure 10.1.6 below.

Long-Term, Across-Generation Categorical Information vs. Short-Term Specific Information

One way to look at learning and genetics involves a general principle governing these two sources of information. Recall from Module 3.1 of this text that natural selection can only act on long-term, recurrent, across-generation environmental conditions in order to create complex adaptations. To illustrate, let's take an example from anatomy. Bones of sufficient strength to support the bodies of land animals against the downward pull of gravity evolved because the force of gravity has been present and stable over countless generations. To take a behavioral example, humans and many other animals evolved neural circuits for thirst as a motivating force causing them to seek out and consume water. However, natural selection could not have created the neural mechanisms for thirst if cellular need for water had not been consistently present over countless generations.

The general principle is this: natural selection can create genetic adaptations only to situations, adaptive problems, or other conditions of the environment that are regularly present generation after generation, because natural selection requires stable selection criteria over long periods of time to evolve complex adaptations. But in the case of behavioral/psychological adaptations, genetics can only give rather general direction to behavior because the environmental situations or conditions that led to the genetic evolution of the adaptation are themselves rather general categories of events; furthermore, these events are variable in their details but constant in their more abstract common features (Koenigshofer, 2017).

For example, the psychological adaptation, thirst, can guide and motivate the search for water and can motivate its consumption when found, but natural selection cannot code the location of water because the location of water in the environment is too variable from individual to individual and over time, and is therefore too unstable for natural selection to genetically encode the location of water in the environment. This is where learning comes in. Thirst, an innate adaptation, motivates the search for water, but once it is found, the specifics of the location and the quality of the water source must be learned and remembered. In this way, learning supplements genetic information. Learning fills in the detailed information needed to solve a particular adaptive problem or exploit a particular environmental opportunity to adaptive advantage within the specific environment of the individual animal. Genetic information is widespread or even universal throughout a species, whereas learned information is often unique, at least in its details, to the individual.

Genetic information acquired over generations of natural selection is more general and categorical (i.e. more abstract)--e.g. the feeling of thirst means "find and consume water," but doesn't provide the critical information about details such as the location of water. Thus, there arises a general principle: we can expect that whenever information acquired through evolution by natural selection is insufficient to specify a solution to an adaptive problem because more detailed and specific or particular information is needed, then learning mechanisms will evolve that are specific to the problem category (Koenigshofer, 2017).

For example, food selection is important in omnivores such as rats, coyotes, and humans (because they eat a wide variety of potential foods; unlike Koala bears that only eat eucalyptus leaves). In omnivores a specialized form of learning, called taste aversion learning, has evolved. Research shows that learned associations between taste and gastrointestinal illness are readily formed by omnivores, including us, but not in other species such as baleen whales that consume only one kind of food. Have you ever eaten some particular food and then gotten sick later and now you can't stand that food or taste? Genetic evolution equipped

omnivores like us with genetic information that allows us to quickly learn taste-illness associations (but not associations between the sight of the food and illness; this is an example of a "biological (i.e. genetic) constraint" on learning). Genetic evolution biologically prepared us to learn taste-illness associations, but it could not tell us which specific tastes we should associate with illness. That detail is left to learning, specific to the experience of the individual during the individual's lifetime.

Another example is that genetic information acquired by natural selection predisposes us, as a species, to learn cause-effect relationships in the environment (see Chapter 14 on Intelligence and Cognition) but doesn't tell us which *specific* things in one's own particular environment are causally related--again, that detail is left to learning and the learning is guided by genetically evolved predispositions to search for and learn causal relations in the environment (Koenigshofer, 2017).

Figure 4.2.23.6: Web construction by spiders is a complex set of movements directed by circuits in the spider nervous system constructed by information in the spider's DNA. The spider's behavior is so stereotyped that experts who study spiders can identify the species of spider from the structure of its web alone, even if the spider is not present. No learned information is required by the spider to construct its species-typical web. By contrast, human construction of structures is highly dependent upon learned information that has been culturally transmitted across generations. The human brain evolved mechanisms for learning, cultural transmission, comprehension of three-dimensional space, and the ability to visualize in imagination forms like the one depicted here. (Images from Wikipedia Commons; Source of image of spider and web: File:Spider weaving it's web.jpg; https://commons.wikimedia.org/wiki/F...it%27s_web.jpg; by Varun V Vasista; licensed under the Creative Commons Attribution-Share Alike 4.0 International license. Slow vs. Fast Mechanisms of Behavioral Change

Genetically organized behavioral adaptations (such as web-building in spiders), like anatomical and physiological adaptations, are organized by genetic information and therefore they change (evolve) only relatively slowly, over many generations by natural selection and other mechanisms of evolution (see Chapter 3). However, for many genes in the organism's phenotype, the gene's *expression* can be affected by multiple environmental factors. The study of this kind of gene-environment interaction is called epigenetics (see section on epigenetics in Chapter 3).

By contrast, learned behavioral adaptations ("adaptive adjustments") can change moment to moment and, as discussed above, may be transmitted (in some species) to future generations by cultural transmission to the benefit of those future generations. For example, the agricultural practices--learned behavioral adaptations or "adjustments"--upon which we have come to depend for our food supply, were invented by people who died generations ago. However, the death of those who invented these behaviors did not result in the loss of the successful behavioral adaptations upon which we depend for our food supply. Instead, these learned behavioral adaptations have been passed on, and refined, over many generations, to our current generation to its adaptive advantage--not by genetic transmission, but by cultural transmission. Our great capacity for cultural transmission is the single thing that makes us most different from other species, and accounts more than anything else for what we think of as being most

characteristically human---technology, art, agriculture, governments, economies, medicine, and science. All would impossible were we, humans, not so powerfully equipped by our brain evolution for efficient cultural transmission of learned behavioral adaptations across generations. By this means, the learning of prior generations is not lost, but remains over generations for each new generation to build upon. Just like flying is a specialty of birds, or swimming is a specialty of fish, cultural transmission is the specialty of the human species.

Summary

In short, learning describes processes whereby information is acquired during the lifetime of an individual animal. Learned information, along with genetic information, helps organize the animal's behavior into adaptive patterns, especially in response to short-term environmental changes where specific, frequently changing details are adaptively significant and therefore must be captured by the organism and put to adaptive use. For example, learning and remembering where a temporary water hole is located on the open savannah is essential to survival for innumerable species that live on the African plains. Because many short-term event details do not regularly recur over generations, such non-recurrent environmental details cannot drive natural selection for genetically evolved instinctual or reflexive adaptations. Instead adaptation to such novel idiosyncratic event details favors the evolution of learning mechanisms (Koenigshofer, 2017). Usually this learned information supplements hereditary (genetic) sources of information in the organization of successful behavioral adaptations--behavioral solutions to the problems of survival and reproduction. As noted above, behavior is one way that organisms (at least animals) adapt. Behavior becomes organized into adaptive patterns by information (i.e. behavior is not random, but guided by laws of nature which govern chances of survival and reproduction--laws of evolution and the laws of learning). The information that organizes behavior comes from the genes after having been perfected by eons of genetic evolution by natural selection. That organizing information can also come from learning by an individual animal during its lifetime (laws which govern learning are also organized to enhance survival and reproduction--see sections below).

Adaptive behaviors can be transmitted to future generations. If the behavior is organized by information in the genes, then that behavior can be transmitted by genetic transmission (heredity). If the information for a particular behavior comes from learning (and is stored in memory), then the behavior can be transmitted to future generations, not by genetic transmission, but instead by cultural transmission (in some species, as noted above). Thus behavioral adaptations in species capable of cultural transmission can undergo not only genetic evolution (true for behaviors organized by genetic information contained in DNA, and also true of anatomical and physiological adaptations) but also cultural evolution (examples of cultural evolution are the development of human technology, modern medical practices, agricultural practices, economies, science, governmental systems and so on, leading over time to generally improved human adaptation). Cultural transmission and the resulting cultural evolution gives our species great survival advantage. Cultural transmission accounts for the success of the human species more than any other single factor.

4.2.24: Types of Learning and Biological Adaptation

Learning Objectives

1. Describe the various types of learning and how each contributes to adaptation
2. Discuss in what ways both classical and operant conditioning involve the learning of predictive relations between different types of events in the world
3. Discuss the learning of predictive relationships among events in the environment and the navigation of "the causal texture of the world"
4. Describe specialized forms of learning and how each contributes to solution of a particular adaptive problem (problem domain) in a particular species
5. Explain classical (Pavlovian) conditioning and instrumental (operant) conditioning
6. Describe similarities and differences between the two types of conditioning
7. Explain the concept of adaptively specialized learning and give examples
8. Discuss the four aspects of observational learning according to Social Learning Theory.
9. Describe how habituation conserves resources
10. Describe research that suggests cognitive learning in animals

Overview

Learning brings to mind school, memorization, tests, and study. But these associations are related to a single type of learning only, human verbal learning. Actually, learning, as you may already know, is a much broader phenomenon. In this module, we examine learning in its various forms and the ways in which it advances adaptation to the environment. First of all, learning of various sorts occurs in a wide range of animal species. For example, experiments have shown that even an insect species, the honey bee, can learn (for example, where a food source is located). Furthermore, across species, a wide range of behaviors can be acquired or modified by learning, giving behavior in many species a great deal of plasticity. In addition, we now know that learning is not a single unitary capacity, but instead there are many different, but related, processes, ranging from imprinting to cognitive learning. As discussed previously, behavior is a type of adaptation. It is not random, but quite orderly, and as such it is dependent upon information for its organization. Remember that the information that organizes behavioral adaptations can come from genes, from learning, or from a combination of both. In this module, preliminary to discussion of the neural mechanisms of learning, we examine several types of learning and how they interact with genetic information to serve adaptation. Imprinting is a clear example of learning that is biologically (genetically) "prepared" (controlled and facilitated by innate factors as a consequence of evolution). Both forms of conditioning, classical and operant, involve learning the predictive relationships between events in the environment and both involve innate genetic facilitation (biological preparedness) and biological constraints just like imprinting does. However, in conditioning, genetic influences on learning involve much more abstract and relational features of the world than in more clearly specialized forms of learning such as imprinting and learned taste aversion. In every kind of learning, learning fills in informational details that are too variable, short-term, and individually experienced to be captured by natural selection and thereby encoded into genes. By contrast, more abstract and general features, common to particular learning situations or problem types across generations, *are* captured by natural selection, genetically encoded, and provide innate, genetic information about the problem type (problem domain) that guides and facilitates the learning.

Habituation and Adaptation

Habituation is a simple form of learning that produces a decrease in response to a repeated stimulus that has no adaptive significance. In other words, as an adaptively unimportant stimulus is repeatedly presented to an animal, it will gradually cease responding to the stimulus as it learns that the stimulus holds no information that might impact its biological fitness (survival and reproduction). Prairie dogs typically sound an alarm call when threatened by a predator, but they become habituated to the sound of human footsteps when no harm is associated with this sound; therefore, they no longer respond to the sound of human footsteps with an alarm call, nor do they run and hide, but instead they spend their time and energy on more productive behaviors. Habituation is a form of non-associative learning given that the stimulus is not associated with any punishment or reward.

Habituation is highly adaptive. It increases the efficient use of an animal's limited resources. Imagine birds feeding in a field along a highway. The first time a bird feeds in this situation, it will probably fly away when a car speeds past. However, over time, as more cars pass by and nothing harmful or otherwise adaptively significant happens to the bird, it learns to ignore the passing

traffic. Instead of flying away, it simply continues to feed, saving time, metabolic energy, and the limited processing capacity of its brain. Habituation conserves these important biological resources of the organism, resources that would otherwise be wasted by responding to adaptively irrelevant stimuli. Without habituation, behavior would lose biological efficiency, decreasing biological fitness in the struggle for survival and reproduction.

Habituation occurs when your brain has already extracted all the adaptive information that a stimulus or an event holds. Once habituation has occurred, as long as the habituated stimulus or event is unchanging, it makes good adaptive sense for the animal to ignore it. Habituation has done its job by conserving the animal's biological resources. But habituation is only half the story. What happens when, after habituation, a change in the stimulus or situation occurs? Stimulus change might signal that something important has happened. If so, the animal must reengage the processing capacity of its brain, its attentional resources, to evaluate whether the stimulus change might signal something that is adaptively important that may require a behavioral response. This recovery of responding to a habituated stimulus is called dishabituation (the undoing of habituation as the organism now responds to the stimulus situation it had previously stopped responding to). For example, suppose there is a loud backfire from one of the passing cars. The birds fly off, at least temporarily.

Figure 4.2.24.1: Habituation is adaptive. Birds feeding along a road eventually habituate to passing traffic preventing them from wasting time and energy by flying away (escape behavior) unnecessarily in the absence of real threat, thereby increasing time and energy available for feeding (Image from Wikimedia Commons; File:Birds feeding on newly ploughed land with Ballymagreehan Hill in the background - geograph.org.uk - 2202208.jpg; https://commons.wikimedia.org/wiki/F..._-_2202208.jpg; by Eric Jones; licensed under the Creative Commons Attribution-Share Alike 2.0 Generic license.).

Another example comes from a former student of mine who had been in the Navy submarine corps. He said that when he was assigned to his first sub, he couldn't sleep for several nights because of the loud metallic noise coming from the engines. However, after several nights of hearing the racket, he finally "got used to it", he habituated to a repeated stimulus that had no adaptive significance, and he was then able to sleep soundly. Can you guess what would now wake him up? It was the *absence* of the noise, when the engines were shut down, that would immediately awaken him. Maybe the sub is under attack, or the engines are damaged and they are sinking, or perhaps the sub has docked in port and there could be some adaptive consequences for the sailor like a potential romantic opportunity on shore, or other adaptive resources such as preferred foods. Habituation is undone by stimulus change. Habituation and dishabituation are constantly at work efficiently conserving or deploying the organism's biological resources (metabolic energy, time, and brain processing capacity) as required by environmental circumstances. The net effect is efficient and adaptive distribution of the organism's biological resources, thereby increasing biological fitness.

Figure 4.2.24.2: After habituation to the loud sound of their submarine's engines, sailors sleep through the noise, but are awakened by the silence if the engines stop. Stimulus change reverses habituation. This is called dishabituation and is highly adaptive; see text (Image from Wikimedia Commons; File:Vladivostok Submarine S-56 Forward torpedo room P8050522 2475.jpg; https://commons.wikimedia.org/wiki/F...50522_2475.jpg; by Alexxx1979; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

One lesson is clear: that stimulus change is very potent in causing the brain to become alert and responsive. This implies that the brain must hold an ongoing representation or neural model of a current situation and must respond to any mismatch between that ongoing memory and the current stimulus situation (see chapter on Intelligence, Cognition, and Language). This is a very adaptive property of the brain's functioning. For example, imagine you are studying psychology late at night. Your window is open and a breeze gently bangs the blinds against the window frame as you read. You will probably habituate to the sound, and thus pay no attention to it, to the point where you don't even hear it as you continue to study. But then, if the lights in your house suddenly go out, you probably will dishabituate and pay attention to every little sound, including the sounds coming from the blinds. Your brain is programmed to respond to stimulus change, to novelty, because in stimulus change there may be information important for survival and reproduction, demanding an adaptive response. Could those sounds in the dark be an intruder who might harm you or your family (who, by the way, carry a portion of your genes; see discussion of kin selection in the chapter on evolution and genetics)?

If there is no danger or other adaptively significant event associated with the stimulus change, then habituation will again occur as the animal or human learns that the stimulus change can be safely ignored. As noted above, habituation prevents the animal or human from wasting time, energy, and processing capacity on things that have no adaptive importance, thereby increasing behavioral efficiency. Habituation is an elegant mechanism for conserving biological resources and thus contributes greatly to adaptation and biological fitness (survival and reproduction). Interestingly, habituation mechanisms appear to be highly conserved across a wide range of species, emphasizing the importance of habituation for survival (see Schmid et al., 2010).

Conditioning and Biological Adaptation

Basic principles of learning are always operating and always influencing human and animal behavior. This section continues by discussing two fundamental forms of associative learning: classical (Pavlovian) and operant (instrumental) conditioning. Through them, we respectively learn to associate 1) stimuli in the environment, or 2) our own behaviors, with adaptively significant events, such as rewards and punishments or other stimuli. The two types of learning have been intensively studied because they have powerful effects on behavior, and because they provide methods that allow scientists to rigorously analyze learning processes in detail, an endeavor important to biological psychologists searching for the physical basis of learning and memory in the brain. This module describes how both classical and operant conditioning involve the learning of predictive relationships between events (if event A occurs, then event B is likely to follow), and how this contributes to adaptation. The module concludes by discussion of adaptively specialized forms of learning and observational learning, which are forms of learning that are largely distinct from classical and operant conditioning.

Classical Conditioning

Many people are familiar with the classic study of “Pavlov’s dog,” but rarely do they understand the significance of Pavlov's discovery. In fact, Pavlov’s work helps explain why some people get anxious just looking at a crowded bus, why the sound of a morning alarm is so hated, and even why we swear off certain foods we’ve only tried once. Classical (or Pavlovian) conditioning is one of the fundamental ways we learn about the world, specifically its predictive relationships between events. This involves

learning *what leads to what* in an organism's environment. This is extremely valuable adaptive information that animals and humans appear to incorporate into brain-mediated cognitive models of how the world works--information which allows prediction and therefore improved organization of behavior into adaptive patterns (a topic to be discussed more in the chapter on Intelligence, Cognition, and Language). But classical conditioning is far more than just a theory of learning; it is also arguably a theory of identity. Your favorite music, clothes, even political candidate, might all be a result of the same process that makes a dog drool at the sound of bell.

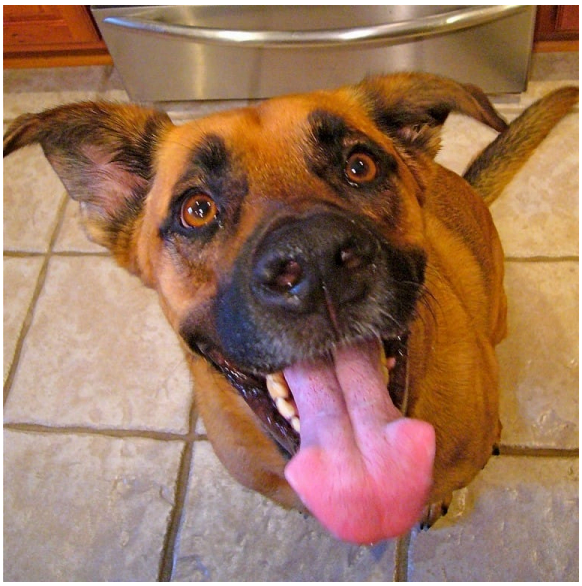

Figure 4.2.24.3: Does your dog learn to beg for food because you reinforce her by feeding her from the table? Classical conditioning signals to your dog when food reward may be available and operant conditioning (see below) occurs when begging is reinforced by a food reward [Image: David Mease, https://nobaproject.com/modules/cond...g-and-learning, CC BY-NC 2.0]

In his famous experiment, Pavlov rang a bell and then gave a dog some food. After repeating this pairing multiple times, the dog eventually treated the bell as a signal for food, and began salivating in anticipation of the treat. This kind of result has been reproduced in the lab using a wide range of signals (e.g., tones, light, tastes, settings) paired with many different events besides food (e.g., drugs, shocks, illness; see below).

We now believe that this same learning process, **classical conditioning**, is engaged, for example, when humans associate a drug they've taken with the environment in which they've taken it; when they associate a stimulus (e.g., a symbol for vacation, like a big beach towel) with an emotional event (like a burst of happiness); and when a cat associates the sound of an electric can opener with feeding time. Classical conditioning is strongest if the conditioned stimulus (CS) and unconditioned stimulus (US) are intense or salient. It is also best if the CS and US are relatively new and the organism hasn't been frequently exposed to them before. And it is especially strong if the organism's biology (its genetic evolution) has prepared it to associate a particular CS and US. For example, rats, coyotes, and humans are naturally inclined by natural selection and the resulting evolution of their brain circuitry to associate an illness with a flavor, rather than with a light or tone. Although classical conditioning may seem "old" or "too simple" a theory, it is still widely studied today because it is a straightforward test of associative learning that can be used to study other, more complex behaviors, and biological psychologists can use it to study how at least some forms of learning occur in the brain.

Conditioning Involves Learning Predictive Relations

Pavlov was studying the salivation reflex, reflexive drooling in response to food placed in the mouth. A **reflex** is an innate, adaptive, genetically built-in stimulus-response (S-R) relationship; in this case, the stimulus is food in the mouth, the unconditioned or **unconditional stimulus** (a stimulus unconditional, i.e. not dependent upon prior learning; **US**), and the **unconditional response** (unconditional, not dependent, upon prior learning; **UR**) is salivation to food in the mouth which lubricates the food and starts to break it down, facilitating mastication, swallowing, and digestion--the adaptive function of the salivation reflex (US--UR).

Recall that Pavlov found that if he rang a bell just before feeding his dogs, the dogs came to associate the sound of the bell with the coming presentation of food. Thus, after this classical conditioning had occurred, the bell alone (the conditioned or **conditional stimulus**--conditional upon prior learning; **CS**) caused the dog to salivate, before the presentation of food. The conditional stimulus (Pavlov's original terminology which was mistranslated from Russian as "conditioned") is a signal that has no importance to the organism until it is paired with something that does have adaptive significance, in this case, food. Reliable pairing of CS and US close together in time (**temporal contiguity**) is important to the processes of classical conditioning. However, temporal contiguity alone is not sufficient for classical conditioning. The pairing of stimuli must be reliable so that a **predictive relationship** is maintained between CS and US. Predictiveness between CS and US determines whether or not an association is formed. If the CS does not predict occurrence of the US, no conditioning occurs (Gallistel, et al., 1991).

Evidence that classical conditioning involves the **learning of predictive relations** between stimuli comes from a phenomenon known as **blocking** (see Kamin, 1969). In blocking, if a CS already predicts the US, and if a new CS is added, no association is formed between the *new* CS and the US, no matter how many times or how closely in time they are paired together. The reason? The *original* CS already predicts the US, so no new or additional predictive information about occurrence of the US is added by the new CS. Thus, the new CS is ignored as a source of predictive information and is therefore "blocked" from becoming a signal for the US, and no conditioning between the new CS and US occurs. Furthermore, other studies show that if the predictive relation between CS and US is "diluted" or weakened by any presentations of the US without the CS preceding it, conditioning between CS and US is impeded. This is because if the US can occur without the CS preceding the US, then this fact reduces the predictive power of the CS and violates the contingency between CS and US, impairing conditioning. This shows that a **predictive contingency** between CS and US is what is learned in classical conditioning and that contingency is the necessary condition for conditioning to take place (Rescorla, 1966, 1968).

Both of these important research findings emphasize that conditioning is about *learning to predict what leads to what* in the environment--**classical conditioning** is the **learning of predictive relations between stimuli**, leading to the learned emission of responses that **prepare for** the coming **US**. Blocking and other related effects indicate that the learning process tends to take in the most valid **predictors of adaptively significant events** and ignore the less useful ones. This is an exceedingly important process that allows the animal or human to learn important adaptive information about its specific environment.

For example, as a result of classical conditioning, Pavlov's dogs learned to anticipate, to predict, one event (US) signaled by earlier occurrence of another (CS). In a sense, the dogs use the bell as a signal to predict that food is on its way; therefore they salivate when the bell is rung, because they now expect that food is coming next. After conditioning, when Pavlov presented the bell, the dogs salivated to the bell alone (**conditional response, CR**), whereas before conditioning they did not. Thus, we have a change in behavior as a result of experience--learning. The animal has acquired information about its environment--i.e. predictive information. The world is full of predictive and causal relations. If the organism is to effectively organize its behavior to maximize adaptation, it must be able to learn these relations and put that information to adaptive use. Classical conditioning is a mechanism for learning these **predictive (sometimes causal) relationships** among things in its specific environment.

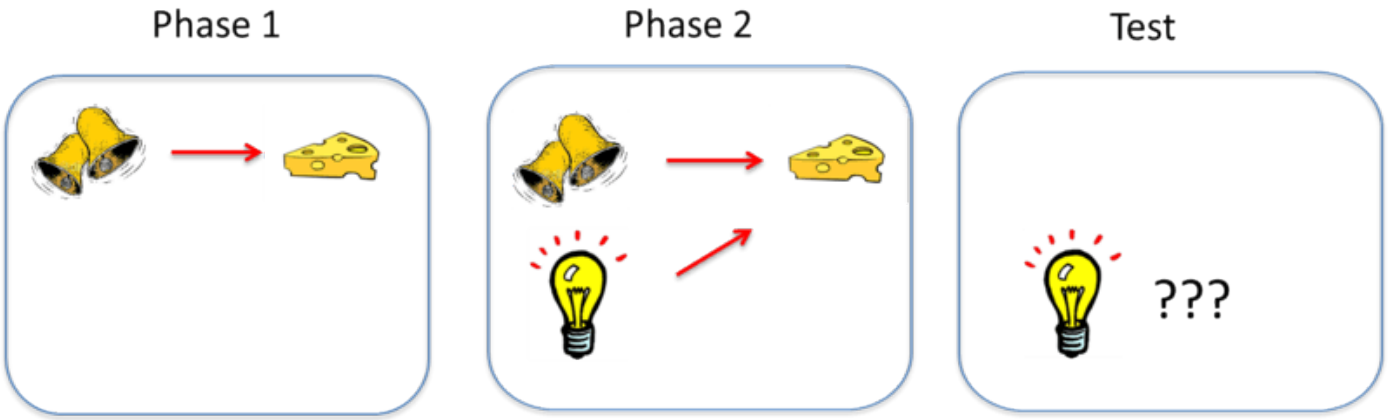

Figure 4.2.24.4: Illustration of blocking. Phase 1: Conditioning where bell is CS, food is US. Phase 2: after Phase 1 conditioning has been completed a second CS, light, is added. Test: When light CS is tested, no CR occurs to it; no conditioning to the light CS occurs. Reason: Bell CS already predicts food; therefore light does not add any additional predictive information so no conditioning to light CS occurs. Conclusion: Classical conditioning involves learning of predictive relations between stimuli. An animal first learns to associate one CS—call it stimulus A—with a US. In the illustration above, the sound of a bell (stimulus A) is paired with the presentation of food. Once this association is learned, in a second phase, a second stimulus—stimulus B—is

presented alongside stimulus A, such that the two stimuli are paired with the US together. In the illustration, a light is added and turned on at the same time the bell is rung. However, because the animal has already learned the association between stimulus A (the bell) and the food, the animal doesn't learn an association between stimulus B (the light) and the food. That is, the conditioned response only occurs during the presentation of stimulus A, because the earlier conditioning of A "blocks" the conditioning of B when B is added to A. (Image from M. Boulton, NOBA, https://nobaproject.com/modules/cond...g-and-learning; courtesy of Bernard W. Balleine).

Classical conditioning is anticipatory, and preparatory for future appearance of the US. A classical CS (e.g., the bell) does not merely elicit a simple, unitary reflex. Pavlov emphasized salivation because that was the only response he measured. But his bell almost certainly elicited a whole *system* of responses that functioned to get the organism ready for the upcoming US (food). For example, in addition to salivation, CSs (such as the bell) that signal that food is coming also elicit the secretion of gastric acid, pancreatic enzymes, and insulin (which gets blood glucose into cells). All of these responses anticipate coming food and prepare the body for efficient digestion, improving adaptation.

Classical conditioning is also involved in other aspects of eating. Flavors associated with certain nutrients (such as sugar or fat) can become preferred without arousing any awareness of the pairing (an example of implicit or unconscious learning). For example, protein is a US that your body automatically craves more of once you start to consume it (UR): since proteins are highly concentrated in meat, the flavor of meat becomes a CS (or cue, that proteins are on the way), which perpetuates the cycle of craving for yet more meat (this automatic bodily reaction now a CR).

In a general way, classical conditioning occurs whenever neutral stimuli are associated with adaptively significant events. Classical conditioning is of great adaptive importance in a wide range of circumstances across species. Significantly, Gallistel (1992) points out that classical conditioning permits an animal to map what Tolman and Brunswik (1935) called the "causal texture of the environment." Understanding *what causes what* in the environment is highly adaptive because it allows successful, accurate prediction about events and makes effective manipulation of the environment possible. In a way, in classical conditioning, the animal learns an **if-then contingency** or **if-then predictive relationship** between two events in its environment. If event A occurs, then event B is likely to follow. If bell rings, then food is likely coming next. Learning *what leads to what* in the world permits prediction and therefore much more effective organization of behavioral adaptation than would otherwise be possible. In the evolution of animal brains, we can speculate that animals who had the capacity in their brains for classical conditioning would certainly have had an adaptive advantage, and thus a selective (as in natural selection) advantage, over other members of their species which lacked that ability or possessed it to a lesser degree (Koenigshofer, 2011, 2016). If you can predict that something is coming, then you can better prepare for it and increase the chances of an adaptive outcome for you (and your genes). Classical conditioning has apparently been conserved during evolution given that classical conditioning is found in an enormous variety of animals from humans to sea slugs.

Modern studies of classical conditioning use a very wide range of CSs and USs and measure a wide range of conditioned responses including emotional responses. If an experimenter sounds a tone just before applying a mild shock to a rat's feet, the tone will elicit fear or anxiety after one or two pairings. Similar fear conditioning plays a role in creating many anxiety disorders in humans, such as phobias and panic disorders, where people associate cues (such as closed spaces, or a shopping mall) with panic or other emotional trauma (Mineka & Zinbarg, 2006). Here, rather than a response like salivation, the CS triggers an emotion. Have you experienced conditioned emotional responses to formerly emotionally neutral stimuli? How about the emotional response you might have to a particular song, or a particular place, that once was your and your ex-partner's favorite song or the place you would go to meet one another? Or after you break up with someone, you seem to see their car (or cars like theirs) everywhere and you have a brief moment of anticipation that you might see them. Classical conditioning plays a large role in our emotional lives, and in the emotional lives of other animals as well.

Figure 4.2.24.5: Intense emotions can be classically conditioned to originally neutral stimuli such as places or songs associated with a special person. (Image from Wikimedia Commons; File:A couple looking at the sea.jpg; https://commons.wikimedia.org/wiki/F...at_the_sea.jpg; by Joydip dutt; https://commons.wikimedia.org/wiki/F...at_the_sea.jpg; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

Where classical conditioning takes place in the nervous systems varies with the nature of the stimuli involved. For example, clearly an auditory CS such as a bell will involve auditory pathways including the auditory system's medial geniculate nucleus of the thalamus (Fanselow & Poulos, 2005) and auditory cortex in the temporal lobe, while a visual CS will involve visual pathways including the visual system's lateral geniculate nucleus of the thalamus and visual areas of cortex. A US such as food will involve taste pathways, whereas presentation of a painful shock US will involve pain and fear pathways. Researchers have identified a number of brain areas that become active during fear conditioning. In response to a painful shock during conditioning, there is increased neural activity in the **red nucleus**, **amygdala**, **dorsal striatum**, the **brainstem**, the **insula**, and parts of the **anterior cingulate cortices**, whereas **anticipation** of a shock that was not delivered increased neural activity in only the **red nucleus**, the **anterior insular** and **dorsal anterior cingulate cortices** (Linnman, et al., 2011). Other biological psychologists found that the **cerebellum** has a special role in simpler forms such as the conditioning of the eye blink reflex in rabbits (Thompson & Steinmetz, 2009), whereas more complex conditioning involves the **hippocampus** and **hippocampal-cerebellar interactions** (Schmajuk & DiCarlo, 1991). Research by scientists such as Eric Kandell (1976) on the neural mechanisms of learning suggests that at the level of the synapse the mechanisms for learning may be very similar for all types of learning, across species, involving changes in synaptic conductance. We will consider mechanisms of learning at the synaptic level later in this chapter.

Pavlov discovered a number of phenomena of classical conditioning. He found that once his dogs were classically conditioned to one bell (one CS), they would also respond (produce a CR, salivation to a bell in this case) to other similar stimuli (other bells). You may recall from Introductory Psychology that this is called **stimulus generalization**. The more similar a new stimulus was to the original CS, the stronger the CR to the new stimulus. This is called **stimulus generalization gradient**. For example, if you get bitten by a German Shepherd dog, you will probably be a little afraid of all dogs (stimulus generalization) and you will be *more* afraid of all big dogs and *even more* afraid of all German Shepherd dogs (stimulus generalization gradient). Clearly, stimulus generalization is very adaptive, because it **permits you to make predictions** not only about the original stimulus but also about **similar stimuli--stimuli of the same category**. Inferences and predictions based on generalization from one member of a category to other members of the same category is one prominent feature of cognition in intelligent creatures, including humans (see chapter on Intelligence, Cognition, and Language).

Pavlov also discovered **extinction**. Recall from Introductory Psychology that if the CS is not followed by the US at least some of the time, then eventually the CR will no longer occur in response to the presentation of the CS. When the animal stops producing the CR in response to the CS, we say that extinction of the CR has occurred. After conditioning of the salivation response, when the dog salivates to the bell, it is really salivating in *anticipation* of coming food. Even though the food may not now occur, the dog will still salivate to the bell for awhile, but eventually it learns to stop responding to the bell (extinction of the conditioned response) once the bell no longer reliably predicts food. In extinction, the animal hasn't forgotten its previous experience of a predictive relationship between stimuli, it simply learns that the predictive relation no longer holds, so it uses this new information and stops responding to the old contingency between previously conditioned events. This is demonstrated by the fact that a

single pairing of the old predictive contingency between CS and US is often sufficient to reinstate the extinguished response. In conditioning the dog learned the rule that bell means coming food; in extinction the dog learns that the rule has changed and bell no longer predicts food, so naturally it stops salivating to the bell--that's extinction of the CR.

This makes good adaptive sense. Remember that in classical conditioning, the animal is learning a predictive relationship between two events in its environment (i.e. If CS occurs, then US is likely to follow, so the animal responds to the CS in anticipation of the expected US). However, if in fact the predictive relationship between those events in the environment no longer exists (that is, occurrence of CS no longer reliably predicts the future occurrence of the US), then it makes good (adaptive) sense that the animal will no longer respond to the CS since the CS no longer signals that the US will follow.

In fact, what is happening during conditioning and extinction is that the animal is **tracking (or adjusting its mental model of) the predictive relationships** among events in its world as those relationships dynamically change. Conditioning is really part of an animal's neural representation of its environment (not necessarily explicit or conscious), including the things in that environment and the relationships among them. Any individual instance of **classical conditioning is just a slice in time** in a continuous; ongoing, dynamic process, within the animal's brain, of **modeling or representing the world and its changing contingencies--**contingencies or predictive relations between stimuli which the animal must successfully "navigate" in order to successfully adapt. Extinction, like acquisition of conditioned responses, is just one component in the animal's ability to **track the predictive relationships** between events in its environment and then to put that information to work guiding behavior. Similar dynamics apply to the second major type of conditioning, operant (or instrumental) conditioning.

Operant Conditioning

Operant conditioning, as you probably recall from your course in Introductory Psychology, is a second kind of conditioning in which the organism actively operates on the environment. Like classical conditioning, it also involves learning a predictive relationship between events, but the events are different than in classical conditioning. In operant or instrumental conditioning, the animal or human learns a **predictive relationship between its own voluntary behavior and the outcome or effect of that behavior**. In the best-known example, a rat in a laboratory learns to press a lever or a bird pecks a display in a cage (called a “Skinner box”) to receive food.

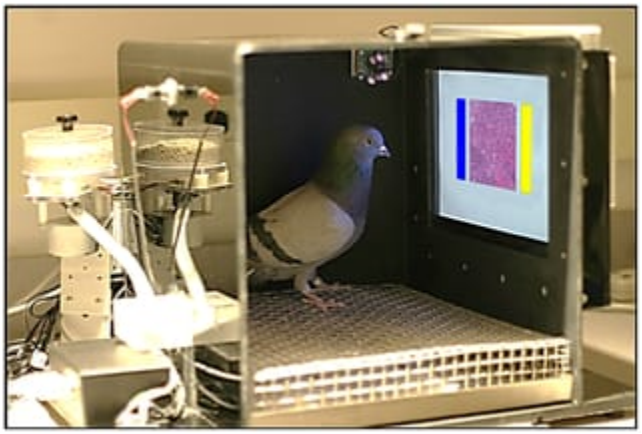

Figure 4.2.24.6: An operant conditioning chamber. Pecking on the correct color will deliver food reinforcement to the pigeon (Image from Wikimedia Commons; File:The pigeons’ training environment.png; https://commons.wikimedia.org/wiki/F...nvironment.png; Creative Commons CC0 1.0 Universal Public Domain Dedication).

Operant conditioning research studies how the effects of a behavior influence the probability that it will occur again. For example, the effects of the rat’s lever-pressing behavior (i.e., receiving a food pellet) influences the probability that it will keep pressing the lever. According to Thorndike’s **law of effect**, when a behavior has a positive (satisfying) effect or consequence, it is likely to be repeated in the future. However, when a behavior has a negative (painful/unpleasant) consequence, it is *less* likely to be repeated in the future. In other words, the **effect of a response, determines its future probability**. Effects that increase the frequency of behaviors are referred to as **reinforcers**, and effects that decrease their frequency are referred to as **punishers**.

In general, operant conditioning involves an animal or human **tracking the reinforcement contingencies** or dependencies in its environment and exploiting them to its advantage. Clearly, operant conditioning is highly adaptive. Operant conditioning shapes the voluntary behavior of the organism to maximize reinforcement and minimize punishment, just as we would expect from the

law of effect. The law of effect in turn depends upon **reward circuits** in the **mesolimbic system** (see Chapter on Psychoactive Drugs) and on circuits for **pain and the emotional response to pain** which are distributed in many regions of the brain including the **somatosensory cortex, insula, amygdala, anterior cingulate cortex, and the prefrontal cortex** (see chapter on Sensory processes). **Reinforcers activate mesolimbic pleasure circuitry** in the brain or reduce activity in pain circuits. This gives the organism feedback about its actions. Reinforcers and activation of pleasure circuits tend to be **associated with enhanced adaptation** (food, a reinforcer to an animal deprived of food, enhances chances of survival). **Punishers activate circuitry for physical or emotional pain** and tend to be **associated with reduced adaptation and biological fitness** (i.e. reduced chances of survival and reproduction; physical pain is associated with potential tissue damage, while emotional pain is often associated with loss of things or persons upon which one depends or highly values, including romantic partners, financial or social status, etc.). Voluntary behaviors by the animal which lead to positive consequences (and increased pleasure; reinforcement) for the animal tend to be repeated (increase in probability in the future). Voluntary behaviors which the animal produces that lead to nothing or lead to negative outcomes for the animal (a reduction in pleasure or the occurrence of pain) tend not to be repeated, but avoided by the animal in the future. In this way, by the law of effect, in psychologically healthy individuals, voluntary behavior becomes molded into more and more adaptive patterns so that animals and humans spend most of their time engaged in activities that improve adaptation and avoid activities that reduce it. By this means, learned voluntary behavior tends to serve successful behavioral adaptation.

Figure 4.2.24.7: Receiving a reward can condition you toward certain behaviors. For example, when you were a child, your mother may have offered you this deal: "Don't make a fuss when we're in the supermarket and you'll get a candy treat on the way out." [Image: Oliver Hammond, https://nobaproject.com/modules/cond...g-and-learning; CC BY-NC-SA 2.0]

This is a wonderful mechanism for assuring the adaptive organization of behavior in species which have behavioral capacities beyond rigidly genetically programmed behavior. In species such as fish, reptiles, amphibians, and many invertebrate species, the larger portion of behavioral adaptation is organized by information in the genes, honed over millions of years of evolution by natural selection. These reflexes and "instincts" generally do not rely very much, if at all, upon information acquired during the lifetime of the individual animal (i.e. learning), but instead upon information acquired over the evolutionary history of the species and stored in DNA.

Learned voluntary behavior is flexible but must also be directed into adaptive patterns by some principle, and that principle is the law of effect. The law of effect allows behavioral flexibility but also provides a mechanism for assuring that the animal (or human) learns adaptive behavior, behavior good for it and its genes, most of the time. "Voluntary" behaviors are not rigidly pre-formed by genetic information, but are organized in a more general way which allows for their modification by information gathered from the animal's current environment (experienced day to day and even moment to moment). This information gathering, moment to moment, continuously modifying "voluntary" behavior into more and more adaptive patterns is the essence of operant conditioning and its evolutionary significance. Without the law of effect, or some similar principle provided by natural selection, voluntary behavior would be chaotic, without direction, and could not be an instrument for adaptation to the environment. Behavior would degenerate into maladaptive form leading to the rapid demise of such creatures with brains so ill-equipped for survival. The law of effect, built into the circuitry of human and animal brains by eons of natural selection, permits behavioral flexibility with an overall adaptive direction--an exquisite evolved mechanism for regulation of behavior that is not under rigid genetic control.

Like classical conditioning, operant conditioning is part of the way an animal forms a **mental model or neural representation** of its environment and the predictive relationships among events in that environment, but, as noted above, the events are different than in the case of classical conditioning. In classical conditioning, it is the predictive relationships between two stimulus events that is learned. In operant conditioning, it is the predictive relationships between a voluntary response and its outcome or consequence that is learned. Prediction allows preparation for future, even if the future is moments away, and preparation for what is coming next improves chances of survival and reproduction (for example, classical conditioning of sexual reflexes gives a reproductive advantage in male chimpanzees competing for mating opportunities; operant conditioning of courtship behaviors in humans can improve reproductive success).

When we examine operant conditioning, we see that it bears some similarities to evolution by natural selection. In operant conditioning, voluntary responses by an animal that are successful usually are reproduced (repeated) and those that are unsuccessful (not reinforced) get weeded out (they are not repeated). In evolution by natural selection, genetic alternatives that are successful (lead to better adaptation) get reproduced (and appear in future generations) and those that are unsuccessful (do not lead to improved adaptation or are maladaptive) get weeded out (they are not replicated in future generations). In each case, a selection mechanism (natural selection or the law of effect) preserves some alternatives (genetic or behavioral, respectively) into the future, while eliminating others. In both cases, the result is improved adaptation.

Instrumental Responses Come Under Stimulus Control

As you know, the classic operant response in the laboratory is lever-pressing in rats, reinforced by food. However, things can be arranged so that lever-pressing only produces pellets when a particular stimulus is present. For example, lever-pressing can be reinforced only when a light in the Skinner box is turned on; when the light is off, no food is released from lever-pressing. The rat soon learns to discriminate between the light-on and light-off conditions, and presses the lever only in the presence of the light (responses in light-off are extinguished). In everyday life, think about waiting in the turn lane at a traffic light. Although you know that green means go, only when you have the green *arrow* do you turn. In this regard, the operant behavior is now said to be under **stimulus control**. And, as is the case with the traffic light, in the real world, stimulus control is probably the rule. We constantly monitor the environment for signals that tell us that a certain voluntary behavior is now called for, when at other times it is not. Will approaching someone to ask for a date be successful? We look for signs telling us whether the voluntary response of asking for a date is likely or unlikely to lead to reinforcement. If positive signs are not present, we may look for a better opportunity.

The stimulus controlling the operant response is called a **discriminative stimulus**. The stimulus can "set the occasion" for the operant response: It sets the occasion for the response-reinforcer relationship. For example, a person who is reinforced for drinking alcohol or eating excessively learns these behaviors in the presence of certain stimuli—a pub, a set of friends, a restaurant, or possibly the couch in front of the TV. These stimuli can be associated with the reinforcer. In this way, classical and operant conditioning are always intertwined.

Stimulus-control techniques are widely used in the laboratory to study perception and other psychological processes in animals. For example, the rat would not be able to respond appropriately to light-on and light-off conditions if it could not see the light. Following this logic, experiments using stimulus-control methods have tested how well animals see colors, hear ultrasounds, and detect magnetic fields. That is, researchers pair these discriminative stimuli with responses they know the animals already understand (such as pressing the lever). In this way, the researchers can test if the animals can learn to press the lever only when an ultrasound is played, for example.

These methods can also be used to study "higher" cognitive processes. For example, pigeons can learn to peck at different buttons in a Skinner box when pictures of flowers, cars, chairs, or people are shown on a miniature TV screen (Wasserman, 1995). Pecking button 1 (and no other) is reinforced in the presence of a flower image, button 2 in the presence of a chair image, and so on. Pigeons can learn the discrimination readily, and, under the right conditions, will even peck the correct buttons associated with pictures of *new* flowers, cars, chairs, and people they have never seen before. The birds have learned to **categorize** the sets of stimuli. Stimulus-control methods can be used to study how such categorization is learned, and for biological psychologists these methods can be used along with specific brain lesions to investigate the brain areas involved in categorization in animals.

Operant Conditioning Involves Choice

Another thing to know about operant conditioning is that the response always requires choosing one behavior over others. The student who goes to the bar on Thursday night chooses to drink instead of staying at home and studying. The rat chooses to press the lever instead of sleeping or scratching its ear in the back of the box. The alternative behaviors are each associated with their own reinforcers. And the tendency to perform a particular action depends on both the reinforcers earned for it and the reinforcers

earned for its alternatives.

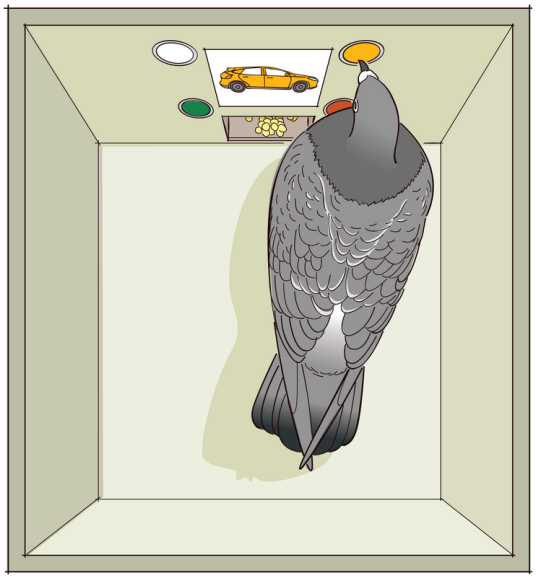

Figure 4.2.24.8: Pigeon in Skinner Box.

To investigate this idea, choice has been studied in the Skinner box by making two levers available for the rat (or two buttons available for the pigeon), each of which has its own reinforcement or payoff rate. A thorough study of choice in situations like this has led to a rule called the **quantitative law of effect** (Herrnstein, 1970), which can be understood without going into quantitative detail: The law acknowledges the fact that the effects of reinforcing one behavior depend crucially on how much reinforcement is earned for the behavior's alternatives. For example, if a pigeon learns that pecking one light will reward two food pellets, whereas the other light only rewards one, the pigeon will only peck the first light. However, what happens if the first light is more strenuous to reach than the second one? Will the cost of energy outweigh the bonus of food? Or will the extra food be worth the work? In general, a given reinforcer will be less reinforcing if there are many alternative reinforcers in the environment. For this reason, alcohol, sex, or drugs may be less powerful reinforcers if the person's environment is full of other sources of reinforcement, such as achievement at work or love from family members. (Image: from NOBA, Conditioning and Learning; https://nobaproject.com/modules/cond...g-and-learning)

An important distinction of operant conditioning is that it provides a method for studying how consequences influence "voluntary" behavior. As discussed above, the rat's decision to press the lever is voluntary, in the sense that the rat is free to make and repeat that response whenever it wants. Classical conditioning, on the other hand, is just the opposite—depending instead on "involuntary" behavior (e.g., the dog doesn't choose to drool; it just does). So, whereas the rat must actively participate and perform some kind of behavior to attain its reward, the dog in Pavlov's experiment is a passive participant. One of the lessons of operant conditioning research, then, is that voluntary behavior is strongly influenced by its consequences (recall the law of effect).

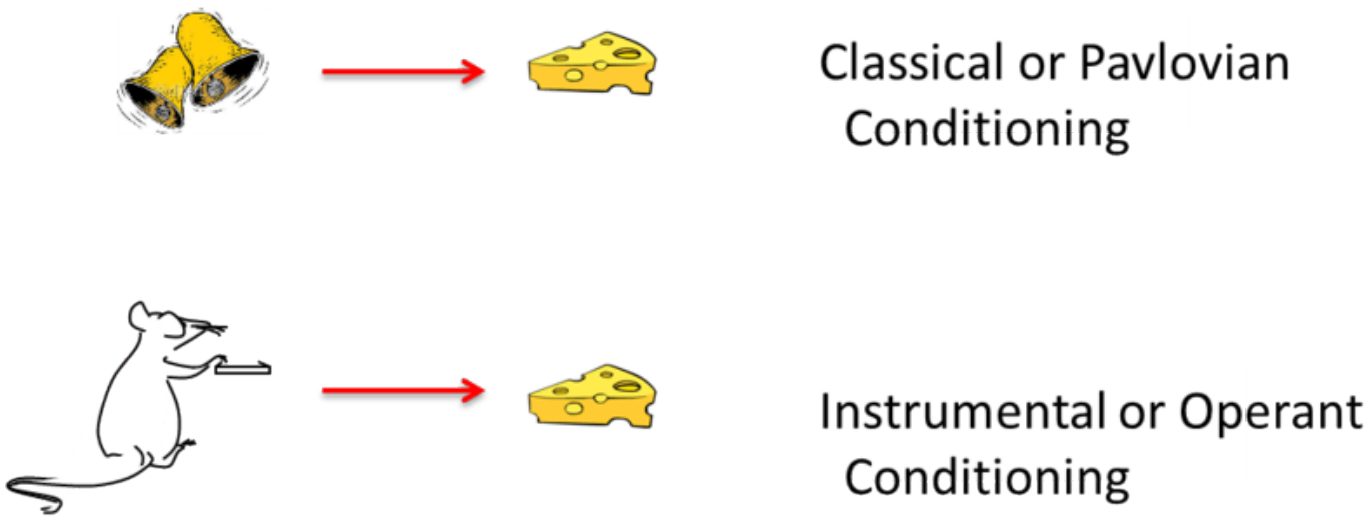

Figure 4.2.24.9: Basic elements of classical and instrumental conditioning. The two types of learning differ in *what* is learned. In classical conditioning, the animal has learned to associate a *stimulus* with an adaptively significant event, food in this case. In operant conditioning, the animal has learned to associate a voluntary *behavior*, pressing the lever, with an adaptively significant event, food. (Image and caption from M. Boulton, NOBA, Conditioning and Learning; courtesy of Bernard W. Balleine; https://nobaproject.com/modules/cond...g-and-learning).

The two types of conditioning occur continuously throughout our lives. It has been said that "much like the laws of gravity, the laws of learning are always in effect" (Spreat & Spreat, 1982).

Cognition in Instrumental Learning

Modern research also indicates that reinforcers do more than merely strengthen or "stamp in" the behaviors they are a consequence of, as was Thorndike's original view. Instead, animals learn about the specific consequences of each behavior, and will perform a behavior depending on how much they currently want—or "value"—its consequence. This idea is best illustrated by a phenomenon called the **reinforcer devaluation effect** (see Colwill & Rescorla, 1986). A rat is first trained to perform two instrumental actions (e.g., pressing a lever on the left, and on the right), each paired with a different reinforcer (e.g., a sweet sucrose solution, and a food pellet). At the end of this training, the rat tends to press both levers, alternating between the sucrose solution and the food pellet. In a second phase, one of the reinforcers (e.g., the sucrose) is then separately paired with illness. This conditions a taste aversion to the sucrose. In a final test, the rat is returned to the Skinner box and allowed to press either lever freely. No reinforcers are presented during this test (i.e., no sucrose or food comes from pressing the levers), so behavior during testing can only result from the rat's memory of what it has learned earlier. Importantly here, the rat chooses *not* to perform the response that once produced the reinforcer that it now has an aversion to (e.g., it won't press the sucrose lever). This means that the rat has learned and remembered the reinforcer associated with each response, and can combine that knowledge with the knowledge that the reinforcer is now "bad." Reinforcers do not merely stamp in responses; response varies with how much the rat wants/doesn't want a reinforcer. As described above, in operant conditioning, the animal tracks the changing reinforcement and punishment contingencies in its environment, as part of a dynamic mental model or neural representation of its world, and it adjusts its behavior accordingly.

Habituation, classical conditioning, and operant conditioning are just three types of learning. Each contributes to adaptation and increases biological fitness (chances of solving the problems associated with survival and reproduction). There are many other types of learning as well, often quite specialized to perform a particular biological function. These specialized forms of learning, also known as adaptive specializations of learning, have been studied mostly by ethologists and behavioral biologists, but biological psychologists are becoming increasingly interested in such forms of learning and their importance. For instance, psychologists have studied one of these specialized forms of learning, taste aversion learning, extensively. In addition to this form, we will now also examine adaptive specializations of learning involved in bird navigation by the stars during migration, bee navigation by the sun, and acquisition of bird song, which some researchers have compared to human language acquisition.

Specialized Forms of Learning (Adaptive Specializations of Learning)

> "Biological mechanisms are adapted to the exigencies of the functions they serve. The function of memory is to carry information forward in time. The function of learning is to extract from experience properties of the environment likely to be useful in the determination of future behavior." (Gallistel, 2003, p. 259).

> "One cannot use a hemoglobin molecule as the first stage in light transduction and one cannot use a rhodopsin molecule as an oxygen carrier, any more than one can see with an ear or hear with an eye. Adaptive specialization of mechanism is so ubiquitous and so obvious in biology, . . . it is odd but true that most past and contemporary theorizing about learning does not assume that learning mechanisms are adaptively specialized for the solution of particular kinds of problems. Most theorizing assumes that there is a general purpose learning process in the brain, a process adapted only to solving the problem of learning. . . . , this is equivalent to assuming that there is a general purpose sensory organ, which solves the problem of sensing." (Gallistel, 2000, p. 1179).

As the quotes above imply, learning, the acquisition of information during the lifetime of the individual animal, comes in many different forms. Many specialized forms of learning are highly specific for the solution of specific adaptive problems (problem domains) often found in only one or a few species. These types of learning probably involve specialized neural circuits, organized for their particular specialized form of learning by natural selection.

A familiar sight is ducklings walking or swimming after their mothers. Hatchling ducks recognize the first adult they see, usually their mother, and make a bond with her which induces them to follow her. This type of non-associative learning is known as imprinting. Imprinting is a form of learning occurring at a particular age or a particular life stage that is very important in the maturation process of these animals as it encourages them to stay near their mother in order to be protected, greatly increasing their chances of survival. Imprinting provides a powerful example of **biologically prepared learning** in response to particular genetically determined cues. In the case of imprinting, the duckling becomes imprinted on the first moving object larger than itself that it sees after hatching. Because of this, if newborn ducks see a human before they see their mother, they will imprint on the human and follow him or her in just the same manner as they would follow their real mother. Because this form of learning is biologically prepared, some cues that trigger the duckling to learn to follow its mother (or a person) are innately programmed into the duckling's genetically controlled brain circuitry while the details of the imprinting object (usually their real mother) are learned from the duckling's initial experience with a moving object larger than itself (again, most likely its real mother). Though this learning is very rapid because it is genetically (biologically) facilitated, it is also very resilient, its effects on behavior lasting well into adulthood. This form of learning illustrates well the general principle that all learning relies upon an underpinning of genetic information about some features of the learning situation while details are filled in by learning through experience. For example, genetic information programs the duckling's brain to follow the first moving thing it sees after hatching that is larger than itself, the details about what that object looks like are added into the bird's memory by learning during imprinting.

Figure 4.2.24.10: Imprinting is the learned attachment of ducklings to their mother or, under rare circumstances, to the first moving object larger than themselves that they see after hatching (Image from LibreTexts, Book: General Biology (Boundless), Learned Animal Behavior 45.7A; caption by Kenneth A. Koenigshofer, Ph.D.; licensed under

Taste Aversion Learning

Taste aversion learning is a specialized form of learning that helps omnivorous animals (those that eat a wide range of foods) to quickly learn to avoid eating substances that might be poisonous. In rats, coyotes, and humans, for example, eating a new food that is later followed by sickness causes avoidance of that food in the future. With food poisoning, although having fish for dinner may not normally be something to be concerned about (i.e., a “neutral stimulus”), if it causes you to get sick, you will now likely associate that neutral stimulus (the fish) with the adaptively significant event of getting sick.

This specialized form of learning is genetically or **"biologically prepared"** so that taste-illness associations are easily formed by a single pairing of a taste with illness, even if taste and illness are separated by extended periods of time from 10-15 minutes up to several hours. Colors of food, or sounds present when the food is consumed, cannot be associated with illness, only taste and illness can be associated. This is known as "belongingness," an example of "biological preparedness," in which learning has specialized properties as a result of genetic evolution--in this case, only taste and illness can be readily associated, not visual or auditory stimuli and illness (Garcia and Koelling, 1966; Seligman, 1971). A second difference is that taste aversion learning requires only a single pairing of taste and illness, whereas classical conditioning usually requires many pairings of the CS and US. The usual requirements for multiple pairings and close temporal contiguity between stimuli don't apply in learned taste aversion. This makes adaptive sense, because in the wild, sickness from a new food which is toxic won't occur immediately, but only after it has had time to pass into the digestive system and be absorbed. And when it comes to poisons, you may not get a second chance to learn to avoid that substance in the future.

This genetically prepared form of learning evolved over generations of natural selection in omnivorous species which consume a large variety of foods. Species that are very specialized feeders, such as Koala bears which eat eucalyptus leaves exclusively or baleen whales which filter ocean water for microscopic organisms, have not evolved taste aversion learning. They simply don't need it because they never experience novel foods that could possibly pose a threat.

Adaptively Specialized Learning for Navigation and Song Acquisition

Another example of a specialized form of learning evolved for the solution of a specific adaptive problem is the **learning of the night sky by** a species of bird called **Indigo Buntings.** Have you ever noticed that the stars appear to rotate throughout the night around an area of the sky, the celestial pole, close to the north star? Indigo buntings migrate south for the winter and then return north when temperatures warm. Experiments have shown that they use the stars, specifically the Big Dipper containing the pole star, Polaris, and the circumpolar stars within about 35 degrees of the center of rotation of the night sky to guide them on their journey of several thousand kilometers. But there is a special problem presented by the Earth's environment. Because of a wobble of the Earth's axis, the celestial pole and the north star change every few thousand years. A different star and star pattern will then indicate north and become the beacon that guides the migration of the Indigo Buntings.

These birds are genetically programmed to migrate and to use the night sky to guide them. But the specific constellation and star patterns that guide them must be learned because celestial north and the stars that mark it change too frequently in evolutionary time to be genetically encoded into their brains by evolution. The north star, whether Polaris, or another star thousands of years from now, is the only star that appears approximately stationary throughout the night, while all the other stars appear to turn around it as the night progresses. Indigo Bunting nestlings essentially sit up at night and watch the night sky from their nests. Because of a genetically programmed set of brain circuits, they note the star which barely moves, picking it out from all the others, which appear to move throughout the night (the movement of course is just apparent; the stars are relatively fixed, what's moving is the Earth rotating under them). By learning which star is essentially stationary in the night sky and the patterns of stars around it, they learn the correct star and star patterns to use for navigation when it comes time to migrate. The time for buntings to learn the night sky is limited. If deprived of exposure to the night sky until later in life they cannot learn the night sky as adults (Gallistel, et al., 1991, p. 16).

Two other examples of specialized forms of learning are of interest here. **Bees learn to navigate by** the position of the **sun** which changes with the date, time, and place on the Earth's surface. When moved to a new location, they learn to update their navigation to compensate for the change in location. This learning is strongly guided by innate, genetically evolved information stored in the bee brain (Dyer & Dickson, 1994; Towne, 2008).

One other example is of special interest, **song learning in song birds**. Birds of a specific species can only learn the song of their own species illustrating genetic constraints on what songs they can learn (Gallistel, et al., 1991, p. 21). White-crowned sparrows show variations in their song depending upon their geographical location, akin to dialects in human language. Experiments have shown that young white-crowned sparrows learn the specific dialect by exposure to it during a critical period for song learning

in the species. A critical period during which learning must occur indicates another genetic constraint on learning and is similar to critical periods evident in imprinting, learning the night sky by Indigo Buntings, and a sensitive period in humans prior to adolescence for language acquisition.

The learning involved in the above examples is not classical or operant conditioning, but each is a very specialized form of learning in one particular species for solution to a specific adaptive problem (a specific domain). Note that the learned information supplements and interacts with information in the genes, guiding the animal to attend to and to readily learn highly specific information. In the case of the buntings, in a sense, the birds "imprint" on the correct stars for navigation later in life.

These examples illustrate a general principle that learning does not occur without genetically evolved information guiding and facilitating the learning in various ways. Note that in each of the examples above, genetically internalized, implicit “knowledge” about invariants in the learning situation pre-structures the learning, facilitating the capture of the problem-relevant details too variable and short-term to be captured directly by natural selection in genetic mechanisms (Koenigshofer, 2017).

This principle applies not only to highly specialized forms of learning such as that in Indigo buntings or the other examples above, but even in more general forms of learning such as classical conditioning (Chiappe & MacDonald, 2005; Gallistel, 1992; Koenigshofer, 2017) and causal learning in children (Koenigshofer, 2017; Walker and Gopnik, 2014), each of which involves innate knowledge about general features of each learning situation. For example, in the cause of causal learning, children have an innate predisposition to understand cause-effect as a general property of the world that guides their learning of specific cause-effect relations in their particular environment (Koenigshofer, 2017). Furthermore, several genetically internalized “default assumptions” built into conditioning and causal learning mechanisms by natural selection are that “causes are reliable predictors of their effects, that causes precede their effects, . . . that in general, causes tend to occur in close temporal proximity to their effects (Revulsky, 1985; Staddon, 1988) . . . and the temporal contiguity of cause and effect is a general feature of the world” (Chiappe and MacDonald, 2005).

In addition, from this perspective, the fact that conditioning (except in taste aversion learning) generally requires multiple pairings of CS and US, or of operant response and its effect, is *not* a shortcoming or a “weakness” of conditioning processes but rather may be an evolved adaptive feature of conditioning fashioned by natural selection to prevent formation of potentially spurious (and therefore, maladaptive) associations (Koenigshofer, 2017).

Gallistel (1992) argues that even classical conditioning is a specialized form of learning that performs important biological functions. According to Gallistel, classical conditioning was shaped by natural selection to discover "what predicts what" in the environment--in mathematical terms, according to Gallistel, a problem in multivariate non-stationary time series analysis. Time series because what is being learned is the temporal dependence or contingency of one event on another; multivariate time series because many events/variables may or may not predict the US; and non-stationary because the contingencies between CS and US often change over time (Gallistel, 2000, p. 1186).

Observation learning

Observation learning is learning by watching the behavior of others. It is obviously an extremely important form of learning in us, but it is also "an ability common to primates, birds, rodents, and insects" (Dawson et al., 2013). It plays a crucial role in human social learning. Imagine a child walking up to a group of children playing a game on the playground. The game looks fun, but it is new and unfamiliar. Rather than joining the game immediately, the child opts to sit back and watch the other children play a round or two. Observing the others, the child takes note of the ways in which they behave while playing the game. By watching the behavior of the other kids, the child can figure out the rules of the game and even some strategies for doing well at the game.

Figure 4.2.24.11: Children observing a social model (an experienced chess player) to learn the rules and strategies of the game of chess. [Image: David R. Tribble, https://nobaproject.com/modules/cond...g-and-learning, NOBA, Conditioning and Learning; CC BY-SA 3.0]

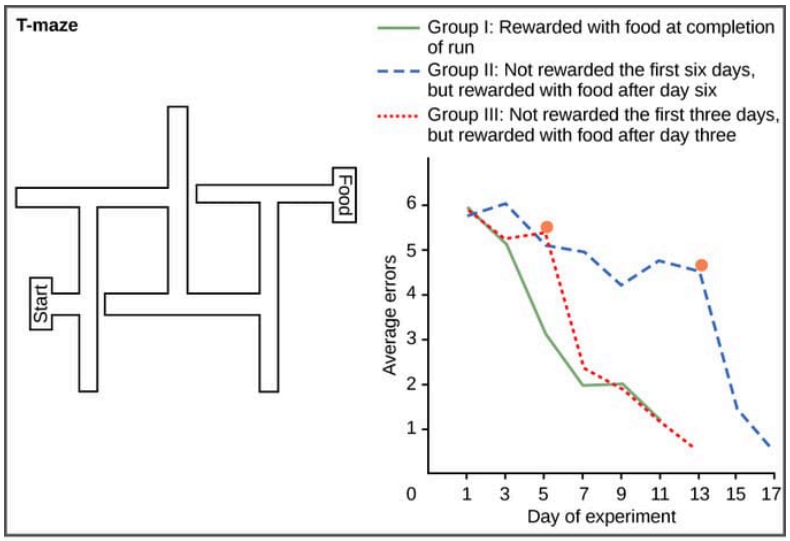
Observational learning is a component of Albert Bandura's **Social Learning Theory** (Bandura, 1977), which posits that individuals can learn novel responses via observation of key others' behaviors. Observational learning does not necessarily require reinforcement, but instead hinges on the presence of others, referred to as **social models**. Social models in humans are typically of higher status or authority compared to the observer, examples of which include parents, teachers, and older siblings. In the example above, the children who already know how to play the game could be thought of as being authorities—and are therefore social models—even though they are the same age as the observer. By observing how the social models behave, an individual is able to learn how to act in a certain situation. Other examples of observational learning might include a child learning to place her napkin in her lap by watching her parents at the dinner table, or a customer learning where to find the ketchup and mustard after observing other customers at a hot dog stand.

Bandura theorizes that the observational learning process consists of four parts. The first is *attention*—as, quite simply, one must pay attention to what s/he is observing in order to learn. The second part is *retention*: to learn one must be able to retain the behavior s/he is observing in memory. The third part of observational learning, *initiation*, acknowledges that the learner must be able to execute (or initiate) the learned behavior. Lastly, the observer must possess the *motivation* to engage in observational learning. In our vignette, the child must want to learn how to play the game in order to properly engage in observational learning. Bandura, Ross, & Ross (1963) demonstrated that children who observed aggression in adults showed less aggressive behavior if they witnessed the adult model receive punishment for their aggression. Bandura referred to this process as **vicarious reinforcement**, as the children did not experience the reinforcement or punishment directly, yet were still influenced by observing it.

Observation Learning and Cultural Transmission Improve Biological Fitness in Non-human Animals

Orangutans in protected preserves have been seen copying humans washing clothes in a river. After watching humans engage in this behavior, one of the animals took pieces of clothing from a pile of clothes to be washed and engaged in clothes washing behavior in the river, imitating behavior it had recently observed in humans. Orangutans also use observation learning to copy behaviors of other orangutans. Observation learning has also been reported in wild and captive chimpanzees and in other primates such as Japanese macaque monkeys. One of the most thoroughly studied examples of observation learning in animals is in Japanese macaques.

There is a large troop of macaques (Old World monkeys; see Chapter 3) which lives near the beaches on an island in Japan, Koshima Island. Researchers were interested to see how these animals would respond if the researchers scattered novel foods such as wheat grain on the sand. The animals meticulously picked out the grain from the sand one grain at a time, laboriously cleaning it a grain at a time. However, researchers reported that after a while one Japanese macaque in the troop invented an efficient method for cleaning the grain by scooping up handfuls of wheat grain and sand and throwing the mixture into the



water. The wheat grains floated while the sand sank. This macaque monkey then scooped up quantities of clean grain floating on the surface of the water and ate its fill, repeating its novel grain cleaning behavior again and again. Although this showed impressive intelligence and inventiveness on the part of this monkey, just as significant was the fact that **other members of the troop observed this behavior and copied it**. By observation learning, most of the troop learned this innovative method of cleaning and separating grain from sand. As time passed, youngsters observed older members engaging in this **learned behavior** and copied it so that the behavior was **passed over several generations** (Schofield et al., 2018). This example of observation learning illustrates one of its most important biological functions--observation learning is a primary mechanism of **cultural transmission of learned behavior across generations**, not only in animals like the macaques, but even more so in humans. The effect of the cultural transmission of learned behavioral adaptations from generation to generation produces "cumulative culture . . . characterized as a 'ratchet,' yielding progressive innovation and improvement over generations (Tomasello et al. 1993). The process can be seen as repeated inventiveness that leads to incrementally better adaptation; that is, more efficient, secure, . . . survival and reproduction" (Schofield et al., 2018, p. 113). Efficient cultural transmission of successful learned behavior is **enormously powerful in boosting biological fitness**, and it accounts for those features of human life, such as science, technology, governments, and so on, that distinguish us most from all other species on the planet (Koenigshofer, 2011, 2016).

Cognitive Learning

Classical and operant conditioning are only two of the ways for humans and other intelligent animals to learn. Some primates, including humans, are able to learn by imitating the behavior of others and by taking instructions. The development of complex language by humans has made cognitive learning, a change in knowledge as a result of experience or mental manipulation of existing knowledge, the most prominent method of human learning. In fact, that is how you are learning right now by reading this information, you are experiencing a change in your knowledge. Humans, and probably some non-human animals, can make mental images of objects or organisms, imagining changes to them or behaviors by them as they anticipate the consequences. Cognitive learning is so powerful that it can be used to understand conditioning (discussed in the previous modules). In the reverse scenario, conditioning cannot help someone learn about cognition.

Classic work on cognitive learning was done by Wolfgang Köhler with chimpanzees. He demonstrated that these animals were capable of abstract thought by showing that they could learn how to solve a puzzle. When a banana was hung in their cage too high for them to reach, along with several boxes placed randomly on the floor, some of the chimps were able to stack the boxes one on top of the other, climb on top of them, and get the banana. This implies that they could visualize the result of stacking the boxes even before they had performed the action. This type of learning is much more powerful and versatile than conditioning.

Cognitive learning is not limited to primates, although they are the most efficient in using it. Maze-running experiments done with rats in the 1920s were the first to show cognitive skills in a simple mammal, the rat. The motivation for the animals to work their way through the maze was the presence of a piece of food at its end. In these studies, the animals in Group I were run in one trial per day and had food available to them each day on completion of the run. Group II rats were not fed in the maze for the first six days and then subsequent runs were done with food for several days after. Group III rats had food available on the third day and every day thereafter. The results were that the control rats, Group I, learned quickly, figuring out how to run the maze in seven days. Group III did not learn much during the three days without food, but rapidly caught up to the control group when given the food reward. Group II learned very slowly for the six days with no reward to motivate them. They did not begin to catch up to the control group until the day food was given; it then took two days longer to learn the maze. Results suggested that although there was no reward for the rats in groups II and III during several days at the beginning of the experiment, the rats were still learning. This is evidenced particularly by the performance of group III. Although not given any food reward in the maze for the first three days of the experiment, nevertheless, once food reward was added on day 4, the maze learning performance of rats in this group rapidly caught up with the control group (Group I) that had received food reward in the maze every day from the start of the experiment. This showed that even in the absence of food reward, the rats were learning about the maze. This was important because at that time many psychologists believed that learning can only occur in the presence of reinforcement. This experiment showed that learning information about a maze, gaining knowledge about it, can occur even in the absence of reinforcement. Some have referred to this as "latent learning." The learning that has taken place remains hidden or latent in behavior until a motivating factor such as food reward stimulates action that reveals the learning that had previously not been apparent in observable behavior. In this case, the latent learning of the maze in groups II and III became apparent once food reward was made available for the rats in these groups on day 6 and day 3 respectively. **Cognitive learning involves acquisition of knowledge**, in this case, about a maze; in this example, it took place in rats without food reward, as evidenced by their performance in the maze once food reward was presented as a motivator. This procedure revealed the learning that had taken place in the first few days of the experiment.

Redrawn after H. C. Blodgett, The effect of the introduction of reward upon the maze performance of rats. Univ. Calif. Publ. Psychol., 1929, 4, No. 8, pages 117 and 120.

Figure 4.2.24.12: **Cognitive learning**: Group I (the green solid line) found food at the end of each trial; group II (the blue dashed line) did not find food for the first 6 days; and group III (the red dotted line) did not find food during runs on the first three days. Notice that rats given food earlier learned faster and eventually caught up to the control group. The orange dots on the group II and III lines show the days when food rewards were added to the mazes. Clearly this type of learning is different from conditioning. Although one might be tempted to believe that the rats simply learned how to find their way through a conditioned series of right and left turns, Edward C. Tolman proved a decade later that the rats were making **a representation** of the maze **in their minds**, which he called a "cognitive map." This was an early demonstration of the power of cognitive learning and how these abilities were not limited just to humans. Research discussed more fully in Chapter 14 indicates that the **visual, motor, and parietal cortical areas as well as the hippocampus** are involved in ability to form **cognitive maps** and engage in cognitive learning.

Key Points

- Cognitive learning involves change in knowledge as a result of experience and the mental manipulation of information; it is a great deal more powerful and flexible than either operant or classical conditioning.
- The development of complex language by humans has made cognitive learning the most prominent method of human learning.
- Cognitive learning is not limited to primates; rats have demonstrated the ability to build cognitive maps, as well, which are mental representations used to acquire, code, store, recall, and decode information about the environment.

Key Terms

- **cognitive map**: a mental representation which serves an organism to acquire, code, store, recall, and decode information about the relative locations and attributes of phenomena in their everyday environment
- **cognitive learning**: the process by which one acquires knowledge or skill in cognitive processes, which include reasoning, abstract thinking, and problem solving

Vocabulary (click on terms for definitions)

Blocking

In classical conditioning, the finding that no conditioning occurs to a stimulus if it is combined with a previously conditioned stimulus during conditioning trials. Suggests that information, surprise value, or prediction error is important in conditioning.

Categorize

To sort or arrange different items into classes or categories.

Classical conditioning

The procedure in which an initially neutral stimulus (the conditioned stimulus, or CS) is paired with an unconditioned stimulus (or US). The result is that the conditioned stimulus begins to elicit a conditioned response (CR). Classical conditioning is nowadays considered important as both a behavioral phenomenon and as a method to study simple associative learning. Same as Pavlovian conditioning. Classical conditioning involves learning the predictive relationship between two stimulus events.

Conditioned compensatory response

In classical conditioning, a conditioned response that opposes, rather than is the same as, the unconditioned response. It functions to reduce the strength of the unconditioned response. Often seen in conditioning when drugs are used as unconditioned stimuli.

Conditioned or conditional response (CR)

The response that is elicited by the conditioned stimulus after classical conditioning has taken place. Pavlov used the term conditional response, the response conditional upon prior learning.

Conditioned or conditional stimulus (CS)

An initially neutral stimulus (like a bell, light, or tone) that elicits a conditioned/conditional response after it has been associated with an unconditioned/unconditional stimulus. The CS comes to act as a signal predicting the coming occurrence of the US (the unconditioned stimulus; the stimulus unconditional upon prior learning and which naturally leads to the unconditioned response, a response unconditional upon prior learning; often a reflex response such as salivation, as in Pavlov's original experiments with dogs).

Context

Stimuli that are in the background whenever learning occurs. For instance, the Skinner box or room in which learning takes place is the classic example of a context. However, "context" can also be provided by internal stimuli, such as the sensory effects of drugs (e.g., being under the influence of alcohol has stimulus properties that provide a context) and mood states (e.g., being happy or sad). It can also be provided by a specific period in time—the passage of time is sometimes said to change the "temporal context."

Discriminative stimulus

In operant conditioning, a stimulus that signals whether the response will be reinforced. It is said to "set the occasion" for the operant response.

Extinction

Decrease in the strength of a learned behavior that occurs when the conditioned stimulus is presented without the unconditioned stimulus (in classical conditioning) or when the behavior is no longer reinforced (in instrumental conditioning). The term describes both the procedure (the US or reinforcer is no longer presented) as well as the result of the procedure (the learned response declines). Behaviors that have been reduced in strength through extinction are said to be "extinguished."

Fear conditioning
A type of classical or Pavlovian conditioning in which the conditioned stimulus (CS) is associated with an aversive unconditioned stimulus (US), such as a foot shock. As a consequence of learning, the CS comes to evoke fear. The phenomenon is thought to be involved in the development of anxiety disorders in humans.

Goal-directed behavior
Instrumental behavior that is influenced by the animal's knowledge of the association between the behavior and its consequence and the current value of the consequence. Sensitive to the reinforcer devaluation effect.

Habit
Instrumental behavior that occurs automatically in the presence of a stimulus and is no longer influenced by the animal's knowledge of the value of the reinforcer. Insensitive to the reinforcer devaluation effect.

Instrumental conditioning
Process in which animals learn about the relationship between their behaviors and their consequences. Also known as operant conditioning.

Law of effect
The idea that instrumental or operant responses are influenced by their effects. Responses that are followed by a pleasant state of affairs will be strengthened and those that are followed by discomfort will be weakened. Nowadays, the term refers to the idea that operant or instrumental behaviors are lawfully controlled by their consequences.

Observational learning
Learning by observing the behavior of others.

Operant
A behavior that is controlled by its consequences. The simplest example is the rat's lever-pressing, which is controlled by the presentation of the reinforcer.

Operant conditioning
See instrumental conditioning.

Pavlovian conditioning
See classical conditioning.

Prediction error or prediction value
When the outcome of a conditioning trial is different from that which is predicted by the conditioned stimuli that are present on the trial (i.e., when the US is surprising; in other words, an event must have predictive value with regard to the occurrence of the US or no conditioning to the event will take place). Prediction error is necessary to create Pavlovian conditioning (and associative learning generally). As learning occurs over repeated conditioning trials, the conditioned stimulus increasingly predicts the unconditioned stimulus, and prediction error declines. Conditioning works to correct or reduce prediction error; i.e. conditioning works to provide reliable prediction, one event reliably predicts a second event. In other words an event must have prediction value, its presence is reliably predictive of a future event that is not already reliably predicted by another stimulus event that is present. That is, stimuli which don't add to the reliability of prediction of another event/stimulus are ignored because they contain no predictive information. This shows that what animals learn in conditioning is the predictive relations between events. If a stimulus does not add to the predictability of the target event, then that stimulus is ignored.

Preparedness
The idea that an organism's evolutionary history can make it easy to learn a particular association. Because of preparedness, you are more likely to associate the taste of tequila, and not the circumstances surrounding drinking it, with getting sick. Similarly, humans are more likely to associate images of spiders and snakes than flowers and mushrooms with aversive outcomes like shocks.

Punisher
A stimulus that decreases the strength of an operant behavior when it is made a consequence of the behavior.

Quantitative law of effect
A mathematical rule that states that the effectiveness of a reinforcer at strengthening an operant response depends on the amount of reinforcement earned for all alternative behaviors. A reinforcer is less effective if there

is a lot of reinforcement in the environment for other behaviors.

Reinforcer
Any consequence of a behavior that strengthens the behavior or increases the likelihood that it will be performed it again.

Reinforcer devaluation effect
The finding that an animal will stop performing an instrumental response that once led to a reinforcer if the reinforcer is separately made aversive or undesirable.

Renewal effect
Recovery of an extinguished response that occurs when the context is changed after extinction. Especially strong when the change of context involves return to the context in which conditioning originally occurred. Can occur after extinction in either classical or instrumental conditioning.

Social Learning Theory
The theory that people can learn new responses and behaviors by observing the behavior of others.

Social models
Authorities that are the targets for observation and who model behaviors.

Spontaneous recovery
Recovery of an extinguished response that occurs with the passage of time after extinction. Can occur after extinction in either classical or instrumental conditioning.

Stimulus control
When an operant behavior is controlled by a stimulus that precedes it.

Taste aversion learning
The phenomenon in which a taste is paired with sickness, and this causes the organism to reject—and dislike—that taste in the future.

Unconditioned response (UR)
In classical conditioning, an innate response that is elicited by a stimulus before (or in the absence of) conditioning.

Unconditioned stimulus (US)
In classical conditioning, the stimulus that elicits the response before conditioning occurs.

Vicarious reinforcement
Learning that occurs by observing the reinforcement or punishment of another person.

4.2.25: Introduction to Memory and the Brain

Learning Objectives

1. Explain the differences between learning and memory
2. Describe the different types of memory and the brain structures involved in each
3. Explain the three stage model of memory
4. Explain the differences between implicit and explicit memory
5. Describe types of declarative memory and their features
6. Discuss the case of H.M. and what it tells us about the role of the medial temporal lobes in declarative memory
7. Describe the concept of the "engram"?

Overview

As you probably remember from your course in introductory psychology, there are a number of different types and stages of memory, involving different brain areas and processes. In this section, we briefly outline the different types of memory and some of what is known about the localization of different types of memory in the brain. We discuss the intriguing case of H.M. whose profound loss of ability to form new long-term memory of facts and events led to much of what we know about declarative memory and the involvement of the medial temporal lobes in memory formation. Formation of memories about how to do things, procedural or motor memory involves different brain areas, in particular, the cerebellum.

Memory and the Brain

As discussed earlier in this chapter, learning can be defined as the acquisition of information during the lifetime of the individual organism. This information is stored in memory systems of the brain of the animal. By contrast, genetic information, which is acquired over the evolutionary history of the species, is stored in DNA. Remember that behavioral adaptations can be organized by information from both sources. The relative contribution of each source of information to the organization of any particular behavior varies with the type of behavior and the species. Typically, learning is more important to organization of behavior in the more complex animal species with larger, more complex brains, yet evidence of memory, as discussed earlier in this chapter, is even found in honey bees and other invertebrates.

Memory refers to the processes of storage and retrieval of learned information.

Types of Memory

Just as there are different types of learning, there are also different types of memory.

One major distinction is between **verbal memory**, memory for words and ideas stated in words (dependent on language areas in **frontal and temporal cortex**) and memories in the form of **visual images** (dependent upon **occipital, temporal, and parietal lobe cortex**; see Figure 10.3.1). For example, when I remember a hotel that I stayed at in Hong Kong many years ago, I get a visual image of the hotel and the streets of Hong Kong nearby. Memories can be in the form of other sensory modalities as well. When I remember talking to a friend on the phone, I can almost "hear" my friend's voice in my mind (memory in the form of an auditory "image"). Verbal memories themselves can often involve auditory "images" in your mind, the sounds of the words you are thinking about. Think about what a lemon tastes like and you will almost "taste" it in your mind (memory in the form of a taste "image").

Another important distinction between different forms of memory is memory for **facts and events**. This is **explicit or declarative memory**, which is of two types, **episodic** (memory of episodes in your life) and **semantic** memory (memory for facts and knowledge). A second type, **implicit memory**, is also of two types, **procedural memory** (memory for how to do things, such as skills like riding a bike, **sometimes called motor memory**), and memory for classically conditioned responses and priming

effects.

Types of Memory and the Brain

Different areas of the brain are involved in these different types of memory. The **cerebellum**, located in the hindbrain, is involved in formation and storage of motor programs for learned skilled movements (**procedural or motor memory**) and is also the source of learning and memory of simple **conditioned reflexes** such classical conditioning of the eye blink reflex (Kim & Thompson, 1997; Christian & Thompson, 2003). By contrast, the **hippocampus** has been implicated in the **"consolidation"** or fixing of **new long term episodic or declarative memories** into permanent storage (see Bird & Burgess, 2008), as well as the **encoding of the temporal sequencing** of events (Ranganath & Hsieh, 2016), **spatial memory** (Bird & Burgess, 2008; Voss, et al., 2017), and **retrieval of memories by reactivating cortical representations** of the retrieved memories (Tanaka, et al., 2014).

The Three Stage Model of Memory and the Brain

One simple and influential model of memory proposes three stages of memory (see Baddeley, 1982):

Sensory memory------Short-term or working memory (STM)-----Long-term memory (LTM)

Sensory memory is very short duration but very high capacity memory. To illustrate, just close your eyes at this moment and you will "see" a **mental image** of what it was you were just looking at. That is visual sensory memory and likely involves the visual cortex in **occipital lobe**. Notice it is nearly a replica of what you were just looking at; the mental image is a very detailed image, an information dense, high information capacity form of storage. But the image quickly fades--that is, this stage of memory is of very brief duration, not more than a few seconds.

Short-term memory is a bit longer in duration, up to a few minutes. But the capacity of STM is not nearly as large as sensory memory. It is usually said that STM has the capacity to store 7 plus or minus 2 separate items of information at a time (Miller, 1956). This is a limited storage capacity compared to the other stages of memory. Short term memory is also called **working memory.** This is because when you use information from your memory to do some task you are using it while it is in this stage of memory, the short term memory store, thus the term working memory is often used to refer to this stage.

According to the three-stage model, information then moves from STM (working memory) into the third stage of memory, **Long term memory** (memories here may last a lifetime; this memory stage has very large capacity and very long duration). This movement of information from STM to LTM and its **"consolidation"** into a long term trace appears to critically involve the limbic system, more specifically, the **hippocampus** (Squire, et al., 2015), located in the **medial temporal lobes** (see Figure 10.3.1). When you are studying for an exam, you are trying to get information encoded into long-term memory. Consolidation of the new semantic memory by your hippocampus, and the surrounding medial temporal lobe, is essential to this process.

Information can also move from LTM back into STM or working memory. For example, if I ask you to name the capital of Japan, you can probably say Tokyo but this information was not in your conscious awareness before I asked you the question. The information had to be pulled from your long term memory into your conscious awareness. This movement of information from LTM (your long duration, large capacity memory) to your conscious awareness (into your "working memory") is **memory retrieval**. How does your brain do it? How can it locate and pull into your conscious working memory a piece of information from among the countless pieces of information stored in your long term memory over your lifetime? Apparently, there are something like **associative networks** formed in long term memory that help facilitate an efficient search when you are trying to locate a particular piece of information for retrieval into conscious working memory.

The Medial Temporal Lobes and Declarative Memory

Research has led to a consensus that the **medial temporal lobes** have an essential function in **declarative memory**. As Squire et al. (2004, p. 279) summarize: "The medial temporal lobe includes a system of anatomically related structures that are essential for declarative memory (conscious memory for facts and events). The system consists of the **hippocampal region** (CA fields, dentate gyrus, and subicular complex) and the adjacent **perirhinal, entorhinal, and parahippocampal cortices**."

A fascinating research enterprise contributing greatly to our understanding of memory is the case of H.M. **H.M.** had **bilateral removal** of much of his **medial temporal lobes** including both of his hippocampi (remember that the hippocampus is located deep beneath the temporal lobe cortex), surgery performed in order to control his epileptic seizures (which were originating from the temporal lobe). Up until his death in December of 2008 of natural causes at age 82, H.M. still believed that Eisenhower was President of the United States. He knew almost nothing about anything that had happened after his brain surgery. According to a researcher working with H.M. with whom I spoke, before H.M. died whenever he was asked to describe his physical appearance, even years after his surgery, H.M. continued to describe himself as a young man with a thick head of wavy black hair, even though, at his age, he had almost no hair at all. After the surgical removal of much of his medial temporal lobes, H.M. could remember most things that happened before his surgery, but he **could not remember any new facts or events** for more than a few minutes. His **old long-term episodic and semantic memory was fine**. His **short-term memory** was also **normal**. What he **could not** do was to consolidate or **fix any new information about facts or events into** his **long-term memory**. Yet, his **implicit memory and his ability to consolidate new procedural memories into permanent storage was normal.** He learned to play computer games with great skill, but never was able to remember having learned them, and he was often puzzled about why he was so good when he couldn't even remember having seen computers or computer games before.

I sometimes speculate about what it must have been like for H.M. when he got up in the morning and looked in the mirror, expecting to see himself as a young man and finding an old man instead. Or I wonder when awoke in the morning and looked over at his wife lying next to him. He can only remember her as she looked as a much younger woman. What must he have experienced when he saw the older woman asleep next to him? Did he know who she was? He must have been puzzled about what could have happened to her overnight (younger and prettier, and now much older and perhaps not so pretty). Soon, however, he would forget what he had just seen minutes before. The life of H.M. must have been truly extraordinary. Studies of H.M. for many decades before his death in 2008 revealed much that we know about memory and the brain today, in particular the role of the **medial temporal lobe** structures in declarative (conscious) memory formation.

The Engram

Many years earlier, Karl Lashley, a physiological psychologist, now well known in the history of psychology, investigated the physical basis of memory in the brain by teaching rats a maze and then destroying various parts and amounts of their brain tissue to see which areas were critical to memory. He was searching for the physical representation of memory in the brain. He referred to the physical changes in the brain, which occur when we learn and remember something, the **"engram," or "memory trace."**

His results were inconclusive, but he did find that the more cortex he destroyed the greater the disruption of memory. He called this the **"principle of mass action."** Today memory research continues and new insights have been discovered about the nature of the "engram," which appears to involve the **modification of synapses** (Howland & Wang, 2008), the **growth of new synapses**, and even the growth of **new neurons** (Deng et al., 2010; Ranganath & Hsieh, 2016). We discuss more about the physical changes in the brain that appear to be involved in learning and memory in later sections of this chapter.

Summary

Different types of memory have been designated by researchers as explicit and implicit, declarative, semantic and episodic, procedural or motor memory, and some forms of memory involve three stages, sensory, short-term, and long-term. Different types of memory and different stages involve different brain areas and processes. The case of H.M. led researchers to recognize the essential role of the hippocampus and other regions of the medial temporal lobes in the formation of long-term declarative memories, while the cerebellum stores motor programs of learned skilled movements and memory of at least some reflexes such as the eye-blink reflex. Mechanisms that seem to be the basis for learning and memory at the more microscopic level appear to depend on synaptic changes.

4.2.26: Synaptic Mechanisms of Learning and Memory

Learning Objectives

1. Describe Hebb's theory of the engram
2. Define Hebb's rule
3. Define Hebb synapses and cell assemblies
4. Describe Kandel's findings about the synaptic changes mediating habituation and sensitization in the sea slug, Aplysia
5. Explain the dual-trace theory of memory
6. Describe the role of the hippocampus in learning and memory
7. Describe the role of the cerebellum and amygdala in learning and memory
8. Discuss Long-term Potentiation (LTP) and Long-term depression and learning and memory
9. Describe changes in dendritic spines associated with learning and memory
10. Discuss how LTP and anatomical changes in synaptic spines might be related to Hebb's dual-trace theory

Overview

Donald Hebb's (1949) dual-trace theory of the physical basis of memory focused on changes at the synapse as the basis for learning and memory. This influential theory led to the discovery of changes in transmitter release associated with learning in the invertebrate nervous system of the sea slug. Other researchers found sustained increases in synaptic conductance caused by high frequency stimulation of the pre-synaptic neuron (Long-term Potentiation, LTP) as well as sustained decrease in synaptic strength known as Long-term Depression (LTD). Researchers have also discovered anatomical changes in dendritic spines associated with LTP and learning and memory, suggesting anatomical changes at synapses as a possible mechanism for learning and long-term memory at the synaptic level. Although early studies in search of the "engram", the physical basis for learning and memory, concluded that these functions were widely distributed throughout the brain, later research found that the hippocampus is critical for formation of long-term explicit memories and that the cerebellum is involved in implicit memory, whle the amygdala plays an essential role in emotional memories.

The Search for Learning and Memory in the Synapse

by Kenneth A. Koenigshofer, Ph.D.

Just as information is stored on digital media such as DVDs, hard drives, and flash drives, the information in our long-term memory must be physically stored in the brain. According to current theory, the ability to maintain information in long-term memory involves a gradual strengthening of the synaptic connections among neurons. When pathways in these neural networks are frequently and repeatedly activated, the synapses become more efficient permitting enhanced communication among neurons in the network, and these changes create memory (Saylor Foundation, 2012). As we will see, this view of the physical basis of memory was heavily influenced by the ideas of a Harvard biological psychologist named Donald Hebb.

Over a century ago a Russian physiologist named Ivan Pavlov proposed a theory of how learning occurred in the brain. As you recall from from module 10.2, Pavlov discovered classical conditioning when he observed that repeated pairings of a bell and food eventually led dogs to salivate at the sound of the bell, even when food was not present. To explain this phenomenon, Pavlov hypothesized that the conditioned stimulus (CS), a bell in this case, generated a locus of neural activity in sensory cortex (auditory cortex in this experiment) which radiated outward over the cortical surface. This was followed by a similar locus of cortical neural activity generated by the unconditioned stimulus (US) (meat powder in Pavlov's classic experiments) which also set up waves of radiating neural activity. Pavlov proposed that these two expanding fields of neural activity, originating from different areas of cortex, would intersect one another. According to Pavlov, this intersection of the cortical fields of neural activity, generated by the CS and US, formed the neurological basis for the association between CS and US.

This early theory of the physical basis of learning and memory was put to the test by experimental psychologist, Karl Lashley, of Harvard and then later, the Yerkes Laboratory of Primate Biology. Lashley made crisscross cuts throughout the cerebral cortex of rats and then attempted to condition them. He did this to disrupt any radiating neural activity in the cortex that might be present during conditioning, as Pavlov had proposed. Lashley found that the rats still could be conditioned and that they retained the

conditioned response later in spite of the crisscross cuts over their entire cerebral cortex. This disproved Pavlov's theory that the physical basis of learning an association by classical conditioning was the intersection of waves of neural activity radiating outward from cortical loci.

Lashley, like Pavlov, was interested in finding the "engram." This term refers to the physical memory trace, the neural representation of memory in the brain. Toward this end, Lashley performed additional experiments in which he trained rats to navigate a maze and then destroyed different parts of their brains. He found that no matter where the brain damage was located, rats still retained some memory of the maze (Lashley, 1929, 1943, 1950). Lashley interpreted these results as evidence that it was the amount of cortical tissue removed, not its location, that determined the degree of impairment in learning and memory. He also hypothesized that memories were widely distributed throughout the brain and that therefore there was no particular area of the brain that was especially critical for memory formation.

Lashley proposed two principles derived from his research on the physical basis of learning and memory: 1) mass action (the amount of cortex destroyed determines degree of impairment in learning and memory) and 2) equipotentiality (any part of cortex within a functional area can take over the functions of any other part of that same functional area).

Lashley's conclusions had two primary impacts. First, his analysis "tended to discredit, or at least deemphasize, the role of the interior [subcortical] parts of the brain in learning and memory and, on the other, tended to localize the mechanisms of learning and memory within the confines of the cerebral cortex" (Thompson, 1974). Second, Lashley's principles of mass action and equipotentiality led to an **anti-localization bias** in the study of learning and memory, which discouraged attempts to find specific brain structures involved in these functions. However, consistent with current views, and **contradicting Lashley's findings**, Kaada, Rasmussen, and Kveim (1961) reported that **lesions of the hippocampo-fornix system impaired maze performance.** This was an early study that confirms what we know today, that a subcortical structure, the **hippocampus**, is critical to many forms of learning and memory.

Hebb's Rule, Cell Assemblies, and the Engram

After receiving his doctorate from Harvard in 1936, one of Lashley's graduate students, Donald Hebb, published *The Organization of Behavior: A Neuropsychological Theory*. In this influential book, Hebb proposed that the **"engram"** consisted of **changes at synapses** during learning and memory formation. A quote from the book (Hebb, 1949, p. 62) explains **Hebb's central principle** of synaptic change in learning and memory:

> “When an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A’s efficiency, as one of the cells firing B, is increased."

Here Hebb is proposing an **increase in the strength of synaptic connections between neurons that consistently fire together** and that this involves growth or metabolic events in one or both of the cells.

More simply stated: "Neurons that fire together, wire together." This is known as "**Hebb's rule**" (retrieved from https://can-acn.org/donald-olding-hebb/ August 8, 2021).

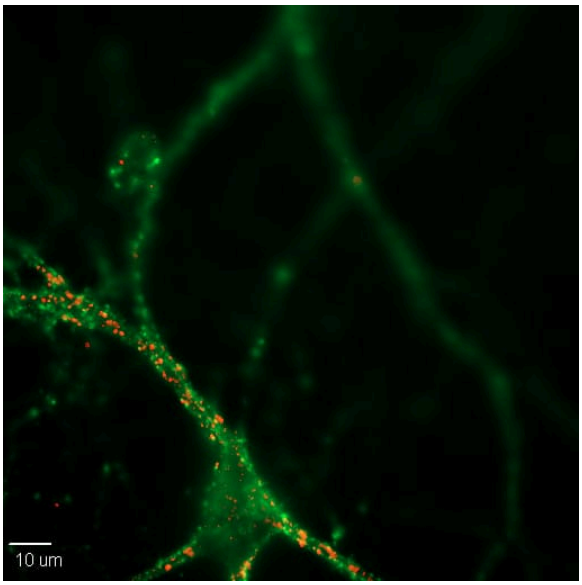

Figure 4.2.26.1: A 20X image of a cultured mouse cortical neuron in cell culture. Synapses are labeled for pre- (green) and post-synaptic (red) proteins, synaptophysin and PSD-95, respectively. (Image and caption from Wikimedia, Synapse; https://commons.wikimedia.org/wiki/F...n_Synapses.jpg; author, Dchordpdx; licensed under the Creative Commons Attribution 4.0 International license).

Neuroscientists use the term, **Hebbian synapses**, to refer to synapses that follow this principle. Hebb also proposed the idea of "cell assemblies." Hebb hypothesized that when cells repeatedly firing together, wired together, eventually they would form larger structures, "**cell assemblies**," which would form neural representations of whole, complex perceptions, ideas, memories, and other cognitive structures, such as schemas, and highly abstract categories and concepts. All of this could be built from changes in the efficiency of synaptic transmission at specific synapses, following Hebb's principle that "neurons that fire together, wire together." One can imagine that *entire cell assemblies* that fire together might also wire together, creating much larger and much more complex neural representations in the brain of complex, abstract ideas including such things as scientific theories and mathematical formulations.

Non-Association Learning in Aplysia

These ideas have inspired the hunt by neuroscientists for changes at synapses and in pre- or post-synaptic neurons, during and after learning--changes which might be the physical basis in the nervous system for learning and memory (Lashley's "engram," which, by the way, has nothing to do with the non-scientific use of the term by Scientology). Much of the pioneering scientific work on the search for the "engram" has involved looking for these physical changes associated with learning in the simple nervous system of a marine species, Aplysia californica, a type of sea slug. A major reason for the selection of this species for study, aside from the simplicity of its nervous system (just 20,000 neurons), is the large size of its neurons which makes the work and the observations easier.

Figure 4.2.26.2: Aplysia californica. (Image from Wikimedia, Aplysia californica; https://commons.wikimedia.org/wiki/F...,_Monterey.jpg; Chad King / NOAA MBNMS; this image is in the ***public domain*** because it contains materials that originally came from the U.S. *National Oceanic and Atmospheric Administration*, taken or made as part of an employee's official duties).

Eric Kandel (1976) and his colleagues did pioneering work which showed synaptic changes that mediate habituation (see sections above) of the Aplysia's siphon and gill defensive withdrawal reflex. A **decrease in conductivity** was found **at synapses** involved in the siphon and gill withdrawal reflex **in Aplysia after habituation** to a repeated presentation of a harmless novel stimulus. Kandel and co-workers showed that the **pre-synaptic sensory neuron released less neurotransmitter onto the post-synaptic motor neuron** as a result of repeated presentation of the novel stimulus leading to habituation of the reflex. The opposite was found for increased responsiveness. Sensitization refers to enhancement of responsiveness to a familiar stimulus. A single small electric shock to the tail of Aplysia heightens its gill withdrawal response for minutes to hours. Kandel and colleagues found that **sensitization** was mediated by an **increase in** release of **neurotransmitter from the pre-synaptic sensory neuron onto** the **post-synaptic motor neuron** serving the gill muscle. Thus, sensitization is the opposite of habituation both behaviorally and at the level of transmitter release (Kolb and Whishaw, 2001). Later studies showed synaptic changes involving **modified transmitter release** during **classical conditioning** as well (Kandel and Schwartz, 1982).

Hebb's Dual-Trace Theory of Memory

Hebb also proposed a **dual-trace theory of memory**--a **short-term dynamic electrical process for short-term memory** (Hebb referred to "reverberating circuits" holding this brief electrical activity) **and,** following sometime **later, an enduring structural change at synapses** as the physical basis (the engram) for long-term memory (Hebb, 1949). Decades of research followed using various agents, including electroconvulsive shock (ECS), shortly after learning in rats to disrupt the short-term memory trace, which according to Hebb, consisted of circulating or "reverberating" electrical activity, thus preventing long-term storage. However, although ECS in rats within about 30 seconds of learning seemed to disrupt consolidation of the short-term memory trace into a permanent long-term trace as evidenced by apparent amnesia for the learning task, additional research suggested alternative explanations for these results. One alternative was that the ECS did not prevent consolidation of the long-term memory trace, but instead disrupted retrieval of the memory. Evidence for this failure of retrieval hypothesis suggests that the original failure of consolidation interpretation of the ECS research was likely incorrect (Miller and Martin, 2014).

The Special Roles of the Hippocampus, Cerebellum, and Amygdala

As discussed above, research since Lashley has revealed that his speculation that all areas of brain were equally involved in learning and memory was incorrect. Now we know that one of the most important brain regions in **explicit memory** is the **hippocampus**, which serves as a preprocessor and elaborator of information (Squire, 1992). The hippocampus helps us encode information about **spatial relationships**, the **context** in which events were experienced, and the associations among memories (Eichenbaum, 1999). The hippocampus also serves in part as a switching point that **holds the memory for a short time and then directs** the information **to other parts of the brain**, such as the **cortex**, to actually do the rehearsing, elaboration, and

long-term storage (Jonides, Lacey, & Nee, 2005; Saylor Foundation, 2015). We also now know that different parts of the brain are involved in different kinds of memory.

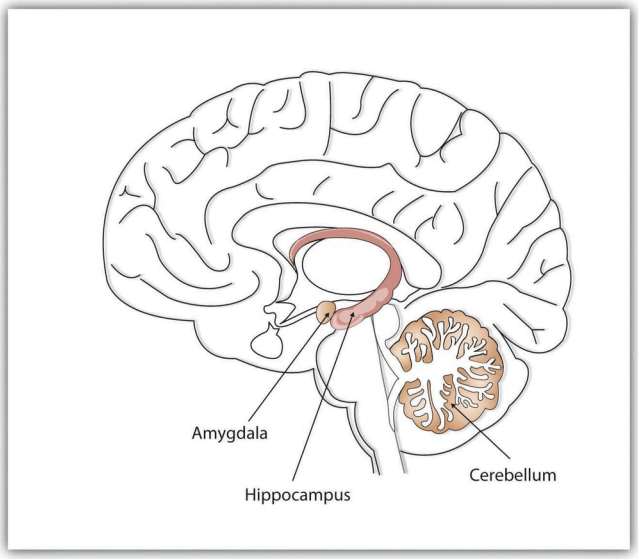

Figure 4.2.26.3: Different brain structures help us remember different types of information. The hippocampus is particularly important in explicit memories, the cerebellum in implicit memories, and the amygdala in emotional memories (Image and caption from the Saylor Foundation, 2015; Remembering and Judging; https://learn.umgc.edu/d2l/le/conten.../25917628/View; licensed under a Creative Commons Attribution 3.0 Unported License.).

While the hippocampus is handling explicit memory, the **cerebellum** and the **amygdala** are critically involved in **implicit and emotional memories, respectively**. Research shows that the cerebellum is more active when we are learning associations and in priming tasks (based on implicit memory), and animals and humans with damage to the cerebellum are impaired in classical conditioning (Krupa, Thompson, & Thompson, 1993; Woodruff-Pak, Goldenberg, Downey-Lamb, Boyko, & Lemieux, 2000). The storage of many of our most important emotional memories, and particularly those related to fear, is initiated and controlled by the amygdala (Sigurdsson, Doyère, Cain, & LeDoux, 2007).

Changes at the Synapse Correlated with Learning and Memory

Hebb's theory that long-term memory was stored by physical changes at the synapse has been so influential that research on the neural basis of learning and memory has focused primarily on synaptic events (see Chapter 5 on synapses and synaptic transmission). Focus on the synapse was reinforced by the discovery in 1973 in rabbit hippocampus that a **long-lasting increase in synaptic conductivity (synaptic strength)** could be produced **by high frequency stimulation of** the **pre-synaptic neuron** (Bliss and Lomo, 1973). This finding that synaptic strength can be increased for an extended period of time following high frequency pre-synaptic stimulation is now referred to as **Long-Term Potentiation (LTP)**. LTP has been found in many species and in many parts of the brain. However, it has been studied most in the hippocampus of the rat. Since this early research, additional forms of synaptic change have also been discovered.

Synaptic Plasticity

Synaptic plasticity is the strengthening or weakening of synapses over time in response to increases or decreases in their activity. Plastic change also results from the alteration of the number of receptors located at a synapse. Synaptic plasticity is the basis of learning and memory, enabling a flexible, functioning nervous system. Synaptic plasticity can be either short-term (synaptic enhancement or synaptic depression) or long-term. Two processes in particular, **long-term potentiation (LTP) and long-term depression (LTD)**, are important forms of synaptic plasticity that occur in **synapses in the hippocampus**.

Synaptic Plasticity: short-term enhancement, long-term potentiation and long-term depression

Key Points

- Short-term synaptic enhancement occurs when the amount of available neurotransmitter is increased, while short-term synaptic depression occurs when the amount of vesicles with neurotransmitters is decreased.
- Synapses are strengthened in long-term potentiation (LTP) when AMPA receptors (which bind to negatively-charged glutamate) are increased, allowing more calcium ions to enter the cell, causing a higher excitatory response.
- Long-term depression (LTD) occurs when the AMPA receptors are decreased, which decreases the amount of calcium ions entering the cell, weakening the synaptic response to the release of neurotransmitters.
- The strengthening and weakening of synapses over time controls learning and memory in the brain.

Key Terms

- **long-term potentiation**: a long-lasting (hours in vitro, weeks to months in vivo) increase, typically in amplitude, of the response of a postsynaptic neuron to a pattern of high frequency stimuli from a presynaptic neuron
- **long-term depression**: a long-term weakening of a synaptic connection
- **plasticity**: the property of neuron's conductivity or synaptic strength that allows it to be strengthened or weakened
- **NMDA receptor**: N-methyl-D-aspartate (NMDA) post-synaptic receptor and ion channel that is activated when Glutamate transmitter binds to it; an ionotropic (see Chapter 5) glutamate receptor
- **AMPA receptor**: Alpha-Amino-3-Hydroxy-5-Methyl-4-Isoxazole Propionic Acid (AMPA) post-synaptic receptor and ion channel that is activated when Glutamate transmitter binds to it; an ionotropic (see Chapter 5) glutamate receptor; both NMDA and AMPA receptors are important in learning and memory

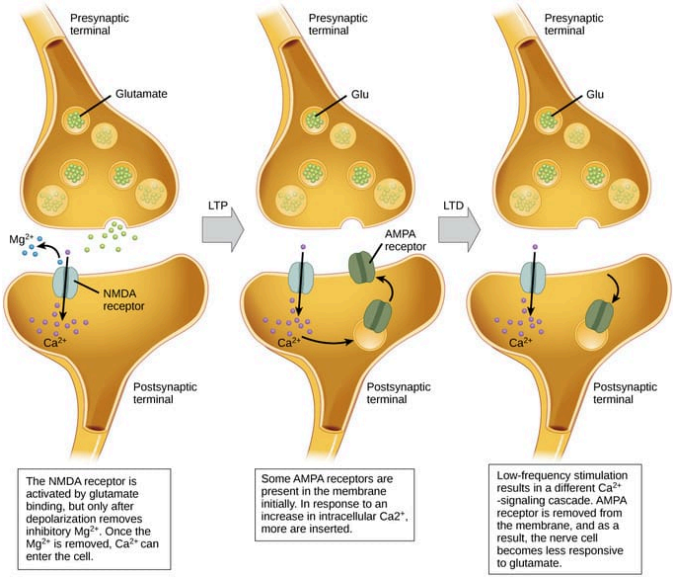

Figure 4.2.26.4: **Long-term potentiation and depression**: Calcium entry through postsynaptic NMDA receptors can initiate two different forms of synaptic plasticity: long-term potentiation (LTP) and long-term depression (LTD). LTP arises when a single synapse is repeatedly stimulated. This stimulation causes a calcium- and CaMKII-dependent cellular cascade, which results in the insertion of more AMPA receptors into the postsynaptic membrane. The next time glutamate is released from the presynaptic cell, it will bind to both NMDA and the newly-inserted AMPA receptors, thus depolarizing the membrane more efficiently. LTD occurs when few glutamate molecules bind to NMDA receptors at a synapse (due to a low firing rate of the presynaptic neuron). The calcium that does flow through NMDA receptors initiates a different calcineurin and protein phosphatase 1-dependent cascade, which results in the endocytosis of AMPA receptors. This makes the postsynaptic neuron less responsive to glutamate released from the presynaptic neuron. Long-term Potentiation (LTP)

Long-term potentiation (LTP) is a persistent strengthening of a synaptic connection, which can last for minutes or hours or even weeks. LTP is based on the Hebbian principle: “cells that fire together wire together.” There are various mechanisms, none of which are fully understood, behind the synaptic strengthening seen with LTP.

One known mechanism involves a type of postsynaptic glutamate receptor: NMDA (N-Methyl-D-aspartate) receptors. These receptors are normally blocked by magnesium ions. However, when the postsynaptic neuron is depolarized by multiple presynaptic inputs in quick succession (either from one neuron or multiple neurons), the magnesium ions are forced out and Ca^{2+} ions pass into the postsynaptic cell. Next, Ca^{2+} ions entering the cell initiate a signaling cascade that causes a different type of glutamate receptor, AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptors, to be inserted into the postsynaptic membrane. Activated AMPA receptors allow positive ions to enter the cell.

Therefore, the next time glutamate is released from the presynaptic membrane, it will have a larger excitatory effect (EPSP) on the postsynaptic cell because the binding of glutamate to these AMPA receptors will allow more positive ions into the cell. The insertion of additional AMPA receptors strengthens the synapse so that the postsynaptic neuron is more likely to fire in response to presynaptic neurotransmitter release.

LTP has many similarities with the synaptic changes Hebb proposed as basis for long-term memory, including two key features. First, LTP is long lasting, up to a year with repeated trials. Second, many forms of LTP require simultaneous activation in pre-synaptic and post-synaptic neurons at the synapse where LTP takes place ("neurons that fire together, wire together"); this is because NMDA (N-methyl-d-aspartate) receptors for glutamate (the most common excitatory transmitter in the brain), which are prominent at synapses where LTP occurs, have the same requirement for simultaneous activity in both pre- and post-synaptic neurons in order for these receptors to become activated. Research showing that many features of LTP are similar to features of long-term memory provides strong circumstantial evidence that LTP is related to the mechanisms of learning and memory. For example, LTP can be stimulated by low intensity stimulation similar to that produced in single neurons; LTP is most prominent in structures associated with learning; LTP is produced in the hippocampus by learning; drugs that enhance or impair learning also enhance or impair LTP; and LTP occurs in the nervous system of simple invertebrates (see discussion of Aplysia above) at the specific synapses involved in the learning (Pinel & Barnes, 2021).

Long-term Depression (LTD)

Another related phenomenon is **long-term depression (LTD)**, associated with decreases in synaptic conductivity. LTD might be part of the processes involved in creating and modifying patterns of excitation and inhibition in large populations of neurons for the coding of learned movements, sensory experience, and perhaps the mental representations of complex cognitive structures such as perceptions, whole memories, concepts, and even abstract ideas (Churchland, 2013). Coding of mental events in terms of patterns of excitation and inhibition in large populations of neurons is discussed later in this chapter when we examine neural network modeling of learning and memory. A related possibility is the pruning away of some synapses to form permanent changes in neural circuitry.Long-term depression (LTD) is essentially the reverse of LTP: it is a long-term weakening of a synaptic connection. One mechanism known to cause LTD also involves AMPA receptors. In this situation, calcium that enters through NMDA receptors initiates a different signaling cascade, which results in the removal of AMPA receptors from the postsynaptic membrane. With the decrease in AMPA receptors in the membrane, the postsynaptic neuron is less responsive to the glutamate released from the presynaptic neuron. While it may seem counterintuitive, LTD may be just as important for learning and memory as LTP. The weakening and pruning of unused synapses trims unimportant connections, leaving only the salient connections strengthened by long-term potentiation.

Short-term Synaptic Enhancement and Depression

Short-term synaptic plasticity acts on a timescale of tens of milliseconds to a few minutes. Short-term synaptic enhancement results from more synaptic terminals releasing transmitters in response to presynaptic action potentials. Synapses will strengthen for a short time because of either an increase in size of the readily- releasable pool of packaged transmitter or an increase in the amount of packaged transmitter released in response to each action potential. Depletion of these readily-releasable vesicles causes synaptic fatigue. Short-term synaptic depression can also arise from post-synaptic processes and from feedback activation of presynaptic receptors.

Changes at the Synapse Correlated with Learning and Memory: Anatomical Changes in Dendritic Spines

Modifications in synaptic strengths in excitatory synapses in the hippocampus appear to play a critical role in storage and recall of information in mammals. In humans at least, the role of the hippocampus is especially critical in explicit episodic (autobiographical) memory. As noted above, it is also crucially involved in spatial memory for many mammal species, including humans. Changes in synaptic strength throughout much of the brain may be important in learning and memory.

Dendritic Spines

Dendritic spines are tiny protruding structures located on the shaft of dendrites and are associated with synaptic connections. These spines "are present in large numbers on the surface of dendrites. For example, a single pyramidal neuron in the hippocampal CA1 region possesses as many as 30,000 dendritic spines. A majority of excitatory synapses are formed on the surface of these dendritic spines" (Irie & Yamaguchi, 2009, p. 1141). The primary sites of excitatory synaptic interaction in the mammalian central nervous system appear to be at dendritic spines.

These spiny protrusions have a head and neck of varied morphology (see Figures 10.4.5 and 10.4.6). Changes in spines play a significant role during brain development. "In a developing brain, spines exhibit a high degree of structural and functional plasticity, reflecting the formation and elimination of synapses during the maturation of neuronal circuits. The morphology of spines in developing neurons is affected by synaptic activity, hence contributing to the experience-dependent refinement of neuronal circuits, learning, and memory. Thus, understanding spine dynamics and its regulation is of central importance to studies of synaptic plasticity in the brain" (Bertling, et al., 2012, p. 391). During brain development synapses are formed, modified and sometimes eliminated as a function of input to them.

As discussed above, LTP has been shown to lead to functional changes at synapses where it is induced. These changes due to LTP are increased synaptic conductivity and enhanced responsiveness of the post-synaptic neuron. It appears that anatomical changes in spines accompany these changes in synaptic strength which occur during LTP and learning and memory.

Remember Hebb's proposal that long-term memory storage involves some persistent anatomical change at synapses. If Hebb was right, then we should expect to see anatomical changes at synapses when learning and memory occur. And if LTP is involved in the formation of these hypothesized anatomical changes, then we should expect to see anatomical modifications at the synapse associated with the LTP-induced increases in synaptic conductivity and responsiveness of the post-synaptic neuron. Consistent with Hebb's hypothesis about the physical basis of learning and memory, this is just what neuroscientists have observed. Changes in synaptic strength, associated with LTP, are accompanied by LTP-induced alterations of the shape and size of dendritic spines (Chidambaram, et al., 2019; Harris, et al., 2003), anatomical changes at the synapse, just as Hebb predicted.

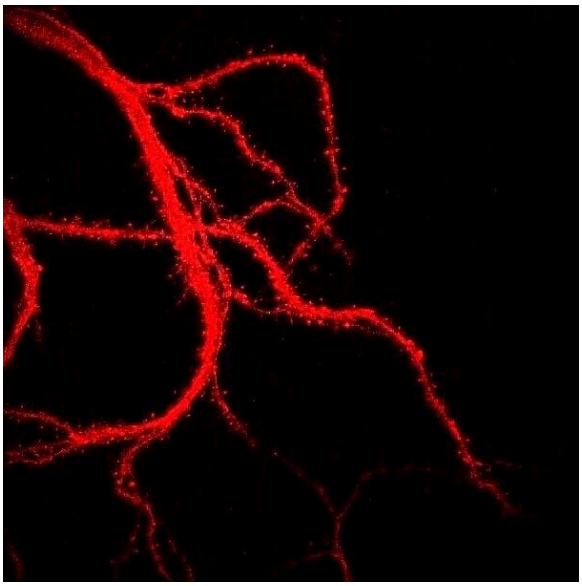

Figure 4.2.26.5: Branching dendrites of a neuron showing dendritic spines (tiny bristle-like projections lining each dendritic

branch). The photograph was obtained with a laser scanning microscope. Dendritic spines can rapidly change in size and shape and numbers, and are important in learning and memory. (Caption by Kenneth A. Koenigshofer, PhD. Image from Wikimedia Commons; File:Нейрональные отростки с шипиками.jpg; https://commons.wikimedia.org/wiki/F...0%BC%D0%B8.jpg; by Sergb95; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

Evidence strongly suggests that new protein synthesis is necessary for these effects on the shape and size of dendritic spines (Chidambaram, et al., 2019). As noted above, both growth and metabolic changes at synapses were proposed by Hebb as possible basis for the long-term memory. These anatomical changes in dendritic spines induced by LTP can be long-lasting. For example, "In mature networks, synaptic connections at dendritic spines can be quite stable, as newly emergent spines generated after motor learning have been shown to persist for months. . . While the distribution of spine size across the dendritic arbor of a single neuron can be quite variable, spine size generally correlates with excitatory synapse strength . . . it is generally accepted that spine head diameter and synapse strength co-vary during the expression of long term potentiation (LTP) . . ." (Henry, et al., 2017). It appears that Hebb's hypothesis about the physical basis of learning and memory in the brain was quite predictive of what later research would show--one mark of a good scientific theory.

Consistent with Hebb's hypothesis, dendritic spines appear to function as storage sites for synaptic strength and help transmit electrical potentials to the neuron's cell body. Dendrites of a single neuron can contain hundreds, even thousands of spines. Dendritic spines usually receive excitatory input from axons, although sometimes both inhibitory and excitatory connections are made onto the same dendritic spine (Kasthuri, et al., 2015). In addition to spines providing a potential anatomical substrate for memory storage and synaptic transmission, they may also increase the number of possible contacts between neurons (Alvarez & Sabatini, 2007). Spines are found on the dendrites of most principal neurons in the brain, including the pyramidal neurons of the neocortex (in prefrontal cortex for cognition; corticospinal tract for movement), the medium spiny neurons (GABAergic inhibitory) of the striatum (striate nucleus of basal ganglia; motor and reward systems; receives Glutamatergic and Dopaminergic inputs), and the Purkinje cells (GABAergic inhibitory neurons) of the cerebellum which receive relatively weaker excitatory (Glutamatergic) synapses to spines on the Purkinje cell dendrite. Hippocampal and cortical pyramidal neurons may receive tens of thousands of mostly excitatory inputs from other neurons onto their spines, whereas the number of spines on Purkinje neuron dendrites in the cerebellum is even greater, up to ten times greater.

Three of the four most notable classes of spine shape are shown in the figure below: "thin", "stubby", and "mushroom." The fourth category, "branched", is not shown. Studies using electron microscopy have revealed a continuum of shapes between these categories (Ofer, et al., 2021). The variable spine shape and volume is correlated with the strength and maturity of each spine-synapse. "Dendritic spines are also highly motile undergoing changes in size and shape over a timescale of seconds to minutes. Because small, thin dendritic spines are most likely to undergo these structural changes, whereas large, so-called ‘mushroom’ spines tend to maintain their form, it has been suggested that mushroom spines are more stable memory spines whereas the more plastic thin spines are learning spines. . . . [L]arge spines are sites of strong synapses and, accordingly, the growth of the spine head likely correlates with a strengthening of synaptic transmission" (Leuner & Shors, 2010, p. 349).

Both shorter-term transient and longer-term sustained changes in structural plasticity of dendritic spines have been observed by researchers--within the first two minutes following stimulation of the pre-synaptic neuron, an initial 300% expansion of the post-synaptic dendritic spine occurs, followed by a reduction of the spine's volume so that it is elevated to about 70-80% larger than the original pre-stimulation volume, a sustained change in structural plasticity lasting about 30 minutes or more. LTP is initiated with the transient stage of dendritic spine growth. Both stages of spine growth are hypothesized to be involved in learning and memory. Large spines are more stable than smaller ones and may be resistant to modification by additional synaptic activity (Kasai, et al., 2003). These structural changes in dendritic spines induced by pre-synaptic stimulation associated with LTP are believed by neurosciences to be important in the encoding, storage, and retrieval of memories (Murakoshi, et al., 2011). These changes in spine size and shape involve changes in the microstructure of the spine and abnormalities at this level may be involved in memory disorders. "The actin cytoskeleton is the structural element underlying changes in dendritic spine morphology and synapse strength. The proper morphology of spines and proper regulation of the actin cytoskeleton have been shown to be important in memory and learning; defects in regulation lead to various memory disorders. Thus, understanding actin cytoskeleton regulation in dendritic spines is of central importance to studies of synaptic and neuronal function" (Koskinen, et al., 2012, p. 47).

The morphogenesis of dendritic spines (the process by which they attain their shape) is critical to the induction of long-term potentiation (LTP) (Kim & Lisman, 1999; Krucker, et al., 2000). Interestingly, Hayashi-Takagi et al. (2015) found that memory could be disrupted if the potentiated spines, within a neuron ensemble involved in motor learning, were specifically shrunk. This suggests that spine growth is essential to at least some forms of memory.

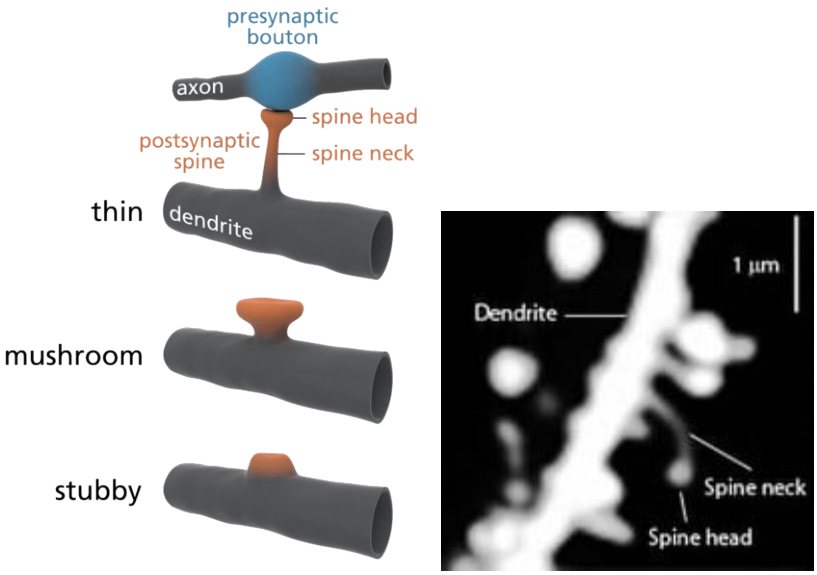

Figure 4.2.26.6: (Left) Varying morphology of types of dendritic spines. Changes in their shape and size are associated with LTP and learning and memory. (Right) Spines on the dendrite of a medium spiny striatal neuron. The image was obtained by expressing Enhanced Green Fluorescent Protein (EGFP) in the neurons and imaging them using a laser scanning two photon microscope. (Caption for image on left by Kenneth A. Koenigshofer, PhD; Image on left from Wikimedia Commons, Dendritic spines; https://commons.wikimedia.org/wiki/F...e_types_3D.png; original work of Thomas Splettstoesser (www.scistyle.com); licensed under the Creative Commons Attribution-Share Alike 3.0 Unported license. Image on right and its caption from Wikimedia Commons, Dendritic spines; https://commons.wikimedia.org/w/inde...=Go&type=image; Released into Public Domain by the image author).

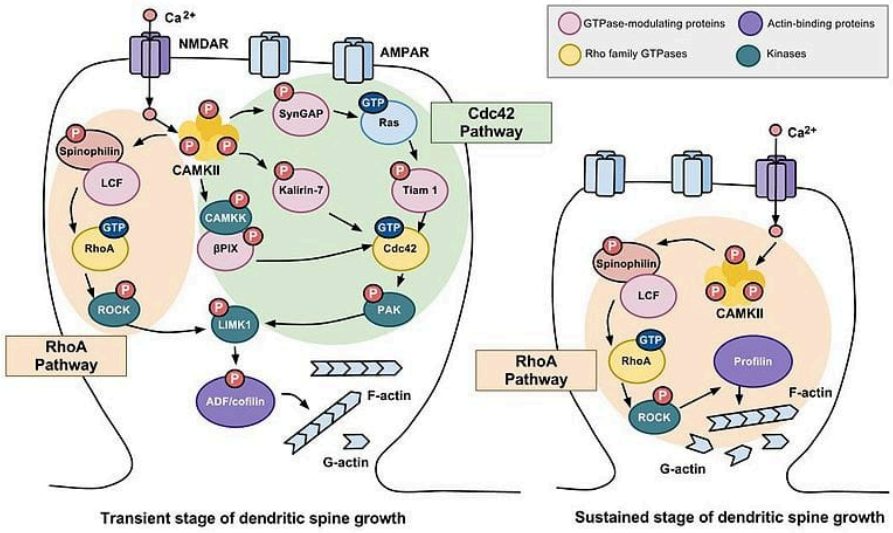

Figure 4.2.26.7: Transient vs. Sustained Dendritic Spine Growth following High-Frequency Stimulation. Details inside each spine show the chemical cascades involved in the two stages of spine growth after pre-synaptic stimulation. It is not necessary for the student to know the details of these cascades. However, note that these cascades begin with calcium influx through NMDA receptors (top of spine) and that the final step is action on actin (bottom right of spine) leading to changes in shape and size of the spine. (Image from Wikimedia Commons; Dendritic spines; https://commons.wikimedia.org/wiki/F...timulation.jpg; author of image and image title, Itzy; licensed under the Creative Commons Attribution-Share Alike 3.0 Unported license; caption by Kenneth A. Koenigshofer, PhD.).

Yang, et al. (2009) studied changes in numbers of synaptic spines during learning and novel sensory experience in mice. They

state that their "results suggest that new experience leads to the pruning of existing synapses and could cause significant functional changes in cortical circuits. Indeed, we found that 1 week after motor training, motor performance strongly correlated with the degree of spine elimination . . . Thus, motor learning and novel sensory experience involve not only new spine formation but also permanent removal of connections established early in life" (Yang, et al. 2009, p. 921). These results are easier to understand if we recall that during prenatal development of the brain there are excess numbers of synaptic connections and that the elimination of nonfunctional synapses is essential to normal brain development and functioning. Learning may involve neural pruning as well as the formation and enhanced conductivity of synapses via changes in dendritic spines. As Yang, et al., note, "In addition to promoting synapse formation, experience plays an important role in eliminating excessive and imprecise synaptic connections formed early during development" (Yang, et al. 2009, p. 921).

Chidambaram, et al. (2019, p.161) summarize the relationship of changes in synaptic conductivity to changes in dendritic spines: "During synaptic plasticity the number and shapes of dendritic spines undergo radical reorganizations. Long-term potentiation (LTP) induction promotes spine head enlargement and the formation and stabilization of new spines. Long-term depression (LTD) results in their shrinkage and retraction." These authors also note some interesting observations relating atypical numbers of synaptic spines to several neurologically based disorders. "Reports indicate increased spine density in the pyramidal neurons of autism and Fragile X syndrome patients and reduced density in the temporal gyrus loci of schizophrenic patients. Post-mortem reports of Alzheimer's brains showed reduced spine number in the hippocampus and cortex" and atypical spines may play a role in neurodegenerative diseases (Chidambaram, et al., 2019, p. 161).

If changes in spines are involved in the formation and retention of long-term memories, then morphological changes in spines must be very durable. According to Yang and colleagues (2009, p. 920), "Stably maintained dendritic spines are associated with lifelong memories. . . . a small fraction of new spines induced by novel experience, together with most spines formed early during development and surviving experience-dependent elimination, are preserved throughout the entire life of an animal. These studies indicate that learning and daily sensory experience leave minute but permanent marks on cortical connections and suggest that lifelong memories are stored in largely stably connected synaptic networks."

Hebb's theory has proven to be impressively predictive of discoveries made many years after his book was published in 1949. Findings like those described in this module continue to confirm many aspects of Hebb's theory.

Cellular and Receptor Level Mechanisms Revisited

In the sections above, we discussed **Long-Term Potentiation (LTP)** and its possible involvement in memory processes. Here, it is appropriate to consider LTP and associated processes in greater detail. As noted previously, Long-term potentiation (LTP) is a process in which synapses are strengthened. It has been the subject of extensive research since the mid-1970s because of its likely role in several types of memory.

A related phenomenon also discussed above is Long-Term Depression **(LTD**), a phenomenon that is the opposite of long-term potentiation (LTP). In LTD, communication across the synapse is silenced. LTD plays an important role in the cerebellum, in implicit procedural memory (motor memory, implicit memory of how to do something like ride a bicycle or hit a baseball), where the neural networks involved in erroneous movements are inhibited by the silencing of their synaptic connections. LTD is what allows us to correct our motor procedures when learning how to perform a task. Thus, long-term depression (LTD) involves a weakening of a synapse as a means of improving performance of learned skilled movements (recall that weakening of synaptic strength is associated with shrinkage of dendritic spines). Imagine that you are trying to learn a gymnastics routine that involves a number of flips and other complicated movements in sequence. When you initially start to learn the routine, you make many incorrect moves that you must suppress if you are going to learn to do the routine correctly with the error free precision that the judges will look for. LTD is the cellular level mechanism that allows you to suppress the incorrect muscle movements that lead to errors in the routine.

As discussed previously, there is another possible role for LTD in coding of perceptions, concepts, ideas, and other complex cognitive structures. One of the most difficult problems in neuroscience is how the activities of large populations of neurons encode and create complex elements of psychological experience such as perceptions, thoughts, ideas, understanding, knowledge, and other complex mental representations. Modeling of brain processes in artifical neural networks (see the supplement later in this chapter on artificial networks) suggests that inhibition is just as important as excitation in neural coding of complex mental representations. Patterns of excitation and inhibition in large populations of neurons may underlie the neural coding of complex cognition and perception. If so, then LTD may be equally as important as LTP in the neural coding of complex representations such as perceptions, thoughts, concepts, ideas and even emotions (see *Matter and Consciousness* by Paul Churchland for a more complete discussion of these ideas). Just as dots and dashes are equally important in Morse Code, excitation and inhibition may be equally important elements in neural coding.

Although a synapse is weakened in LTD , by contrast, in LTP, after intense stimulation of the pre-synaptic neuron, a synapse is strengthened and the amplitude of the post-synaptic neuron's response increases. The stimulus applied to the pre-synaptic neuron to produce LTP is generally of short duration (less than 1 second) but high frequency (over 100 Hz). The excitatory potential (EPSP; see Chapter 5) measured in a post-synaptic neuron, after high frequency pre-synaptic stimulation, is increased for a long period. For example, when the axons that make connections to the pyramidal neurons of the hippocampus are exposed to a high-frequency stimulus, the amplitude of the excitatory potential measured in these pyramidal neurons is increased for up to several weeks. What synaptic events are involved in the production of LTP? Let's review, now in greater detail.

Glutamate, the neurotransmitter released into these hippocampal synapses (glutamate is excitatory and mediates fast synaptic neurotransmission in the brain), binds to several different sub-types of receptors on the post-synaptic hippocampal neuron. Two of these glutamate receptor sub-types, the receptors for AMPA and NMDA, are especially important for LTP (Traynelis, et al., 2010).

The AMPA receptor (a glutamate receptor named after the derivative that activates it, AMPA short for Alpha-Amino-3-Hydroxy-5-Methyl-4-Isoxazole Propionic Acid) is paired with an ion channel so that when glutamate binds to this receptor, this channel lets sodium ions enter the post-synaptic neuron. This influx of sodium causes the post-synaptic dendrite to become locally depolarized (an EPSP, a positive shift in voltage).

The **NMDA receptor**, which also uses glutamate as its transmitter, is also paired with an ion channel (NMDA is N-methyl-D-aspartate, a derivative of glutamate). This channel admits calcium ions into the post-synaptic cell when it is activated. However, when the cell is at resting potential, the calcium channel is blocked by magnesium ions (Mg2+), so that even if glutamate binds to the receptor, calcium cannot enter the neuron. For these magnesium ions to withdraw from the channel, the dendrite's membrane potential must be depolarized. And that is exactly what happens during the high-frequency stimulation that causes LTP: the post-synaptic neuron becomes depolarized following the sustained activation of its AMPA receptors! The magnesium then withdraws from the NMDA receptors and allows large numbers of calcium ions to enter the cell.

This increased concentration of calcium in the dendrite sets off several biochemical reactions that make this synapse more efficient for an extended period (Bliss & Collingridge, 1993; Bliss, et al., 2018; Citri & Malenka, 2008). These calcium ions are extremely important intracellular messengers that activate many enzymes by altering their conformation. One of these enzymes is calmoduline, which becomes active when four calcium ions bind to it. It then becomes Ca2+/calmodulin, the main second messenger for LTP. Ca2+/calmodulin then in turn activates other enzymes that play key roles in this process, such as **adenylate cyclase** and Ca2+/calmodulin-dependent protein kinase II **(CaM kinase II)**. These enzymes in turn modify the spatial conformation of other molecules, usually by adding a phosphate ion to them. This common catalytic process is called **phosphorylation**.

The activated adenylate cyclase manufactures cyclic adenosine mono-phosphate **(cAMP)**, which in turn catalyzes the activity of another protein, kinase A (**PKA**). In short, there is a typical cascade of biochemical reactions which can have many different effects.

For example, PKA phosphorylates the AMPA receptors, allowing them to remain open longer after glutamate binds to them. As a result, the post-synaptic neuron becomes further depolarized, thus contributing to LTP.

Other experiments have shown that **CREB** protein is another target of PKA, protein kinase A. CREB plays a major role in gene transcription, and its activation leads to the creation of new AMPA receptors that can increase synaptic efficiency still further.

According to Park, et al. (2021), Long-term potentiation (LTP) at hippocampal CA1 synapses (see Figure 10.4.8) can be expressed by an increase either in the number (N) of AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid) receptors or in their single channel conductance (γ)--that is, increased synaptic strength. In their experiments, they established how these distinct synaptic processes contribute to the expression of LTP in hippocampal slices obtained from young adult rodents. LTP induced by compressed theta burst stimulation (TBS), with a 10 second inter-episode interval, involves purely an increase in the number of AMPA receptors (LTP_N). In contrast, either a spaced TBS, with a 10 min inter-episode interval, or a single TBS, delivered when PKA is activated, results in LTP that is associated with a transient increase in single channel conductance (γ) or increased synaptic strength ($LTP_γ$), caused by the insertion of calcium-permeable (CP)-AMPA receptors. Activation of CaMKII is necessary and sufficient for LTP_N (increase in numbers of AMPA receptors, while PKA is additionally required for $LTP_γ$ (increase in single channel conductance). Thus, two mechanistically distinct forms of LTP co-exist at these synapses.

The other enzyme activated by Ca2+/calmodulin, CaM kinase II, has a property that is decisive for the persistence of LTP: it can phosphorylate itself! Its enzymatic activity continues long after the calcium has been evacuated from the cell and the Ca2+/calmodulin has been deactivated.

CaM kinase II can then in turn phosphorylate the AMPA receptors and probably other proteins such as MAP kinases, which are involved in the building of dendrites, or the NMDA receptors themselves, whose calcium conductance would be increased by this phosphorylation.

LTP involves at least two phases: **establishment** (or **induction**), which lasts about an hour, and **maintenance** (or **expression**), which may persist for several days.	The first phase, **establishment**, can be experimentally induced by a single, high-frequency stimulation. It involves the activity of various enzymes (kinases) that persist after the calcium is eliminated, but no protein synthesis occurs.	To trigger the **maintenance** phase, however, a series of high-frequency stimuli must be applied. Unlike the establishment phase of LTP, the maintenance phase requires the synthesis of new proteins–for example, the ones that form the receptors and the ones that contribute to the growth of new synapses (another phenomenon that occurs during the maintenance phase of LTP).

Table 10.4.1: Establishment and Maintenance Phases of LTP

To let the calcium enter the cell, the **NMDA receptor must be activated by glutamate and subjected to depolarization simultaneously.** The necessity for **these two simultaneous conditions gives this receptor associative properties**. This lets it **detect the coincidence of two events** and makes it the **key element in long-term potentiation.**

Significantly, if this receptor is blocked with a drug, or if the gene involved in its construction is disabled, LTP cannot occur.

The spines on post-synaptic dendrites form separate compartments to isolate biochemical reactions that occur at some synapses but not at others. This anatomical specialization probably helps to ensure a certain specificity in neural connections.

The most interesting characteristic of **LTP** is that it c**an cause the long-term strengthening of the synapses between two neurons that are activated simultaneously.** In other words, exactly the kind of **association mechanism** that **Hebb** (1949) had imagined years earlier.

Experimental Evidence for Components of LTP

Many methods have been used to determine the role of a particular ion, or a second messenger, or an enzyme in a synaptic process.

For example, the role of calcium in long-term potentiation (LTP) has been confirmed in a number of ways. One experiment involved injecting the post-synaptic neuron with chelating agents such as EGTA and BAPTA, two molecules that bind to calcium and render it inactive. As a result, it becomes impossible to induce LTP. The reverse procedure has also been used. Researchers have injected special molecules into the post-synaptic neuron and then illuminated them with UV light, thus causing them to release enough calcium to induce LTP in this neuron.

Another approach is to produce mutations that make a protein non-functional or that block its action with another molecule. Blocking CaM kinase II in this way prevents LTP from becoming established, which also demonstrates the central role of this protein.

Similarly, inhibiting PKA or CREB prevents LTP from reaching its second phase and being sustained.

In certain cases, researchers have even identified the one amino acid, among the hundreds of amino acids that make up a protein, whose phosphorylation is essential for LTP (in case you want to know: Ser831 for the GluR1 sub-unit of the AMPA receptor and Thr286 for the autophosphorylation site of CaM kinase II).

Researchers have also shown that a mouse whose gene for the GluR1 sub-unit of the AMPA receptor had been knocked out could not have any LTP, thus confirming the role of CaM kinase II once again.

In mice for which the site Thr286 in CaM kinase II was deactivated, their basic synaptic transmission was maintained, but LTP could no longer be induced in them, thus proving the need for CaM kinase II. The reverse procedure also led to the same conclusion: adding activated CaM kinase II to the pyramidal neurons of the hippocampus causes a potentiation phenomenon similar to LTP.

Additional Mechanisms of LTP

“Silent synapses” are another mechanism that was discovered in the mid-1990s and that may contribute to long-term potentiation (LTP). These synapses are physically present, but under normal conditions do not contribute to synaptic transmission.

Some of these silent synapses have been found in the hippocampus. They appear to have receptors for NMDA but not for AMPA. It is thought that these synapses may be activated during LTP and thus help to strengthen the synaptic response. The discovery that after LTP, these synapses do display an electrical current associated with AMPA channels suggests that some newly synthesized AMPA receptors may be inserted into the post-synaptic membrane.

In addition to all of the post-synaptic mechanisms involved in the **establishment of LTP**, it has long been postulated that some pre-synaptic modifications occur during the ensuing **maintenance phase**. But certain modifications, such as an increase in the amount of glutamate released by the pre-synaptic neuron, would imply the presence of a retrograde messenger that goes back to this neuron and modifies it. Because nitric oxide (**NO**) is a gas in its natural state, and can thus diffuse through cell membranes, it would be an ideal candidate for this role. But its involvement is still the subject of much debate and controversy.

Video Reviews of LTP and Memory

For a review, take a look at these brief videos of the events in LTP:

LTP, Neurochemical Cascades, and Stages of Memory

According to Rozensweig (2007), different parts of the neurochemical cascade, associated with learning and memory, can be related to different stages in memory processing. Bennett, et al. (1964), made an early discovery that enriched experience in rats causes increased rates of protein synthesis and increased amounts of protein in the cortex. Mizumori, et al. (1985), using the protein-synthesis inhibitor, anisomycin, found that protein must be synthesized in the cortex soon after training if LTM is to be formed; however, short-term memory (STM) did not require protein synthesis, findings consistent with the two kinds of memory traces that Hebb (1949) had proposed: transient, labile memory traces on the one hand and stable structural traces on the other. Using chicks, several investigators traced a cascade of neurochemical events from initial sensory stimulation to synthesis of protein and structural changes in the brain (Rose, 1992). Rozensweig (2007) summarizes some of these events as follows:

"The cascade is initiated when sensory stimulation activates receptor organs that stimulate afferent neurons by using various synaptic transmitter agents such as acetylcholine (ACh) and glutamate. Inhibitors of ACh synaptic activity such as scopolamine and pirenzepine can prevent STM as can inhibitors of glutamate receptors including both the NMDA and AMPA receptors. Alteration of regulation of ion channels in the neuronal membrane can inhibit STM formation, as seen in effects of lanthanum chloride on calcium channels and of ouabain on sodium and potassium channels. Inhibition of second messengers is also amnestic, for example, inhibition of adenylate cyclase by forskolin or of diacylglycerol by bradykinin. These second messengers can activate protein kinases — enzymes that catalyze additions of phosphate molecules to proteins. We found that two kinds of protein kinases are important in formation, respectively, of ITM (an intermediate stage in memory formation noted by Rozenzweig, 2007) or LTM. Agents that inhibit calcium/calmodulin protein kinases (CaM kinases) prevent formation of ITM, whereas agents that do not inhibit CaM kinases, but do inhibit protein kinase A (PKA) or protein kinase C (PKC) prevent formation of LTM (Rosenzweig, et al., 1992; Serrano P.A., et al., 1994)."

Rose (1995) suggested that in chicks a kind of LTM that lasts a few hours (Rozensweig's ITM) involves a first wave of glycoprotein synthesis, whereas “true long-term memory” (LTM) requires a second wave of glycoprotein synthesis, occurring about 6 hours after training.

Rozensweig (2007) reviews evidence that the neurochemical cascades in *memory* in the chick are similar to the cascades in formation of LTP in different species. He states:

"The neurochemical cascade involved in formation of memory in the chick was soon shown to be similar to the cascade involved in

long-term potentiation in the mammalian brain (Colley & Routtenberg, 1993) and in the nervous systems of invertebrates (Krasne & Glanzman, 1995). DeZazzo and Tully (1995) compared STM, ITM, and LTM in fruit flies, chicks, and rats. Tully and coworkers have shown that the three stages of memory in the fruit fly depend on three different genes (Tully et al., 1996)."

More recent research on LTP also confirms a three-stage process in LTP. In a review of the literature on LTP, Bliss, et al. (2018) note:

"The labels LTP1 and LTP2 equate to the forms of LTP that are, respectively, independent of and dependent on *de novo* protein synthesis. These are frequently referred to as early-phase LTP and late-phase LTP (E-LTP and L-LTP, respectively) implying that protein synthesis is not required initially but is required at later stages, with the switch-over [between E-LTP and L-LTP] occurring during a period of a few hours."

Although LTP has many properties that make it a good candidate for the mechanism of learning and memory in the brain, critical evidence in behaving animals is still needed. Nevertheless, neuroscientists are optimistic, and for good reason. According to Bliss, et al. (2018), "Today, LTP can be studied at every level from the purely molecular to the cognitive. Although definitive proof that the mechanisms of LTP subserve learning and memory in the behaving animal is still lacking, few neuroscientists doubt that such proof will eventually be forthcoming . . . there is now very strong evidence that an LTP-like mechanism mediates at least some aspects of memory." Much of this optimism comes from numerous studies showing that physiological, genetic, or pharmacological manipulations of LTP (either facilitating it or inhibiting it) have similar effects on learning and memory (Bliss, et al., 2018; Rozenzweig, 2007).

Anatomical Subregions of the Hippocampus and Memory

As mentioned above, hippocampal and cortical pyramidal neurons may receive tens of thousands of mostly excitatory inputs from other neurons onto their dendritic spines. As shown below in Figure 4.2.26.8, the hippocampus consists of a number of subregions. These regions are involved in different functions related to learning and memory. "The hippocampus proper is defined by the dentate gyrus and Cornu Ammonis (CA). While the dentate gyrus contains the fascia dentata and the hilus, the CA is anatomically and functionally differentiated into distinct subfields named CA1, CA2, CA3, and CA4. . . . [T]he CA3 subfield . . . with inputs from the dentate gyrus and entorhinal cortex . . . is implicated in encoding spatial representations and episodic memories. . . The mossy fiber pathway . . . translates . . . cortical signals to a . . . hippocampal code, essential for memory formation" (Cherubini & Miles, 2015, p.19). According to Yang et al. (2014), "CA3 pyramidal neurons form extensive recurrent connections with each other. Such connections are able to learn to associate components of an input pattern with each other." Perhaps this capacity would be required to link the components of a memory into a unified whole.

A prominent model of the organization of the hippocampus highlights what neuroscientists have dubbed the "trisynaptic circuits," circuits with three synapses (dentate--CA3--CA1), which according to the "lamellar hypothesis," are stacked upon one another along the body of the hippocampus. According to this model, "the hippocampus is organized as a stack of parallel, trisynaptic circuits" (Yang et al., 2014, p. 12919).

However, additional research suggests a network oriented perpendicular to the trisynaptic circuits. Yang et al. (2014, 12919-20) found a "well-organized, longitudinally projecting synaptic network among CA1 pyramidal neurons . . . [and] that synapses of this network are capable of supporting synaptic plasticity, including long-term potentiation, and a short-term memory mechanism called 'dendritic hold and read.' . . . [Furthermore,] LTP can strengthen interlamellar CA1-to-CA1 connections as well as the well-established CA3-to-CA1 connections in the transverse plane" (Yang et al., 2014, p. 12921). Might these two networks in planes perpendicular to one another in the hippocampus suggest a kind of grid-like arrangement which might code location of objects, including oneself, in three-dimensional space? As mentioned above, CA3 is implicated in the representation of space and spatial relationships. In addition, neuroscientists have found "place cells" in the hippocampus which fire when an animal is in a specific place in a maze, for example, and "place cells" tuned to fire to specific locations also seem to be present in the human hippocampus. According to Yang et al. (2014, p. 12923), "These properties suggest that this system may be an integral component of the larger 3D information processing network of the hippocampus." Clearly, processing of three-dimensional space and one's spatial relations to other objects is critical to navigating the world successfully.

However, Yang and colleagues consider another possibility--that the CA1 network may "transform a time sequence into a spatial sequence" so that the "resulting 'time-to-space' transform is effectively an efficient sequence memory mechanism" such as would be necessary when "information typically arrives as a time sequence over a finite interval and its meaning can only be revealed if each sequence is viewed as a whole and in proper order. . . [Furthermore,] behavioral studies have suggested that area CA1 possesses the capacity for sequence memory" (Yang et al., 2014, p. 12923). To understand what this means, think about events in the world--they take place over time and their meaning, including often their adaptive significance, may only become apparent

when they are perceived as a whole sequence. If you introspect for a moment and consider what a memory is like when you recall it, you may get a sense of this. For example, I have a very distinct memory of the first time I saw the planet Saturn and its rings through a telescope I bought when I was 14 (which I still have) using money I had saved from delivering newspapers door-to-door on my paper route (yes, I am that old). After what is now 61 years ago, I still remember setting up my telescope on a cold night in the driveway of my parents' house, finding Saturn almost by accident, viewing the rings around the planet, and then running inside through the kitchen door to tell my parents what I was seeing. Could it be that the CA1 subregion of the hippocampus is an important component in the ability to remember events in their proper sequence? Sequence memory appears to be an essential property of the brain in order to represent and store vital information about the temporal order of events we experience in the world.

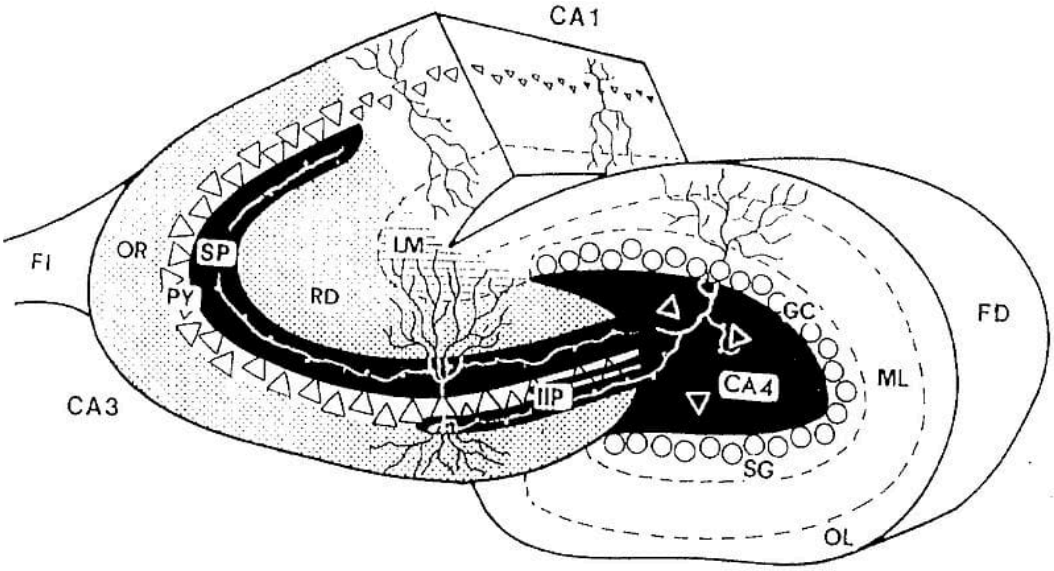

Figure 4.2.26.8: Diagram showing anatomy of the hippocampus. Pyramidal neurons in area CA1 have as many as 30,000 dendritic spines per neuron on their dendrites. Spines are associated with synapses which are primarily excitatory. The hippocampal subregion CA3-CA4 is indicated in black, stippled, and hatched areas. Black areas: suprapyramidal (SP), intra- and infrapyramidal (IIP) and hilar (CA4) mossy fiber terminal fields originating from the dentate gyrus. Stippled area: strata oriens (OR) and radiatum (RD). Hatched area: stratum lacunosum-moleculare (LM). CA1, subregion of the hippocampus without mossy fibers; FI, fimbria hippocampi; FD, fascia dentata; OL and ML, outer and middle molecular layers of the fascia dentata; SG, supragranular layer; GC, granular cells (Image and caption from Wikimedia Commons; File:Diagram of a Timm-stained cross-section of the hippocampus.JPEG; https://commons.wikimedia.org/wiki/F...ppocampus.JPEG; by Sluyter, Frans; Laure Jamot, Jean-Yves Bertholet, Wim Crusio (2005-04-22). 4.2.27: Brain Mechanisms of Memory Disorders

Learning Objectives

1. Explain the roles of the hippocampus and medial temporal lobes in memory.
2. Describe the case of H.M. and how it contributed to our understanding of the brain mechanisms in memory.
3. Describe global amnesic syndrome.
4. Discuss retrograde and anterograde amnesias including temporally graded amnesia.
5. Describe amnesia of the frontal lobes.
6. Discuss specific amnesias due to specific and circumscribed cortical damage.

Overview

We now examine the roles of the hippocampus and medial temporal lobes in memory and memory loss, focusing on amnesic syndromes associated with Korsakoff's Syndrome and Alzheimer's Disease. We also consider frontal lobe amnesia and highly specific forms of amnesia for highly specific types of information due to localized cortical damage. Damage to the amygdala disrupts emotional memories including memories of traumatic events. Diseases or other causes of cellular loss in the hippocampi can produce amnesia.

Amnesia, Hippocampus, and Medial Temporal Lobes

The Russian psychologist A. R. Luria (1968) has described the abilities of a man known as “S,” who seems to have unlimited memory. S remembers strings of hundreds of random letters for years at a time, and seems in fact to never forget anything. But what would this be like?

Shereshevsky, or “S,” the mnemonist studied by Luria was a man who almost never forgot. His memory appeared to be virtually limitless. He could memorize a table of 50 numbers in under 3 minutes and recall the numbers in rows, columns, or diagonals with ease. He could recall lists of words and passages that he had memorized over a decade before. Yet Shereshevsky found it difficult to function in his everyday life because he was constantly distracted by a flood of details and associations that sprung to mind. His case history suggests that remembering everything is not always a good thing. You may occasionally have trouble remembering where you parked your car, but imagine if every time you had to find your car, every single former parking space came to mind. The task would become impossibly difficult to sort through all of those irrelevant memories. Thus, forgetting is adaptive in that it makes us more efficient. The price of that efficiency is those moments when our memories seem to fail us (Schacter, 1999).

Clearly, remembering everything would be maladaptive, but what would it be like to remember nothing? We will now consider a profound form of forgetting called amnesia that is distinct from more ordinary forms of forgetting. Most of us have had exposure to the concept of amnesia through popular movies and television. Typically, in these fictionalized portrayals of amnesia, a character suffers some type of blow to the head and suddenly has no idea who they are and can no longer recognize their family or remember any events from their past. After some period of time (or another blow to the head), their memories come flooding back to them. Unfortunately, this portrayal of amnesia is not very accurate. What does amnesia typically look like?

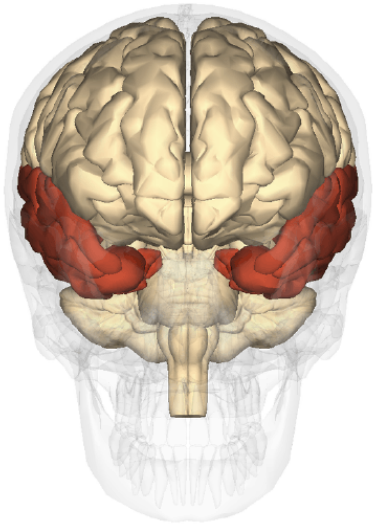

Figure 4.2.27.1: Patients with damage to the temporal lobes may experience anterograde amnesia and/or retrograde amnesia. [Image from Wikimedia Commons; File:Temporal lobe - anterior view.png; https://commons.wikimedia.org/wiki/F...erior_view.png; by Anatomography; licensed under the Creative Commons Attribution-Share Alike 2.1 Japan license; CC BY-SA 2.1 JP, https://goo.gl/BDF2Z4]

As previously discussed, the most widely studied amnesic patient was known by his initials H. M. (Scoville & Milner, 1957). H.M.'s disorder is an example of **global amnesic syndrome** characterized by severe anterograde amnesia and more moderate retrograde amnesia (see below). This syndrome results from bilateral lesions of the medial portion of the temporal lobe, and more specifically, of the hippocampus and its neighboring structures (the parahippocampal, entorhinal, and perirhinal cortices). These lesions can be due to surgical ablation, as in the case of H.M., or to other causes such as tumors, ischemic episodes, head traumas, and various forms of encephalitis.

As a teenager, H. M. suffered from severe epilepsy, and in 1953, he underwent surgery to have both of his medial temporal lobes removed to relieve his epileptic seizures. The **medial temporal lobes** encompass the hippocampus and surrounding cortical tissue. Although the surgery was successful in reducing H. M.'s seizures and his general intelligence was preserved, the surgery left H. M. with a profound and permanent memory deficit. From the time of his surgery until his death in 2008, H. M. was unable to learn new information, a memory impairment called **anterograde amnesia**. H. M. could not remember any event that occurred since his surgery, including highly significant ones, such as the death of his father. He could not remember a conversation he had a few minutes prior or recognize the face of someone who had visited him that same day. He could keep information in his short-term, or working, memory, but when his attention turned to something else, that information was lost for good. It is important to note that H. M.'s memory impairment was restricted to **declarative memory**, or conscious (explicit) memory for facts and events. H. M. could learn new motor skills and showed improvement on motor tasks even in the absence of any memory for having performed the task before (Corkin, 2002).

In addition to anterograde amnesia, H. M. also suffered from **temporally graded retrograde amnesia**. **Retrograde amnesia** refers to an inability to retrieve old memories that occurred before the onset of amnesia. Extensive retrograde amnesia in the absence of anterograde amnesia is very rare (Kopelman, 2000). More commonly, retrograde amnesia co-occurs with anterograde amnesia and shows a temporal gradient, in which memories closest in time to the onset of amnesia are lost, but more remote memories are retained (Hodges, 1994). In the case of H. M., he could remember events from his childhood, but he could not remember events that occurred a few years before the surgery.

Amnesiac patients with damage to the **hippocampus and surrounding medial temporal lobes** typically manifest a similar clinical profile as H. M. The degree of anterograde amnesia and retrograde amnesia depend on the extent of the **medial temporal lobe damage**, with greater damage associated with a more extensive impairment (Reed & Squire, 1998). Anterograde amnesia provides evidence for the role of the **hippocampus** in the formation of long-lasting declarative memories, as damage to the hippocampus results in an inability to create or consolidate this type of new long-term memory. Similarly, temporally graded retrograde amnesia can be seen as providing evidence for the importance of **memory consolidation** (Squire & Alvarez, 1995). A memory depends on the hippocampus until it is consolidated (or "fixed") and transferred into a more durable form that is **stored in the cortex**. According to this theory, an amnesiac patient like H. M. could remember events from his remote past because those memories were fully consolidated and no longer depended on the hippocampus, but instead had been transferred to other brain areas, primarily to particular areas of the cerebral cortex.

The classic amnesiac syndrome we have considered here is sometimes referred to as **organic amnesia**, and it is distinct from functional, or dissociative, amnesia. Functional amnesia involves a loss of memory that cannot be attributed to brain injury or any obvious brain disease and is typically classified as a mental disorder rather than a neurological disorder (Kihlstrom, 2005). The clinical profile of dissociative amnesia is very different from that of patients who suffer from amnesia due to brain damage or deterioration. Individuals who experience **dissociative amnesia** often have a history of trauma. Their amnesia is retrograde, encompassing autobiographical memories from a portion of their past. In an extreme version of this disorder, people enter a dissociative fugue state, in which they lose most or all of their autobiographical memories and their sense of personal identity. They may be found wandering in a new location, unaware of who they are and how they got there. Dissociative amnesia is controversial among research psychologists, as both the causes and existence of it have been called into question. The memory loss associated with dissociative amnesia is much less likely to be permanent than it is in organic amnesia.

Korsakoff's Amnesia

Another well-known form of amnesia is **Korsakoff's syndrome**, encountered for the first time in chronic alcoholics. Korsakoff's syndrome is similar to global amnesic syndrome, except that people with Korsakoff's are more prone to confabulation to cover up gaps in their memories of their own past. Korsakoff's syndrome is also known as **diencephalic amnesia** (or Wernicke-Korsakoff syndrome), because the vitamin B1 deficiency that results from alcoholism causes bilateral damage to the **mammillary bodies of the hypothalamus**. Similar symptoms are also produced by damage to the **dorsomedial thalamic nuclei, the mammillothalamic tract, and the upper portion of the brainstem**. Once again, other etiologies, such as strokes and tumors, can affect the same structures and produce the same results.

Alzheimer's Disease

In Alzheimer's disease, beta-amyloid, an insoluble toxic substance, forms clumps known as "senile plaques" around the neurons. These plaques release free radicals that strip atoms from organic molecules that are vital to the neurons, including molecules in their cell membranes. Holes thus develop in these membranes, allowing large amounts of harmful substances to enter and kill the neurons. The memory circuits that depend on them, especially those in the hippocampus, are thus permanently damaged.

The National Institute on Aging reports on research indicating that the brains of Alzheimer's patients also contain neurofibrillary tangles which consist of a protein called tau. This protein normally plays a role in healthy microtubules inside neurons that assist with the transport of vital substances within the neuron cell body to the axon and dendrites. In Alzheimer's they form clumps that disrupt the neuron's transport system interfering with synaptic transmission. Complex interactions between beta-amyloid and tangles and other factors may then result in Alzheimer's. "It appears that abnormal tau accumulates in specific brain regions involved in memory. Beta-amyloid clumps into plaques between neurons. As the level of beta-amyloid reaches a tipping point, there is a rapid spread of tau throughout the brain" (https://www.nia.nih.gov/health/what-...eimers-disease; retrieved 5/11/2022).

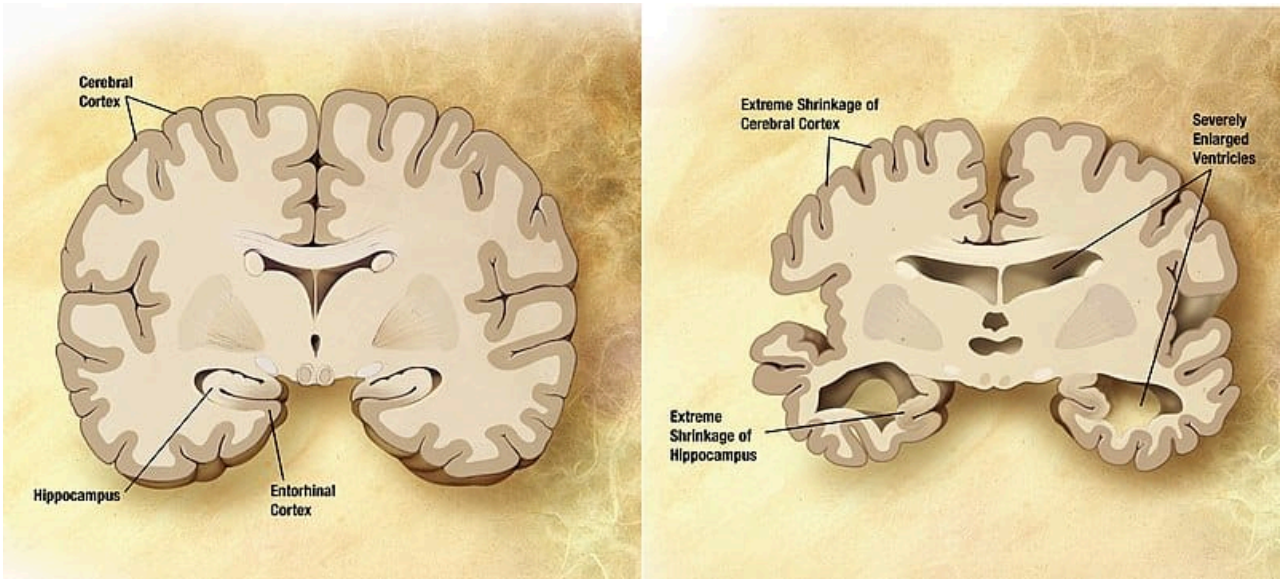

Figure 4.2.27.3: Diagram showing changes of the brain caused by Alzheimer's disease. Note extreme shrinkage of cerebral cortex and hippocampus, and extensive deterioration and loss of brain tissue resulting in extremely enlarged cerebral ventricles (Image and caption from Wikimedia Commons; File:Alzheimer's disease brain comparison.jpg; https://commons.wikimedia.org/wiki/F...comparison.jpg; by SEVERESLICE_HIGH.JPG: ADEAR: "Alzheimer's Disease Education and Referral Center, a service of the National Institute on Aging," modifications by Garrondo; this work is in the **public domain**. This applies worldwide).

According to the National Institute on Aging, "at first, Alzheimer's disease typically destroys neurons and their connections in parts of the brain involved in memory, including the entorhinal cortex and hippocampus. It later affects areas in the cerebral cortex responsible for language, reasoning, and social behavior. Eventually, many other areas of the brain are damaged. Over time, a person with Alzheimer's gradually loses his or her ability to live and function independently. Ultimately, the disease is fatal" (https://www.nia.nih.gov/health/what-...eimers-disease; retrieved 5/11/2022).

Specific Cortical Damage and Memory Loss

There is also an **amnesia of the frontal lobe** due to damage at this site. People with this disorder do not suffer from global amnesia, but do show a memory deficit in tasks involving temporal planning of sequences of events. These people also have problems with the sources of newly acquired knowledge and have deficient meta-memory (they cannot make judgments about their memory's contents).

Other types of damage to the cortex can cause forms of amnesia that are **sometimes highly specific**. For example, if the part of the cortex that perceives colors is damaged, people can lose their knowledge of color. And since the memory of colours is reconstructed at this same location, this memory disappears as well.

Other localized cortical lesions can prevent people from accessing certain items in their semantic memory and thus cause all sorts of specialized aphasias (language disorders).

Other Specific Forms of Memory Loss

A specific injury to the amygdala can prevent people from recording memories of traumatic events. In normal people, such memories are formed when particularly stressful conditions make certain details of a scene practically unforgettable.

Certain encephalopathies due to anoxias, ischemias, hypoglycemias, carbon monoxide poisoning, or prolonged epileptic attacks can cause the **loss of large numbers of neurons in both hippocampi.**

The pyramidal neurons of hippocampal area CA1, as well as the cortical neurons of layers 3, 5 and 6, the Purkinje cells, and the striate neurons are especially sensitive to lack of oxygen and energy.

Since these neurons are involved in various memory systems, malfunctions in their circuits inevitably lead to memory problems.

Thus, damage to the temporal lobes of the cortex can cause severe, permanent anterograde amnesia, as well as retrograde amnesia extending back from three to ten years before the accident.

When selective neuronal losses occur in area CA1 of the hippocampus, the resulting anterograde amnesia is just as severe, but the resulting retrograde amnesia generally remains slight (extending only one to two years before the accident).

Lastly, certain **transitory global amnesias** can be triggered suddenly, causing people to completely lose their memory for a few hours. Though these transitory amnesic episodes are frightening, they are brief and do not cause any permanent damage to the brain. They seem to be due to a temporary vascular insufficiency in the brain tissue.

Summary

Amnesiac patients show us what a life without memory would be like. Amnesiac patients suggest a special role for the hippocampus and surrounding medial temporal lobe structures in memory. Korsakoff's Syndrome is caused by vitamin B1 deficiency due to long term use of alcohol. Alzheimer's disease is associated with damage to neurons caused by plaques and tangles. Damage to specific cortical areas can cause very specific forms of memory loss including specific aphasias.

4.2.28: Localization of Types and Stages of Memory

Learning Objectives

1. Explain the role of the dorsolateral prefrontal cortex in memory, problem-solving and reasoning.
2. Discuss working memory and its various components including the central executive, the phonological loop, episodic buffer, and visuospatial sketch pad
3. Describe the region of brain associated with the operation of the central executive
4. Describe the brain structures involved in consolidation of new memories into long-term storage
5. Explain the different types of memory, three stages of memory, and the brain areas associated with each as discussed below
6. Describe the role of place cells in the formation of spatial maps in the hippocampus
7. Explain the trisynaptic circuit of the hippocampus and its role in memory

Overview

Here we examine memory from the standpoint of its different types focusing on the role of the hippocampus and other medial temporal lobe structures and circuits in the consolidation of new declarative memories. The hippocampal/mammillothalamic tract, also called Papez's circuit, plays an essential role in this process. After consolidation, long-term memories are stored in the cerebral cortex and become independent of the hippocampus. We also consider the role of the prefrontal cortex in working memory, important for the retention of information during problem-solving and reasoning. In addition, we discuss the role of the hippocampus in spatial memory and in the formation of cognitive maps or mental models of space.

Types and Stages of Memory Localized in Different Brain Regions

A large body of evidence indicates that the **dorsolateral prefrontal cortex** plays an important role in certain forms of memory work (Barbey, et al., 2013), in particular those that involve alternating between two memory tasks and exploring various possibilities before making a choice (Hunt et al., 2015). It seems fairly certain that dorsolateral prefrontal cortex holds information required for reasoning processes that are in progress.

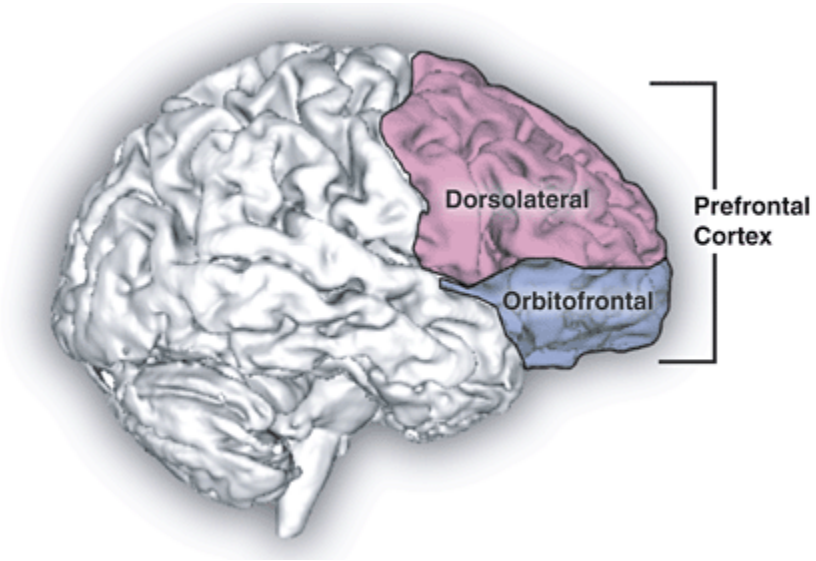

Figure 4.2.28.1: Divisions of Human Prefrontal Cortex (Image from Wikimedia Commons; File:Prefrontal cortex.png; https://commons.wikimedia.org/wiki/F...tal_cortex.png; by Natalie M. Zahr, Ph.D., and Edith V. Sullivan, Ph.D.; image is a work of the National Institutes of Health and is in the public domain).

Short-term Memory

Short-term memory depends on the attention paid to the elements of sensory memory. Short-term memory lets you retain a piece of information for less than a minute and retrieve it during this time. One typical example of its use is the task of repeating a list of items that has just been read to you, in their original order. In general, you can retain 5 to 9 items (or, as it is often put, 7±2 items) in short-term memory. It is clear that **short-term memory does not depend on** the **medial temporal cortex including the hippocampus and surrounding structures**. We know this because H.M. who had bilateral removal of his medial temporal lobe still retained his short-term explicit memory. If someone came into the room, he could remember the visit for a short time. Of course, as you have learned, if we checked his recollection a few minutes later, without ability to consolidate the memory into a long-term form, he would have no recollection of the visit that occurred just minutes before. This suggests that the **dorsolateral prefrontal cortex**, left intact in H.M., may be at least **one of the structures capable of retaining information for a brief period, particularly when engaged in reasoning and decision-making.** But its precise role remains the subject of much debate.

Working Memory

Working memory is a more recent extension of the concept of short-term memory. As techniques for studying memory have become more refined, it has become increasingly apparent that the original conception of short-term memory as a mere temporary receptacle for long-term memory is too simplistic. In fact, it is becoming increasingly clear that there is no strict line of demarcation between memories and thoughts. In order to test some hypotheses that may provide a better understanding of this complex phenomenon, the concept of working memory has therefore been advanced.

Working memory is used to perform cognitive processes on the items that are temporarily stored in it. It would therefore be heavily involved in processes that require reasoning, such as reading, or writing, or performing computations. One typical example of the use of working memory is the task of repeating a list of items that has just been read to you, but in the reverse of their original order. Another good example is the task of simultaneous language interpretation, where the interpreter must store information in one language while orally translating it into another. In the course of a day, there are many times when you need to keep some piece of information in your head for just a few seconds. Maybe it is a number that you are “carrying over” to do a subtraction, or a persuasive argument that you are going to make as soon as the other person finishes talking. These are good examples of why you usually hold information in your short-term/working memory: to accomplish something that you have planned to do. Perhaps the most extreme example of working memory is a chess master who can explore several possible solutions mentally before choosing the one that will lead to checkmate.

Working memory appears to be composed of several independent systems, which would imply that we are not aware of all the information that is stored in it at any given time. For example, when you drive a car, you are performing several complex tasks simultaneously. It is unlikely that all of the various types of information involved are being handled by a single short-term memory system.

Baddeley & Hitch (1974) proposed a model of **working memory** with **several components**: a certain number of auxiliary “slave” systems and a **central executive** that supervises and controls the flow of information to and from the "slave systems," which are short-term storage repositories for particular types or domains of information. One of these slave systems, the **phonological or articulatory loop**, specializes in processing linguistic information, while another, the **visuospatial sketchpad**, specializes in processing visual-spatial information. The **episodic buffer** is a third storage system, **dedicated to linking information across domains to form integrated units of visual, spatial, and verbal information** (e.g., the memory of a story, a movie scene, or an integrated autobiographical memory). The episodic buffer is also assumed to have **links to long-term memory**.

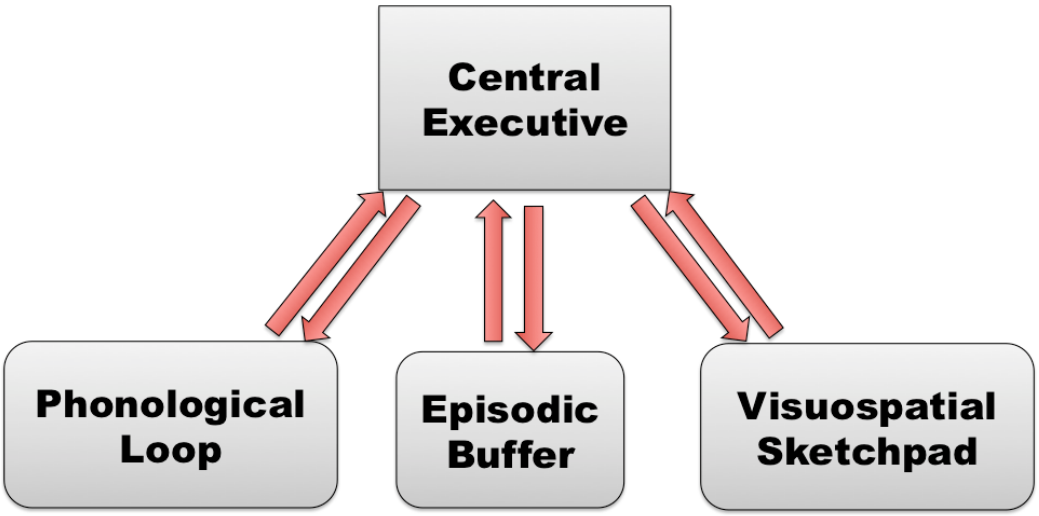

Figure 4.2.28.2: Baddeley's Model of Working Memory. (Image from Wikimedia Commons; Baddeley's Model of Working Memory; https://commons.wikimedia.org/wiki/F...ing_Memory.png; author, AmandaSilver15; permission is granted to copy, distribute and/or modify this document under the terms of the **GNU Free Documentation License**, Version 1.2 or any later version published by the Free Software Foundation).

The phonological or articulatory loop plays an important role in everyday life. For example, when you repeat a phone number to yourself in your head, you are activating this loop. This loop is also heavily involved in reading and writing. The presence **in working memory of another slave system that can manipulate mental images** of visual objects is suggested by tests where subjects are asked to rotate such images.

Perhaps the most important but least understood component in Baddeley's model of working memory is the **central processor or central executive**, whose job would be to select, initiate, and halt the routines performed by its slave systems.

Baddeley's model of **working memory** has proven especially fruitful for research on the brain areas involved in problem solving. This model posits a **central executive** or **central processor** that coordinates the activity of two sub-systems. Many brain-imaging studies show high activity in the frontal lobe, in particular the **prefrontal lobe,** when this central executive is working. For example, the image shown below (see Figure 10.5.3.2) was produced by **functional magnetic resonance imaging (fMRI)**. As you have learned in a previous chapter, fMRI is a technique based on the increased blood flow to the most active areas of the brain. In this image, taken while the subject was holding an image of a face in his memory, the yellow area in the **prefrontal cortex** is very active, confirming the role of these prefrontal cortical areas in working memory.

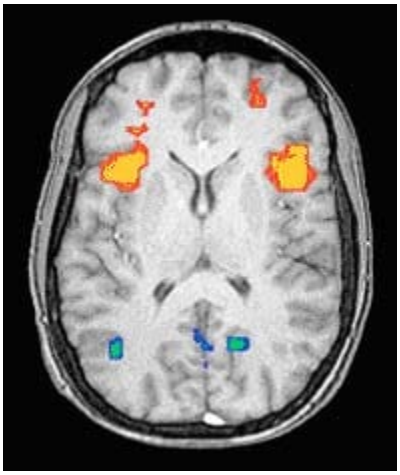

Figure 4.2.28.3: fMRI images of brain showing increased activity in the frontal lobes while the subject is keeping an image of a

face in his memory (Image from NIMH Laboratory of Brain and Cognition. Published in *Nature*, Vol 386, April 10, 1997, p. 610, Courtney et al., 1997).

As you have learned in an earlier chapter, this region, at the very front of the brain, is highly developed in humans. It appears that the **prefrontal cortex**, by holding information in storage during **working memory**, may play a significant role in functions related to **attention, problem-solving, and intelligence** (Conway et al., 2003; Engle et al., 1999; Kane & Engle, 2002; Matzel and Kolata, 2010; Barbey et al., 2014; Waltz et al., 1999).

Recall that Baddeley's model also postulates the existence of a **phonological** (acoustic and linguistic) memory and a **visual/spatial** memory (containing mental images). Brain imaging studies have also revealed distinct neuroanatomical bases for both of these forms of short-term working memory.

The **phonological loop** activates certain areas in the **left hemisphere** that are associated with the production of language, such as **Wernicke's area in the temporal lobe** and **Broca's area in the frontal lobe**. **Visual/spatial memory** seems to be associated with a region of the **occipital cortex** generally associated with visual processing. This is consistent with the hypothesis that visual imagination in which humans can manipulate visual images in the "mind's eye" to mentally test out and anticipate future consequences of action involves parts of the visual system "recruited" into this new function during evolution (Koenigshofer, 2017).

Meanwhile, certain sub-regions of the **prefrontal cortex** are activated only if the memorization exercise is somewhat difficult for the subject, thus confirming the coordinating role of the **central executive**.

The phenomenon of working memory is made all the more complex by the fact that it takes place over time. For example, the experimental results illustrated below show how various areas of the subjects' brains alter their activity levels as the subjects are presented with various visual stimuli. When the subjects are shown a blurred image, the activity level (represented by the blue bars in the graph) becomes highest in area 1, the visual part of the brain. When the subjects are shown an image of a face, brain activity (black bars) becomes highest in the **associative and frontal regions** (4, 5, and 6). Lastly, when the subjects are retaining an image of a **face** in their working memory, brain activity (red bars) is highest in the **frontal** regions, while the **visual areas are scarcely stimulated at all**.

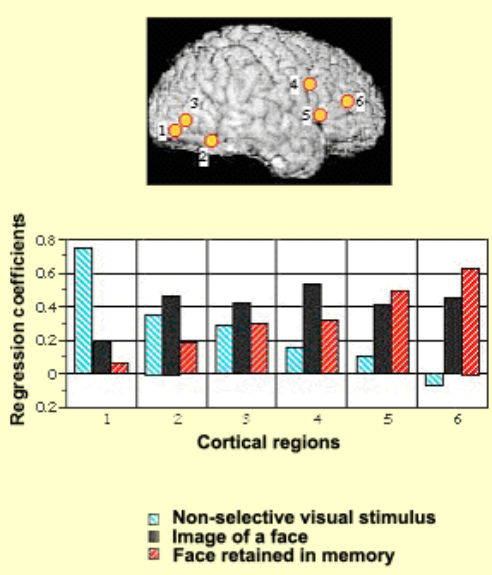

Figure 4.2.28.4: Activity in cortical areas (labeled 1-6 in image of cortical surface) primarily in occipital lobe with presentation of blurred image (blue bars, tallest in area 1), in frontal and association cortical areas with presentation of a photo of a face (black bars), and in frontal areas (areas 5 and 6), with little activity in visual areas (red bars in cortical areas 1 and 2), when subject retains memory of a face in working memory (red bars). (Image source: NIMH Laboratory of Brain and Cognition. Published in *Nature*, Vol. 386, April 1997, p. 610, Courtney et al., 1997).

It has also been observed that distinct processes appear to be involved in the storage and recall of items memorized with the phonological loop and the visual/spatial sketchpad. One thing is certain: the **prefrontal cortex** plays a fundamental role in **working memory**. It enables people to keep information available that they need for their current reasoning processes. For this

purpose, the prefrontal cortex must cooperate with other parts of the cortex from which it extracts information for brief periods. For this information to eventually pass into longer-term memory, the limbic system has to be brought into play.

Long-Term Memory

Recent research has provided a complex, highly intricate picture of memory functions and their loci in the brain. The **hippocampus, the temporal lobes, and the structures of the limbic system that are connected to them** are essential for the **consolidation of long-term declarative memory**. The **hippocampus receives** connections **from** the **cortex's primary sensory areas, unimodal associative areas** (those that involve only one sensory modality), and **multimodal associative areas**, as well as from the **rhinal and entorhinal cortexes.** While these anterograde connections converge at the hippocampus, other, retrograde **pathways emerge from it**, returning **to** the **primary cortexes**, **where** they record in the cortical synapses the **associations facilitated by the hippocampus**. Thus, in the mechanism of memorization, we find **feedback loops among these various brain structures.**

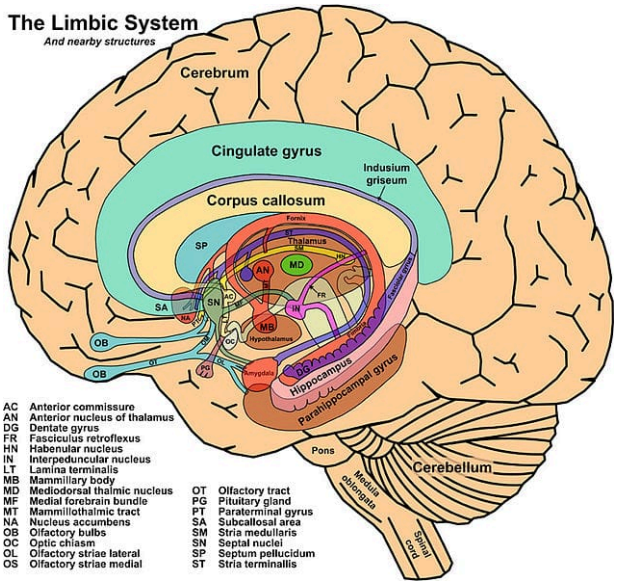

Figure 4.2.28.5: Limbic system and surrounding structures (Image from Wikimedia; Structures of the Limbic System; https://commons.wikimedia.org/wiki/F...ohn_Taylor.jpg; This work has been released into the **public domain** by its author, John Taylor).

Hippocampus

The **hippocampus facilitates associations among various parts of the cortex**, for example, between a tune that you heard at a dinner party represented in auditory cortex in the temporal lobe and the faces of the other guests who were at the table, represented in the visual areas and frontal areas of cortex. However, all other things being equal, such associations would naturally fade over time, so that your mind did not become cluttered with useless memories. What might cause such associations to be strengthened and eventually etched into long-term memory very often depends on "limbic" factors, such as how interested you were in the occasion, or what emotional charge it may have had for you, or how gratifying you found its content.

Recall from prior modules of this chapter that the **hippocampus, the cortical structures surrounding it, and the neural pathways that connect them to the cortex** as a whole are all heavily involved in **declarative memory**–the memory of facts and events. Declarative (explicit) memory is composed of **semantic memory** (memory for facts and knowledge) and **episodic memory** (memory for episodes in your life).

Semantic memory is the system that you use to store your knowledge of the world. It is a knowledge base that we all have and much of which we can access quickly and effortlessly. It includes our memory of the meanings of words–the kind of memory that lets us recall not only the names of the world's great capitals, but also social customs, the functions of things, and their color and odor and other sensory properties.

Semantic memory also includes our memory of the rules and concepts that let us construct a **mental representation of the**

world without any immediate perceptions. Its content is thus **abstract and relational** and is associated with the meaning of verbal symbols.

The **hippocampus** also plays a fundamental role in **episodic memory** (sometimes called **autobiographical memory**), the kind of memory that lets you remember events that you personally experienced at a specific time and place. For example, episodic memory lets you remember an especially pleasant dinner party years later. In fact, it seems to be the **hippocampus** that **enables** you to "**play the scene back**", by reactivating this particular activity pattern in the various regions of the cortex. This phenomenon would be very important during dreams, and would explain the incorporation of events from the last few days into them.

The various structures of the limbic system exert their influence on the hippocampus and the temporal lobe via **Papez's circuit**, also known as the **hippocampal/mammillothalamic tract**. This circuit is a sub-set of the numerous connections that the limbic structures have with one another. The route that information travels in this circuit is **from** the **hippocampus to** the **mammillary bodies of** the **hypothalamus,** then on to the **anterior thalamic nucleus,** the **cingulate cortex,** and the **entorhinal cortex,** before finally returning **to** the **hippocampus** (see Figure 10.5.5).

Once the temporary associations of cortical neurons generated by a particular event have made a certain **number of such "passes" through Papez's circuit**, they will have undergone a physical remodeling that **consolidates** them. Eventually, these associations will have been strengthened so much that they will stabilize and become **independent of the hippocampus**. As you have already learned, bilateral lesions of the hippocampus will prevent new long-term memories from forming, but will not erase those that were encoded and consolidated before the injury.

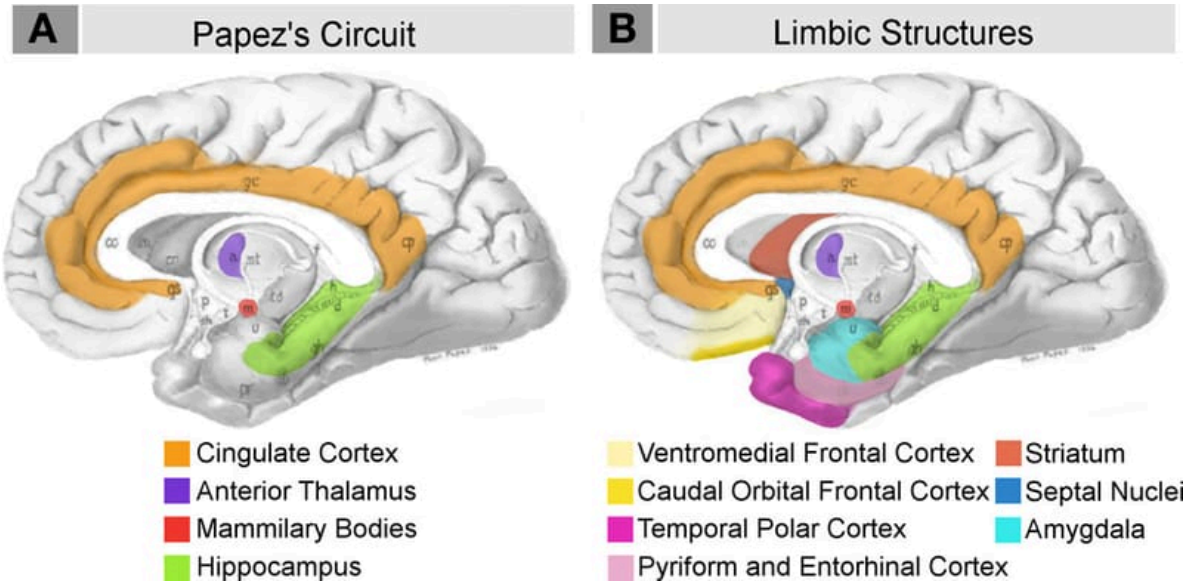

Figure 4.2.28.6: Papez Circuit and Limbic system structures some of which are involved in memory and emotion. (Images from Wikimedia Commons; File:Neural systems proposed to process emotion.png; https://commons.wikimedia.org/wiki/F...ss_emotion.png; by Barger N, Hanson KL, Teffer K, Schenker-Ahmed NM and Semendeferi K; licensed under the Creative Commons Attribution 3.0 Unported license. Caption by Kenneth A. Koenigshofer, PhD).

With this gradual disengagement of the **limbic system**, the **memories** will **no longer pass through Papez's circuit**, but **instead will be encoded in specific areas** of the **cortex:** the **same ones where the sensory information that created the memories was initially received** (the occipital cortex for visual memories, the temporal cortex for auditory memories, etc.).

Some very intense personal memories that bring what is sometimes called **emotional memory** into play appear to involve another structure of the limbic system besides the hippocampus. This structure is the **amygdala**, located beneath temporal lobe cortex near the hippocampus, and not surprisingly, as discussed in an earlier chapter, the amygdala is already known to manage our reactions to fear. Emotional memories can be very strong and particularly long-lasting. The **release of norepinephrine** during highly emotional events may contribute to the rapid and effective **consolidation** of memory for emotionally-charged events.

Injury to the Limbic System Pathways and Memory

As described above, for a piece of information to be recorded in long-term memory, it must pass through **Papez's circuit**. Injuries to this circuit can result in memory impairments. For example, a **lesion in the mammillary bodies** is responsible for an **amnesic syndrome** whose most classic example is **Korsakoff's** syndrome. In addition to the confabulation, confusion, and disorientation that accompany this syndrome, patients suffer from **anterograde amnesia**: they cannot store new information in their long-term memory. The most typical cause of this syndrome is **vitamin B1 deficiency**, often seen in chronic alcoholics.

Spatial Memory and a Role in Episodic Memory

The **hippocampus** appears to play a fundamental role in **spatial memory** in many animal species, including humans. For example, in a British study, the researchers asked taxi drivers to imagine their travels through the city of London, while their brain activity was monitored by positron emission tomography (PET scan). This task, which was so familiar to these subjects, caused a specific activation of their **right hippocampus**. Unlike our memory of facts and events, **spatial memory** appears to be confined to the hippocampus. And more specifically to the right hippocampus. This structure seems to be able to create a **mental map of space**, thanks to certain cells called **place cells**.

An amazing discovery in the 1970s demonstrated that a rat's **hippocampus** is a veritable **spatial map** of the environment through which it moves. Certain pyramidal neurons in **area CA1** of the **rat hippocampus** become active only when the rat is located in a specific part of its environment. There are 1 million of these "**place cells**" in area CA1 of the rat hippocampus, so that if each one is assigned a specific point in space, together they can form a very precise **cognitive map** that tells the animal where it is at any given time. Moreover, when a rat explores a new environment, it forms a new cognitive map that can be very stable, lasting weeks or months.

According to O'Keefe and Nadel (1978), the researchers who discovered the existence of these **cognitive maps**, one of their functions might be to provide a **context** to which **episodic memories** can be **attached**, in particular, their **location in space and time**. An event recorded in memory could **thus** be made **autobiographical** (situated in personal time and space). This would explain the fundamental **role** that the **hippocampus** plays in **episodic memory** in humans.

The **hippocampus** proper is **composed of** regions with tightly packed pyramidal neurons, mainly areas **CA1, CA2, and CA3.** ("CA" stands for Cornu Ammonis, or Horn of Ammon. The reference is to the ram's horns of the Egyptian god Ammon, whose shape these three areas together roughly resemble.) This is what is called the **trisynaptic circuit** or trisynaptic loop **of** the **hippocampus. Information enters this one-way loop via** the **axons of the entorhinal cortex** (part of the medial temporal cortex), known as **perforant fibers** (or the **perforant path,** because it penetrates through the subiculum and the space that separates it from the dentate gyrus, which is also in the temporal lobe, adjacent to the hippocampus; some anatomists consider it part of the hippocampus). These axons of the **perforant path** make the loop's **first connection**, **with** the **granule cells** of the **dentate gyrus**, the **first region where all sensory modalities merge together** to form representations and **memories that bind stimuli together** (Science Direct; https://www.sciencedirect.com/topics...0and%20memory.), a critical step in learning and memory.

From granule cells of the dentate, the **mossy fibres** in turn project to make the loop's **second connection**, **with** the dendrites of the **pyramidal cells** in area **CA3** of the hippocampus.

The **axons of these CA3 cells divide** into **two branches**. **One** branch forms the commissural **fibers** that project **to** the **contralateral hippocampus via** the **corpus callosum**. The **other branch** forms the Schaffer collateral pathways that make the **third connection** in the loop, **with** the cells in area **CA1** of hippocampus. It is in these synapses that the **spatial memory,** associated with the hippocampus, seems to be encoded.

This region also displays a **high propensity for long-term potentiation (LTP)**, though this same phenomenon is **also** observed **in many other parts of the hippocampus** as well as in the **cortex**.

Lastly, the **axons of** the **cells in CA1** project **to** the neurons of the **subiculum** and of the **entorhinal cortex**. The **receiving portion of** the **hippocampal formation** thus consists of the **dentate gyrus**, while the **sending portion** consists of the **subiculum**. The axons of the **large pyramidal neurons of** the **subiculum** then **project to** the **subcortical nuclei via** the **fimbria**, a thin tract of white matter at the inner edge of the hippocampus (see Figure 10.4.8). **Lastly**, the information **returns to** the **sensory cortical areas from which it came** before it was processed by the hippocampus.

Thus, **entorhinal cortex projects strongly to dentate gyrus and hippocampus** and then **from hippocampus back to cortex**

(Van Hoesen and Pandya, 1975b). Being **situated between cortex and the hippocampus, entorhinal cortex plays a critical role in memory** (Zola-Morgan et al., 1989). Even though the neurons of the hippocampus may seem like just a transit point in the establishment of long-term memory, they actually display a great deal of plasticity. This plasticity, as you have learned in previous sections, is manifested chiefly through **long-term potentiation (LTP)**, which was first discovered in the **hippocampus** but has subsequently been demonstrated in **many regions of** the **cortex**.

Summary

Memory can be understood in terms of types and stages. Different brain structures and circuits are involved in these different types and stages of memory. Dorsolateral prefrontal cortex appears to hold information required for reasoning and decision making processes. The prefrontal cortex is important for retention of information during working memory. Working memory has several components which interact and which have links to long-term memory. Consolidation of new declarative memories depends upon feedback loops between the cortex, the hippocampus, and other limbic structures in the medial temporal lobes. A group of these structures involved in memory, called Papez's circuit or the hippocampal/mammillothalamic tract, includes the hippocampus, cingulate cortex, mammillary bodies, and anterior thalamus. Damage to the mammillary bodies, commonly due to B1 vitamin deficiency associated with alcoholism, causes Korsakoff's amnesia. The hippocampus in rats forms spatial cognitive maps involving the use of hippocampal pyramidal neurons that function as place cells which code particular locations in the environment that the rat moves through.

4.2.29: Hormones, Learning, and Memory

Learning Objectives

1. Describe the structures involved in hormone release
2. Discuss the role of hormones in neuromodulation mediating the effects of motivation, reward, and emotion on learning and memory

Overview

Hormone release is under the control of the pituitary which in turn is under the control of parts of the hypothalamus at the base of the brain below the thalamus. Memory and learning can be influenced by hormones which may act as neuromodulators associated with motivation, rewards, and emotions. The effects of hormones are slower to act but produce more long-lasting effects widely distributed over large regions of the brain.

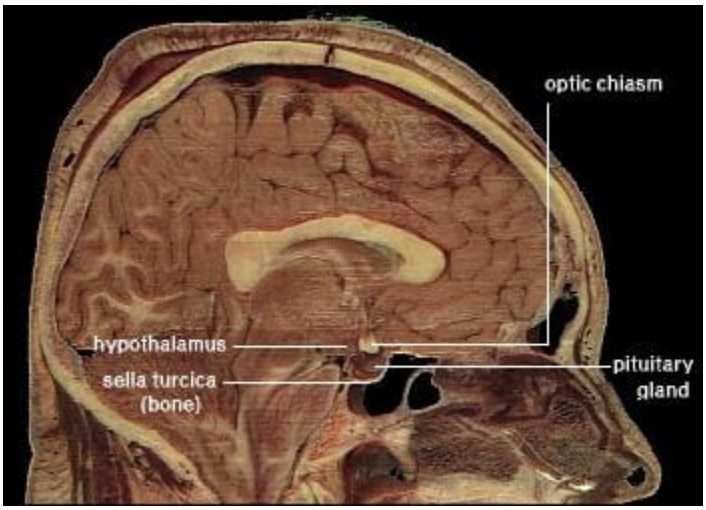

Figure 4.2.29.1: Cross-section of the human head showing hypothalamus and pituitary gland. The hypothalamus control the pituitary gland, the "master gland" of the endocrine system, which releases pituitary hormones into the bloodstream which control other endocrine glands throughout the body. (Image from Wikimedia Commons; File:LocationOfHypothalamus.jpg; https://commons.wikimedia.org/wiki/F...pothalamus.jpg; by NIH; *mage is a work of the **National Institutes of Health**, part of the **United States Department of Health and Human Services**, taken or made as part of an employee's official duties. As a work of the U.S. federal government, the image is in the **public domain***).

Hormonal Influences on Memory

It is important to be aware that memory does not depend solely on a few synapses in the hippocampus or elsewhere in the brain. For example, several studies indicate that the major neuromodulation systems in the brain (such as those which use dopamine or serotonin) also greatly influence synaptic plasticity.

These neuromodulators are part of the molecular mechanisms through which factors such as motivation, rewards, and emotions can influence learning. A major source of neuromodulation is hormones. The hormonal neurons are concentrated mainly in the brainstem and the central region of the brain including the hypothalamus which regulates the pituitary gland. The neurons of the brain secrete substances that regulate the functions of the glands in the rest of the body. The main pathway through which this regulation occurs passes through the pituitary gland, a small gland that is located at the base of the brain and whose hormones influence practically all of the other glands in the body. The pituitary gland is strongly influenced by the neuromodulators produced by the hypothalamus (which are therefore classified as neurohormones). These neurons form small masses of thousands of cells, but these cells project their axons into large areas of the forebrain and the midbrain.

Just one of these neurons can therefore influence over 100,000 others through the neuromodulators that it secretes into the brain's extracellular space (rather than into a synaptic gap). Each of these groups of neurons projects its axons into large areas of the central nervous system and thus modulates numerous behaviors, including sexual motivation and sexual behavior.

The effects of these neuromodulators take longer to become established and last longer than those of the neurotransmitters in the circuits of the brain. One reason for these differences is that many of these neuromodulator effects are mediated by "second messengers."

Neuroscientists are getting closer to tying psychological activities in humans and animals to specific molecular processes, even though we are still far from understanding all of the influences acting on the billions of connections in our brains--synaptic connections continuously undergoing modification moment to moment throughout our lives.

4.3.1: Introduction to Language

Learning Objectives

1. List some of the adaptive functions of animal communication; how do these compare to the adaptive functions of human language
2. Explain why memory is a component of language function
3. List brain structures involved in various types of memory
4. List the stages of speech production during the first 12 months after birth
5. Describe Alzheimer's Disease and the Autism Spectrum Disorders and brain changes associated with each

Overview

In this section, we examine communication in other species, the role of memory in language function, language acquisition, and two disorders, Alzheimer's Disease and Autism, both of which involve language dysfunction as well as other alterations of function.

Communication in Animals

by Kenneth A. Koenigshofer, Ph.D., Chaffey College

Humans are highly social animals, along with many other social species, including social mammals such as wolves, lions, elephants, baboons, chimpanzees, gorillas, water buffalo, dolphins, sea lions, and whales, and social insects such as bees, ants, and wasps. Living in groups has many adaptive advantages such as group hunting, predator defense, food gathering and other forms of cooperation, helping, and, in some mammals such as the mothers in a lion pride, even cooperative nursing of the young within their social group.

Contrast social species with species which are solitary, such as tigers which have no interactions with other tigers except during mating, and when females nurse and care for their offspring. Although both lions and tigers are big cat species, they are highly dissimilar in regard to social life. One reason for this vast difference between lions and tigers is that lions evolved into social creatures because they lived in the open plains of the savannah where group hunting was far more successful than solitary hunting. By contrast, tigers evolved in dense forest where plenty of cover favored quiet stalking and stealth, best accomplished by solitary hunting strategies.

It will come as no surprise to you that animals that live in groups communicate with one another, in part to coordinate their activities, to strengthen social bonds within the group, to warn of danger, to share the location of a food source, to express emotions, to attract mates, to reinforce dominance hierarchies, and so on.

Animal communication can involve any sensory modality. For example, lions of the same group who have been separated greet one another by rubbing their bodies together as they walk past one another. Humans use touch to express affection and sometimes sexual interest. Chimpanzees, like humans, hug and even kiss one another to express affection. Many species mark territory by using the smell of their urine (think of dogs, but male lions do the same, and some species of monkey have scent glands that release a smelly substance on the leaves of the trees they move through). Many animals use visual signals such as bright coloration in many species of birds and tropical fish; other species use visual gestures and facial expressions. For example, chimpanzees raise a hand high above their head and shake it vigorously to signal their displeasure and to threaten other chimps. Bees communicate the direction and distance to a food source by their waggle dance. Wolves and dogs, lions, tigers, primates, and many other species bare their teeth and lower their head as a visual signal communicating threat. Finally, many species utilize auditory means of communication such as screeches, howls, croaks, barks, songs (birds and whales), clicks (dolphins), screams, crying (visual and auditory cues) and laughing in humans, and many other sounds such as those made by crickets or other insects.

Figure 4.3.1.1: Here a chimpanzee uses visual and auditory signals to communicate threat. A coyote howls to call its pack. (Images from Wikimedia Commons; (left) File:Chimpanzee, Kibale, Uganda (15244558084).jpg; https://commons.wikimedia.org/wiki/F...244558084).jpg; by Rod Waddington; licensed under the Creative Commons Attribution-Share Alike 2.0 Generic license. (right) File:Howl (cropped).jpg; https://commons.wikimedia.org/wiki/F..._(cropped).jpg; by USFWS Mountain-Prairie; licensed under the Creative Commons Attribution 2.0 Generic license).

All of these various forms of communication use sensory signals received by others who interpret their meaning. However, none have the special properties of human language. Human languages use arbitrary symbols (words do not have innate meaning but acquire meaning by learning; there are approximately 600,000 words in English), and words can be strung into sentences by rules of grammar which permit an infinite number of different and complex meanings to be communicated, a situation which linguists sometimes refer to as "the infinite use of finite means," an infinite number of sentences can be constructed from a finite number of words using a finite number of grammatical rules. Although some animals such as chimpanzees, bonobo chimpanzees, and gorillas have been taught American Sign Language with interesting results, the full bloom of human language appears to require specialized brain circuitry present only in specific, although somewhat widespread, areas of the human brain.

Memory and Language

"You need memory to keep track of the flow of conversation" (Goldstein, 2005).

The interaction between memory and language does not seem very obvious at first, but this interaction is necessary when trying to have a conversation. Memory is also required to know and recall the meanings of words.

This is not a simple process which can be learned within days. In childhood everybody learns to communicate, but it is a process lasting for years.
The connection between memory and language becomes most obvious when an impairment occurs when certain brain areas are damaged.

Basics of Memory and Language Interactions

Memory

Explicit memory, also known as declarative, can be subdivided into semantic and episodic memory. Procedural memory and priming effects are components of the implicit memory.

Table 14.9.1. Brain regions important in memory and language and their interaction.

Brain regions	Memory
Frontal lobe, parietal lobe, dorsolateral prefrontal cortex	Short-term Memory/ Working Memory
Hippocampus	Short-term Memory → Long-term Memory
Medial temporal lobe (neocortex)	Declarative Memory
Amygdala, Cerebellum	Procedural Memory

Language

Language is an essential system for communication which highly influences our life. This system uses sounds, symbols and gestures for the purpose of communication. Visual and auditory systems are the entrance-pathway for language to the brain. The motor system is responsible for speech and writing production, the exit-pathway for language. In this sense, language processing in the brain (like other types of cognition) occurs between processing by the sensory and motor systems. Most of the knowledge about brain mechanism for language comes from studies of language deficits resulting from brain damage. Though there are about 10,000 different languages and dialects in the world, all of them express the subtleties of human experience and emotion.

Acquisition of language

A phenomenon which occurs daily and in everybody's life is the acquisition of language. Theorists like Catherine Snow and Michael Tomasello think that acquisition of language begins at birth. Babbling in the first six months of life activates brain regions later involved in speech production.

The ability to understand the meaning of words begins before the first birthday, and progresses faster than the ability to speak. Babies show comprehension of more complex sentences, even though they may still be in the one-word stage of speech development.

The different stages of speech production in the first year of life are listed in the table below.

Age	Stage of Acquisition	Example
6th month	Stage of babbling: - systematic combining of vowels and consonants	
7th – 10th month	Stage of repetitive syllable-babbling: - higher part of consonants → paired with a vowel – monosyllabic reduplicated babbling	da, ma, ga mama, dada, gaga
11th – 12th month	Stage of variegated babbling: - combination of different consonants and vowels	bada, dadu
12th month	Usage of first words - : - prephonological → consonant-vowel (-consonant)	car, hat

Researchers like Charlotte Bühler (1928), a German psychologist, think that speaking the first word occurs around the tenth month, whereas Elizabeth Bates et al. (1992) proposed a period between eleven and 13 months. The one-word stage described above can last from two to ten months. Until the second year of life a vocabulary of about 50 words develops, four times more than the child

actually uses in speech. Two thirds of the language processed is still babbling. After this stage of learning, vocabulary increases rapidly. The so-called vocabulary spurt causes an increment of about one word every two hours. From that point on children learn to have fluent conversations with a simple grammar usually containing some errors. Over the first three years of life, the length of sentences and the grammatical output improves.

Children first learn to conjugate verbs and to decline nouns using regular rules. To produce irregular forms is more difficult, because they have to be learned and stored in Long-term memory one by one. The observation of speech is important for acquisition of grammatical skills. Around the third birthday the complexity of language increases exponentially.

Disorders

Alzheimer's Disease

Discovered in 1906 by Alois Alzheimer, this disease is the most common type of dementia. Alzheimer's is characterized by symptoms such as loss of memory, loss of language skills and impairments in skilled movements. Additionally, other cognitive functions such as planning or decision-making which are connected to the frontal and temporal lobe can be also be impaired. The correlation between memory and language in this context is very important because the two work together in order to establish and maintain conversations. When both are impaired, communication becomes a difficult task. People with Alzheimer's have reduced working memory capability, so they cannot keep in mind all of the information they have heard during a conversation. They also forget words which they need to denote items, express their desires, and to understand what they are told. Affected persons also change their behavior; they become anxious, suspicious or restless and they may have delusions or hallucinations.

In the early stages of the disorder, affected persons become less energetic and may suffer little loss of memory. They are still able to dress themselves, to eat and to communicate enough to get by. Middle stages of the disease are characterized by problems of navigation and orientation. Affected persons may not be able to find their way home or they may even forget where they live. In the late stages of the disease, the patients' ability to speak, read and write is severely impaired. They are no longer able to denote objects and to talk about their feelings and desires. So their family and the nursing staff have great difficulty finding out what the patients want to tell them. In the end-state, persons with Alzheimer's disease do not show any response or reaction. They lie in bed, have to be fed and are totally helpless. Most of them die after four to six years following diagnosis, although the disease can last from three to twenty years. It is sometimes difficult to distinguish Alzheimer's from other related disorders. Only after death when observing the shrinkage of the brain can one definitely diagnose Alzheimer's disease.

In the Alzheimer brain:
· The cortex shrivels up, damaging areas involved in thinking, planning and remembering.
· Shrinkage is especially severe in the hippocampus, which, as discussed in earlier modules, plays a key role in formation of new memories.
· Ventricles (fluid-filled spaces within the brain) grow larger as the surrounding brain tissue dies away.

Long before the first symptoms appear, nerve cells that store and retrieve information have already begun to degenerate. There are two theories about the causes of Alzheimer's disease. The first describes plaques, protein fragments, which impair the synaptic connections between nerve cells. They arise when little fragments released from nerve cell walls associate with other fragments from outside the cell. These combined fragments, the plaques, attach to the outside of nerve cells and destroy the synaptic connections. Then the nerve cells start to die. The second theory explains that tangles limit the functions of nerve cells. They are twisted fibers of another protein that form inside brain cells and destroy a vital cell transport system made of proteins. But scientists have not yet found out the exact role of plaques and tangles.

- Alzheimer tissue has many fewer nerve cells and synapses than a healthy brain.
- Plaques, abnormal clusters of protein fragments, build up between nerve cells.
- Dead and dying nerve cells contain tangles, which are made up of twisted fibers of another protein.

Alzheimer's progress is separated into three stages: In the early stages (1), tangles and plaques begin to evolve in brain areas where learning, memory, thinking and planning takes place. This may begin 20 years before diagnosis. In the middle stages (2), plaques and tangles start to spread to areas for speaking and understanding speech. The sense of where your body is in relation to objects around you is impaired. This may last from 2–10 years. In advanced Alzheimer's disease (3), most of the cortex is damaged, so that the brain starts to shrink seriously and cells begin to die. The people affected lose their ability to speak and communicate and they do not recognize their family or people they know. This stage may generally last from one to five years.

Today, more than 18 million people suffer from Alzheimer's disease. Alzheimer's is often only related to older people. Five percent of the people older than 65 years and fifteen to twenty percent of the people older than 80 years suffer from Alzheimer's. But people in their late thirties and forties can also be affected by this heritable disease. Though heritable, the probability of getting Alzheimer's when one's parents suffer from the typical older-generation-Alzheimer's is not very high.

Autism

Autism is a condition of neurodevelopment, which causes neurodevelopmental disorders in several ways. For more than a decade, autism has been studied in the context of Autistic Spectrum Disorders, including mild and severe autism, as well as Asperger's syndrome. Individuals with autism, for example, have restricted perception and problems in information processing. The often associated intellectual giftedness (savants) only holds for a minority of people with autism; most possess normal or below average intelligence.

There are different types of autism:

- Asperger's syndrome – usually arising by the age of three years
- infantile autism – arising between nine and eleven months after birth

Two different types of infantile autism are low functioning autism (LFA) and high functioning autism (HFA). LFA describes children with an IQ lower than 80, while HFA refers to those with an IQ higher than 80. The disorders in both types are similar, but they are more severe in children with LFA.

The disorders are mainly defined by the following symptoms:

1. the inability for normal social interaction, e.g. normal relations with other children, perhaps related to impairments in Theory of Mind (TOM), the ability to "read/understand the minds" and intentions of others
2. the inability for ordinary communication, e.g. disorder of spoken language/idiosyncratic language
3. stereotypical behavior, e.g. stereotypical and restricted interests with an atypical content

To investigate the inability of children with autistic disorder to manage normal communication and language, the University of Pittsburgh performed experiments to provide possible explanations for some of their symptoms. Sentences, stories or numbers were presented to children with autism and to normal children. The researchers concluded that the disorders in people with HFA and LFA are caused by an impairment in declarative memory. This impairment leads to difficulties in learning and remembering sentences, stories or personal events, whereas the ability to learn numbers is still available. It has been shown that these children are not able to link words they have heard to their general knowledge, thus the words are only partially learned, often with an idiosyncratic meaning. This may in part explain why LFA and HFA affected children differ in their way of thinking from normal children. It is often difficult for them to understand others and vice versa (perhaps due to deficits in TOM or one or more social processing modules in the brain). Furthermore scientists believe that the process of language learning depends on an initial vocabulary of fully meaningful words. It is assumed that these children do not possess such a vocabulary, thus their language development is impaired. In a few cases the acquisition of language fails completely, therefore in some cases the children are not able to use language in general. The inability to learn and use language may be a consequence of an impairment of declarative memory. This might also cause a low IQ because much of the process of human learning is language-mediated. In HFA the IQ is not significantly lower than the IQ of normal children. This milder form of autism correlates well with their better understanding of word meanings.

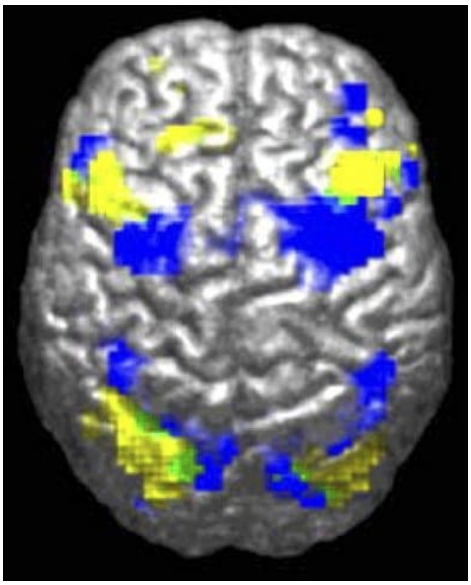

Figure 4.3.1.2: fMRI-derived image of difference between brains of autistic and control groups. Activation during visuomotor coordination: Autism Group [yellow], Control Group [Blue], Overlap (both groups) [green]. Even researchers who study autism can display a negative bias against people with the condition. For instance, researchers performing functional magnetic resonance imaging (fMRI) scans systematically report changes in the activation of some brain regions as deficits in the autistic group — rather than evidence simply of their alternative, yet sometimes successful, brain organization. (Image and caption from Wikimedia Commons; File:Powell2004Fig1A.jpeg; https://commons.wikimedia.org/wiki/F...2004Fig1A.jpeg; by Ralph-Axel Müller, Modifications made by Eubulides; licensed under the Creative Commons Attribution 2.5 Generic license. Laurent Mottron, *Changing perceptions: The power of autism* ; Nature 479, 33–35 (03 November 2011) ; doi:10.1038/479033a En ligne : 2011-11-02).

The causes of autism are not yet known. It is still not clear whether the Spectrum Disorders are caused by genetic abnormalities, or non-genetic neurological factors such as brain damage or biochemical abnormalities. One possibility is that during brain development prior to birth new neuron migration and/or neural pruning may be impaired leading to atypical brain circuit formation (Koenigshofer, 2011, 2016).

Summary

Although forms of communication exist even in species which are primarily solitary, social species communicate more frequently with other members of their species. Animal communication can utilize signals from any of the sensory modalities. Vocal communication is common in many species, however only our species has developed a form of communication with the complexity of human language. Language use requires memory. Different areas of the brain are involved in different types of memory (as was covered previously in Chapter 10). Normal children begin to comprehend language before the end of their first year. Language expression begins with several stages of babbling typically followed by the production of first words by a year old. Both Alzheimer's and Autism are disorders of the brain that involve language difficulties. fMRI studies reveal that persons with autism have brain organization different from that in persons without autism.

4.3.2: Broca's Area, Wernicke's Area, and Additional Language-Processing Areas in the Brain

Learning Objectives

1. Describe the classic Wernicke-Lichtheim-Geschwind model of the neurobiology of language.
2. Identify the temporal planum and specific gyri involved in language processing and list the role of each
3. Explain the idea of a universal grammar and what it implies about human language acquisition and a "language acquisition device" (LAD)
4. On what neuroanatomical basis are the Brodmann areas defined?
5. Describe the functions of the three sub-areas within Wernicke's area
6. Which gyrus gives evidence of involvement of the right hemisphere in language processing and what is that evidence?
7. Briefly describe what is meant by a distributed model of cognitive function; provide examples from neurobiological models of intelligence (from previous modules) and of language function

The Classical Wernicke-Lichtheim-Geschwind model of the neurobiology of language

The brain areas included in the best known model of how language is processed by the brain are **Broca's area** in the frontal lobe, **Wernicke's area** in the temporal lobe, and the **arcuate fasciculus** which connects the two. In this model, Broca's area is associated with language expression and Wernicke's area with language comprehension. Damage to any of these produces various forms of **aphasia** (language disorder) with different symptoms. Damage to Broca's area produces **Broca's aphasia** characterized by difficulties with language expression. **Wernicke's aphasia** involves difficulty with speech and language comprehension. Damage to the arcuate fasciculus produces **conduction aphasia** characterized by impaired ability to repeat simple phrases while expression and comprehension remain otherwise unimpaired.

Table 10.14.1: Features of two forms of aphasia (based on National Aphasia Association; https://www.aphasia.org/aphasia-reso...QaAhX6EALw_wcB).

Broca's (Expressive) aphasia	Speech output is severely reduced and is limited mainly to short utterances of less than four words. Finding the right words is often extremely difficult and clumsy. Comprehension can be relatively preserved. Difficulty producing grammatical sentences. May be able to read but limited in writing. Difficulty understanding complex grammatical sentences. Cognitive capabilities not related to speech and language may be fully preserved.
Wernicke's (Receptive) aphasia Additional forms of aphasia are global, mixed transcortical, transcortical motor, transcortical sensory, and anomic aphasia.	Damage in brain areas important for processing meaning of words and spoken language. Profound language comprehension deficits, even for single words or simple sentences. Reading and writing are often severely impaired. Often speak using grammatically correct sentences with normal rate and prosody but sentences make little sense and may include non-existent or incorrect and irrelevant words. Show little awareness of the lack of meaning of their speech. Cognitive capabilities not related to speech and language may be fully preserved.

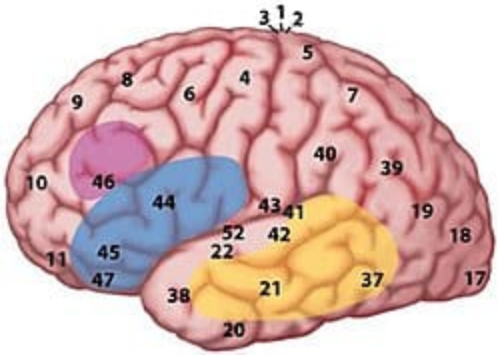

Figure 4.3.2.1: Lateral view of the human left cerebral cortex. The numbers indicate Brodmann areas. Brodmann areas are cortical regions differentiated by cytoarchitectonics (i.e., composition of cell types).

Broca's area is generally defined as comprising Brodmann areas 44 and 45, which lie anterior to the premotor cortex in the inferior posterior portion of the frontal lobe. Though both area 44 and area 45 contribute to verbal fluency, each seems to have a separate function, so that Broca's area can be divided into two functional units.

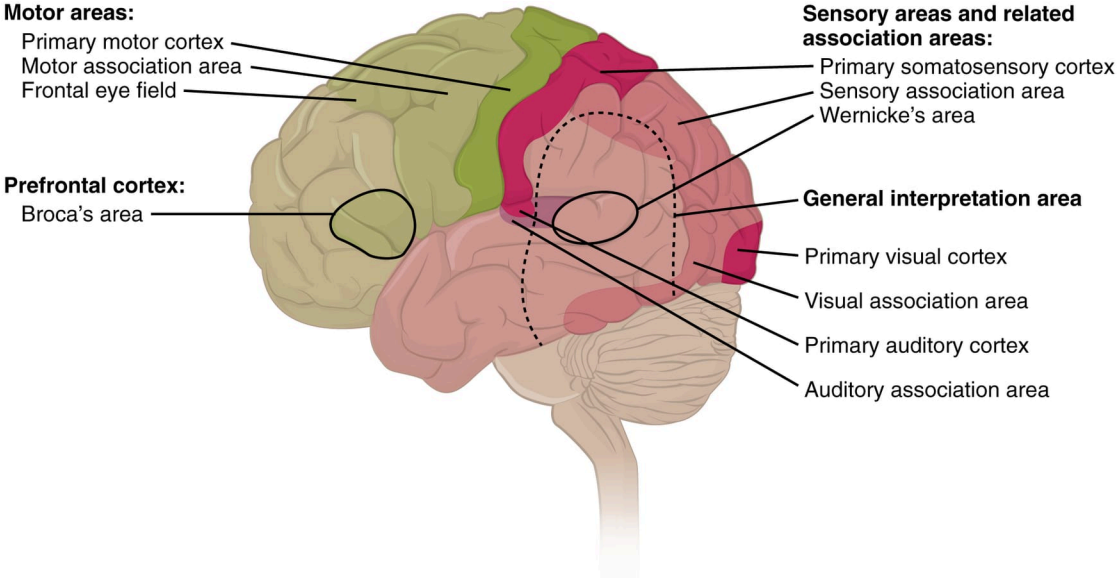

Figure 4.3.2.2: Locations of Broca's and Wernicke's areas and surrounding cortical regions. (Image from Wikimedia Commons; retrieved 10/18/21).

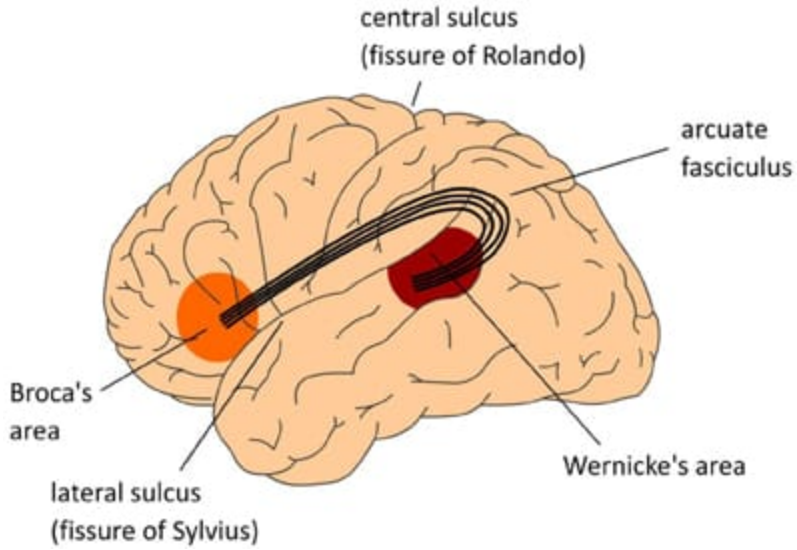

Figure 4.3.2.3: The classical **Wernicke-Lichtheim-Geschwind model of the neurobiology of language**. In this model Broca's area is crucial for language production, Wernicke's area subserves language comprehension, and the necessary information exchange between these areas (such as in reading aloud) is done via the arcuate fasciculus, a major fiber bundle connecting the language areas in temporal cortex (Wernicke's area) and frontal cortex (Broca's area). The language areas are bordering one of the major fissures in the brain, the so-called Sylvian fissure. Collectively, this part of the brain is often referred to as perisylvian cortex. (Image and caption from Wikimedia Commons; retrieved 10/18/21).

Area 44 (the **posterior** part of the **inferior frontal gyrus**) seems to be involved in phonological processing and in language production as such; this role would be facilitated by its position close to the motor centres for the mouth and the tongue. Area 45 (the **anterior** part of the **inferior frontal gyrus**) seems more involved in the semantic aspects of language. Though not directly involved in accessing meaning, Broca's area therefore plays a role in verbal memory (selecting and manipulating semantic elements).

Wernicke's area lies in the **left temporal lobe** and, **like Broca's area**, is **no longer regarded as a single, uniform anatomical/functional region** of the brain. By analyzing data from numerous brain-imaging experiments, researchers have now distinguished **three sub-areas within Wernicke's area**. The first responds to spoken words (including the individual's own) and other sounds. The second responds only to words spoken by someone else but is also activated when the individual recalls a list of words. The third sub-area seems more closely associated with producing speech than with perceiving it. All of these findings are still compatible, however, with the **general role of Wernicke's area**, which relates to the representation of phonetic sequences, regardless of whether the individual hears them, generates them himself or herself, or recalls them from memory.

Wernicke's area, of which the **temporal planum** is a key anatomical component, is located on the **superior temporal gyrus**, in the superior portion of Brodmann area 22. This is a strategic location, given the language functions that Wernicke's area performs. The temporal planum lies **between** the **primary auditory cortex** (Brodmann areas 41 and 42) **and the inferior parietal lobule**.

This lobule is composed mainly of **two distinct regions:** caudally, the **angular gyrus** (area 39), which itself is bounded by the visual occipital areas (areas 17, 18, and 19), and dorsally, the **supramarginal gyrus** (area 40) which arches over the end of the lateral sulcus, adjacent to the inferior portion of the somatosensory cortex.

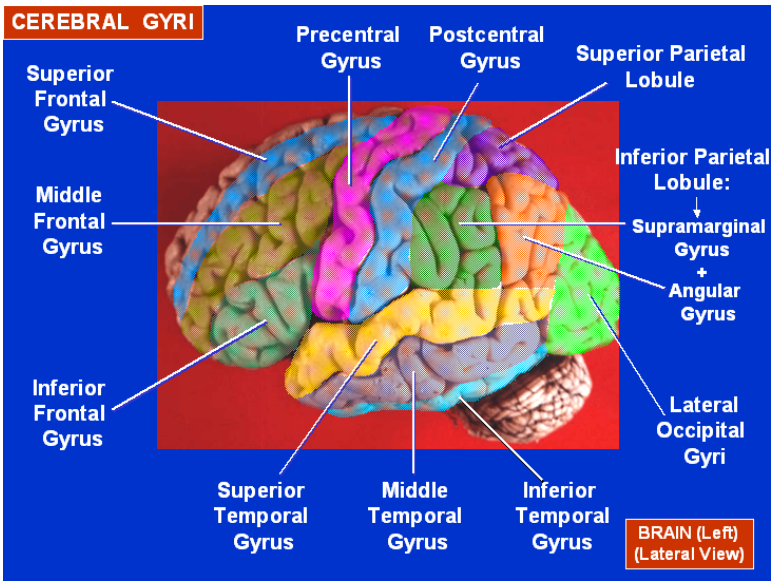

Figure 4.3.2.4: . Gyri ("hills") on the cerebral cortex, several of which are involved in language processing. (Image from Wikimedia Commons; File:Cerebral Gyri - Lateral Surface.png; https://commons.wikimedia.org/wiki/F...al_Surface.png; by John A Beal, PhD. Dep't. of Cellular Biology & Anatomy, Louisiana State University Health Sciences Center Shreveport; licensed under the Creative Commons Attribution 2.5 Generic license).

The supramarginal gyrus seems to be involved in phonological and articulatory processing of words, whereas the angular gyrus (together with the **posterior cingulate gyrus**) seems more involved in semantic processing. The **right angular gyrus** appears to be **active as well as the left**, thus revealing that the right hemisphere also contributes to semantic processing of language.

Together, the **angular and supramarginal gyri** constitute a **multimodal associative area** that receives auditory, visual, and somatosensory inputs. The neurons in this area are thus very well positioned to process the phonological and semantic aspect of language that enables us to identify and categorize objects.

The **language areas of the brain are distinct from the circuits responsible for auditory perception of the words we hear or visual perception of the words we read.** The auditory cortex lets us recognize sounds, an essential prerequisite for understanding language. The visual cortex, which lets us consciously see the outside world, is also crucial for language, because it enables us to read words and to recognize objects as the first step in identifying them by a name.

There are wide variations in the size and position of Broca's area and Wernicke's area as described by various authors.

Brain areas such as these, which perform high-level integration functions, are more heterogeneous than areas that perform primary functions. This greater heterogeneity might reflect greater sensitivity to environmental influences and greater plasticity (Links to an external site.) (ability to adapt to the environmental influences). The functional organization of language would even appear to vary within the same individual at various stages of his or her life!

Any attempt to define the precise boundaries of a particular area of the brain, such as Broca's area or Wernicke's area, will involve some serious problems. But we do know that the **cytoarchitectonic areas described by Brodmann provide better anatomical correlates for brain functions than do the shape of the brain's convolutions**. That said, a cortical area such as Broca's cannot be precisely described by reference to Brodmann areas alone. Though many authors regard **Broca's area** as consisting of **Brodmann areas 44 and 45**, other authors say it consists only of area 44, still others only of area 45, and yet others of areas 44, 45, and 47.

Broca's area may also include the most ventral portion of Brodmann area 6, as well as other parts of the cortex lying deep within the lateral sulcus (sulcus is a "valley" between gyri). It is even possible that only certain parts of these areas are actually dedicated to language.

Brain-imaging studies have shown to what a large extent **cognitive tasks** such as those involving language **correspond to a complex pattern of activation of various areas distributed throughout the cortex.** That a particular area of the brain becomes activated when the brain is performing certain tasks therefore does not imply that this area constitutes the only clearly

defined location for a given function. In the more **distributed model of cognitive functions** that is now increasingly accepted by cognitive scientists, all it means is that the neurons in this particular area of the brain are more involved in this particular task than their neighbors. It in no way excludes the possibility that other neurons located elsewhere, and sometimes even quite far from this area, may be just as involved.

Thus, just because the content of a word is encoded in a particular neuronal assembly does not necessarily mean that all of the neurons in this assembly are located at the same place in the brain. On the contrary, **understanding or producing a spoken or written word can require** the simultaneous contribution of several modalities (auditory, visual, somatosensory, and motor). Hence the **interconnected neurons** in the assembly responsible for this task may be **distributed across the various cortexes dedicated to these modalities.**

In contrast, the neuronal assemblies involved in encoding grammatical functions appear to be less widely distributed.

It may therefore be that the **brain processes language functions in two ways simultaneously**: in **parallel** mode by means of **distributed networks**, and in **serial** mode by means of **localized** convergence zones in the brain.

Language Acquisition

Language acquisition in humans is based on our **capacities for abstraction and for applying rules of syntax**—capacities that other animals lack. For example, brain-imaging experiments have shown that Broca's area becomes active when subjects are learning actual rules of grammar in another language, but not when they are exposed to fictitious rules that actually violate the grammar of that language.

These findings suggest that in Broca's area, biological constraints interact with experience to make the acquisition of languages possible. **Broca's area** may thus represent the neuronal substrate of the **"universal grammar"** shared by all of the world's languages. The idea of the universal grammar is that in spite of the great variation in human languages, there still exists basic universal commonalities shared by all human languages and that these basic similarities in grammar reflect **genetically determined** features of the brain areas that acquire language. The linguist, Noam Chomsky, proposed that the **universal grammar** shared by all languages originates from innate brain organization that biologically prepares humans to learn language naturally and easily despite its great complexity. This idea is expressed in Chomsky's proposal of a **Language Acquisition Device (LAD)**--innate, genetically organized brain circuitry found in every normal human specialized for the easy acquisition of a human language that one is exposed to during childhood. Though popular among many psychologists and linguists for some time, more recently others have proposed that language acquisition does not require an LAD and that general learning mechanisms may be sufficient to account for language acquisition (Behme & Deacon, 2008).

Summary

In the classical **Wernicke-Lichtheim-Geschwind model of the neurobiology of language,** Broca's area is crucial for language production, Wernicke's area subserves language comprehension, and the information exchange between these areas (such as in reading aloud) is done via the arcuate fasciculus. Damage to any of these produces various forms of **aphasia**. Distributed models of cognitive function suggest that language function involves many areas of the brain not included in the classic neurobiological model of language function.

4.3.3: Other Brain Models of Spoken and Written Language

Learning Objectives

1. Contrast Mesulam's model with the Wernicke-Lichtheim-Geschwind model of the brain's processing of language
2. Describe and explain the distributed model of language processing by the brain
3. Explain why in a split brain patient objects presented in the right visual field are processed by the left side of the brain and can be verbally identified and why objects presented in the left visual field cannot be verbally identified
4. Describe the major evidence for and the basic facts of brain lateralization
5. Outline the auditory and visual processing of language
6. Describe the features and anatomical structures involved in three types of aphasia
7. Describe the types of alexia and agraphia and their causes
8. Briefly explain what the processing of sign language, music, and other symbolic systems reveals about language processing

Overview

In this module we consider other models of language representation and function in the brain. The first follows the traditional locationist model which posits specific circuits involved in language processing. The second hypothesizes a non-locationist view which emphasizes distributed networks engaged in parallel processing of language.

An Alternative to the Wernicke-Lichtheim-Geschwind Model

In the 1980s, American neurologist Marsel Mesulam proposed an alternative to the Wernicke-Lichtheim-Geschwind model for understanding the brain's language circuits. Mesulam's model posits a hierarchy of networks in which information is processed by levels of complexity.

For example, when you perform simple language processes such as reciting the months of the year in order, the motor and premotor areas for language are activated directly. But when you make a statement that requires a more extensive semantic and phonological analysis, other areas come into play first.

When you hear words spoken, they are perceived by the **primary auditory cortex**, then processed by unimodal associative areas of the cortex: the **superior and anterior temporal lobes** and the **opercular part of the left inferior frontal gyrus.**

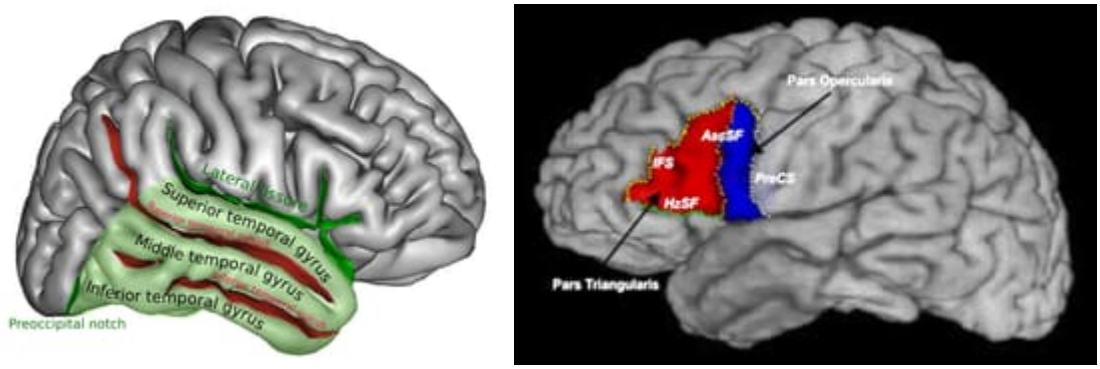

Figure 4.3.3.1: (Left) Right **temporal lobe**. (Right) Broca's area (left hemisphere) of the **inferior frontal gyrus** divided into the pars triangularis (PTri, red) and pars opercularis (POp, blue). **PreCS**: Precentral sulcus. **IFS**: Inferior frontal sulcus. **AscSF** Ascending ramus of Sylvian fissure. **HzSF** Horizontal ramus of Sylvian fissure (Images and caption for image on the right from Wikimedia Commons, retrieved 10/18/21).

According to Mesulam's model, these unimodal areas then send their information on to two separate sites for integration. One of

these is the temporal pole of the **paralimbic system**, which provides access to the long-term memory system and the emotional system. The other is the posterior terminal portion of the **superior temporal sulcus**, which provides access to meaning. The triangular and orbital portions of the **inferior frontal gyrus** also play a role in semantic processing. One important idea in Mesulam's model is that the function of a brain area dedicated to language is not fixed but rather varies according to the "neural context". In other words, the function of a particular area depends on the task to be performed, because these areas do not always activate the same connections between them. For instance, the left inferior frontal gyrus interacts with different areas depending on whether it is processing the sound of a word or its meaning.

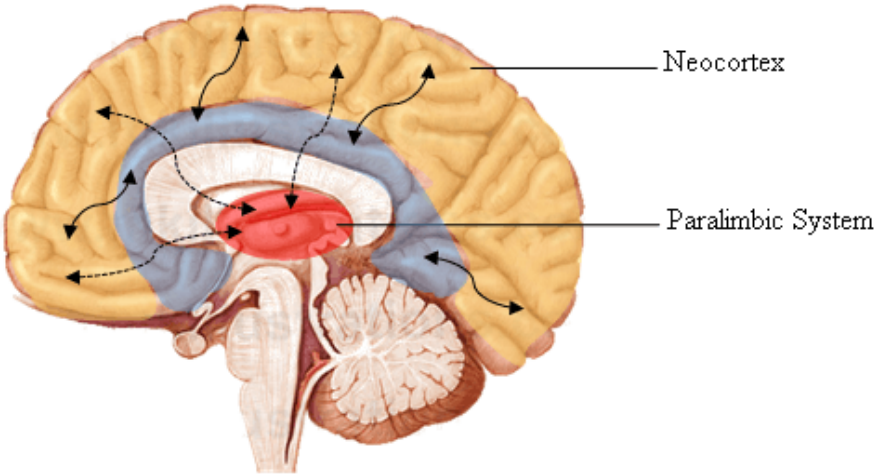

Figure 4.3.3.2: Paralimbic system, area of three-layered cortex that consists of the pyriform cortex, entorhinal cortex, and parahippocampal cortex on the medial surface of the temporal lobe, and the cingulate cortex just above the corpus callosum. The paralimbic cortex lies close to the limbic structures, and is directly connected with them. (Image, Wikimedia. Caption from Kolb & Whishaw: *Fundamentals of Human Neuropsychology*, 2003).

This networked type of organization takes us beyond the "one area = one function" equation and explains many of the sometimes highly specific language disorders. For example, some people cannot state the names of tools or the colors of objects. Other people can explain an object's function without being able to say its name, and vice versa.

Mesulam does, however, still believe that there are two "epicenters" for semantic processing, i.e., Broca's area and Wernicke's area. This new conception of these two areas is consistent with the fact that they often work synchronously when the brain is performing a word processing task, which supports the idea that there are very strong connections between them.

Mesulam's concept of epicenters resembles that of convergence zones as proposed by other authors: zones where information obtained through various sensory modalities can be combined. This combining process is achieved through the forming of cell assemblies: groups of interconnected neurons whose synapses have been strengthened by their simultaneous firing, in accordance with Hebb's law. This concept of language areas as convergence zones where neuronal assemblies are established thus accords a prominent place to epigenetic influences in the process of learning a language.

Unquestionably, one of these convergence zones is the **left inferior parietal lobule**, which comprises the **angular gyrus and the supramarginal gyrus** . In addition to receiving information from the right hemisphere , the left inferior parietal lobule also integrates emotional associations from the **amygdala** and the **cingulate gyrus**.

Some scientists believe that over the course of evolution, language remained under limbic control until the inferior parietal lobule evolved and became a convergence zone that provides a wealth of inputs to Broca's area . Some scientists also think that it was the emergence of the inferior parietal lobule that gave humans the ability to break down the sounds that they heard so as to make sense of them and, conversely, to express sounds in a sequential manner so as to convey meaning. In this way, primitive emotional and social vocalizations would have eventually come to be governed by grammatical rules of organization to create what we know as modern language.

Distributed Models of Language Function

Lastly, a number of researchers now reject classic locationist models of language such as Geschwind's and Mesulam's. Instead, they conceptualize language, and cognitive functions in general, as being distributed across anatomically separate areas that process information in parallel (simultaneously, rather than serially, from one "language area" to another).

Even those researchers who embrace this view that linguistic information is processed in parallel still accept that the primary language functions, both auditory and articulatory, are localized to some extent.

This concept of a parallel, distributed processing network for linguistic information constitutes a distinctive epistemological paradigm that is leading to the reassessment of certain functional brain imaging (fMRI) studies.

The proponents of this paradigm believe that the extensive activation of various areas in the left hemisphere and the large number of psychological processes involved make it impossible to associate specific language functions with specific anatomical areas of the brain. For example, the single act of **recalling words** involves a highly **distributed network** that is located primarily in the left brain and that includes the **inferolateral temporal lobe,** the **inferior posterior parietal lobule,** the **premotor areas of the frontal lobe,** the **anterior cingulate gyrus,** and the **supplementary motor area.** According to this paradigm, with such a widely distributed, parallel processing network, there is **no way to ascribe specific functions to each of these structures** that contribute to the performance of this task.

The **brain does seem to access meanings by way of categories that it stores in different physical locations**. For example, if the **temporal pole** (the anterior end of the temporal lobe) is damaged, the category "famous people" is lost; if a lesion occurs in the **intermediate and inferior parts of the temporal lobe**, the category "animals" disappears. It also seems that the networks involved in encoding words activate areas in the motor and visual systems. The task of **naming tools** activates the **frontal premotor areas**, while that of **naming animals** activates the **visual areas**. But in both cases, Broca's area and Wernicke's area are not even activated.

Among those scientists who argue that the brain's language processing system is distributed across various structures, some, such as Philip Lieberman, believe that the **basal ganglia** play a very important role in language. These researchers further believe that other subcortical structures traditionally regarded as involved in motor control, such as the **cerebellum** and the **thalamus**, also contribute to language processing. These views stand in opposition to Chomsky's on the exceptional nature of human language and fall squarely within an adaptationist (emphasizing natural selection), evolutionary perspective.

Lateralization, Auditory and Visual Language Processing

Introduction

What is happening inside my head when I listen to a sentence? How do I process written words? This chapter will take a closer look on brain processes concerned with language comprehension. Dealing with natural language understanding, we distinguish between the neuroscientific and the psycholinguistic approach. As text understanding spreads through the broad field of cognitive psychology, linguistics, and neurosciences, our main focus will lay on the intersection of two latter, which is known as neurolinguistics.

Different brain areas need to be examined in order to find out how words and sentences are being processed. For long time scientist were restricted to draw conclusions from certain brain lesions to the functions of corresponding brain areas. During the last 40 years techniques for brain imaging and ERP-measurement have been established which allow for a more accurate identification of brain parts involved in language processing.

Scientific studies on these phenomena are generally divided into research on auditory and visual language comprehension; we will discuss both. Not to forget is that it is not enough to examine English: To understand language processing in general, we have to look at non-Indo-European and other language systems like sign language. But first of all we will be concerned with a rough

localization of language in the brain.

Lateralization of language

Although functional lateralization studies and analyses find individual differences in personality or cognitive style don't favor one hemisphere or the other, some brain functions occur in one or the other side of the brain. Language tends to be on the left and attention on the right (Nielson, Zielinski, Ferguson, Lainhart & Anderson, 2013). There is a lot of evidence that each brain hemisphere has its own distinct functions in language comprehension. Most often, the right hemisphere is referred to as the non-dominant hemisphere and the left is seen as the dominant hemisphere. This distinction is called lateralization (from the Latin word lateral, meaning sidewise) and reason for it first was raised by experiments with split-brain patients. Following a top-down approach we will then discuss the right hemisphere which might have the mayor role in higher level comprehension, but is not quite well understood. Much research has been done on the left hemisphere and we will discuss why it might be dominant before the following sections discuss the fairly well understood fundamental processing of language in this hemisphere of the brain.

Functional asymmetry

Anatomical differences between left and right hemisphere

Initially we will consider the most apparent part of a differentiation between left and right hemisphere: Their differences in shape and structure. As visible to the naked eye there exists a clear asymmetry between the two halves of the human brain: The right hemisphere typically has a bigger, wider and farther extended frontal region than the left hemisphere, whereas the left hemisphere is bigger, wider and extends farther in it's occipital region (M. T. Banich,"Neuropsychology", ch.3, pg.92). Significantly larger on the left side in most human brains is a certain part of the temporal lobe's surface, which is called the planum temporale. It is localized near Wernicke's area and other auditory association areas, wherefore we can already speculate that the left hemisphere might be stronger involved in processes of language and speech treatment.

In fact such a left laterality of language functions is evident in 97% of the population (D. Purves, "Neuroscience", ch.26, pg.649). But actually the percentage of human brains, in which a "left-dominance" of the planum temporale is traceable, is only 67% (D. Purves, "Neuroscience", ch.26, pg.648). Which other factors play aunsolved yet.

Evidence for functional asymmetry from "split brain" patients

In hard cases of epilepsy a rarely performed but popular surgical method to reduce the frequency of epileptic seizures is the so-called corpus callosotomy. Here a radical cut through the connecting "communication bridge" between right and left hemisphere, the corpus callosum, is done; the result is a "split-brain". For patients whose corpus callosum is cut, the risk of accidental physical injury is mitigated, but the side-effect is striking: Due to this eradicative transection of left and right half of the brain these two are not longer able to communicate adequately. This situation provides the opportunity to study differentiation of functionality between the hemispheres. First experiments with split-brain patients were performed by Roger Sperry and his colleagues at the California Institute of Technology in 1960 and 1970 (D. Purves, "Neuroscience", ch.26, pg.646). They lead researchers to sweeping conclusions about laterality of speech and the organization of the human brain in general.

A digression on the laterality of the visual system

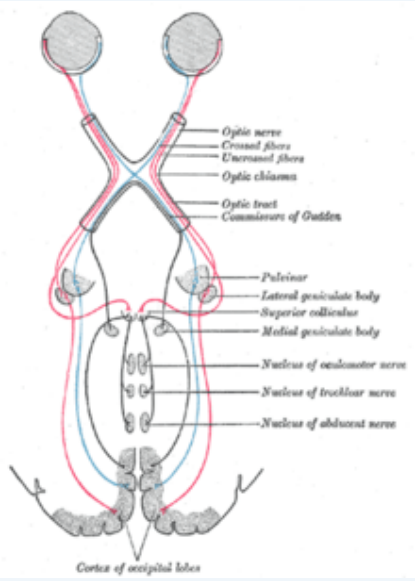

Figure 4.3.3.3: Visual system showing wiring from each half of the eye to brain. A visual stimulus, located within the left visual field, projects onto the nasal (inner) part of the left eye's retina and onto the temporal (outer) part of the right eye's retina. Images on the temporal retinal region are processed in the visual cortex of the same side of the brain (ipsilateral), whereas nasal retinal information is mapped onto the opposite half of the brain (contralateral). The stimulus within the left visual field will completely arrive in the right visual cortex to be processed and worked up. In "healthy" brains this information furthermore reaches the left hemisphere via the corpus callosum and can be integrated there. In split-brain patients this current of signals is interrupted; the stimulus remains "invisible" for the left hemisphere. (Image from Wikimedia Commons; File:Gray722.png; by Henry Vandyke Carter; This work is in the **public domain** in the United States).

Figure 4.3.3.4: Split Brain Experiments. (Image from Wikimedia Commons; File:SplitBrainExperiments.jpg; https://commons.wikimedia.org/wiki/F...xperiments.jpg; by TilmanATuos at English Wikibooks; released into the **public domain** by its author).

The experiment we consider now is based on the laterality of the visual system: What is seen in the left half of the visual field will be processed in the right hemisphere and vice versa. Aware of this principle a test operator presents the picture of an object to one half of the visual field while the participant is instructed to name the seen object, and to blindly pick it out of an amount of concrete objects with the contralateral hand.

It can be shown that a picture, for example the drawing of a die, which has only been presented to the left hemisphere, can be named by the participant ("I saw a die"), but is not selectable with the right hand (no idea which object to choose from the table). Contrarily the participant is unable to name the die, if it was recognized in the right hemisphere, but easily picks it out of the heap of objects on the table with the help of the left hand.

These outcomes are clear evidence of the human brain's functional asymmetry. The left hemisphere seems to dominate functions of speech and language processing, but is unable to handle spatial tasks like vision-independent object recognition. The right hemisphere seems to dominate spatial functions, but is unable to process words and meaning independently. In a second experiment evidence arose that a split-brain patient can only follow a written command (like "get up now!"), if it is presented to the left hemisphere. The right hemisphere can only "understand" pictorial instructions.

The following table (D. Purves, "Neuroscience", ch.26, pg.647) gives a rough distinction of functions:

Left Hemisphere	**Right Hemisphere**
• analysis of right visual field • language processing ◦ writing ◦ speech	• analysis of left visual field • spatial tasks • visuospatial tasks • object and face recognition

First it is important to keep in mind that these distinctions comprise only functional dominances, no exclusive competences. In cases of unilateral brain damage, often one half of the brain takes over tasks of the other one. Furthermore it should be mentioned that this experiment works only for stimuli presented for less than a second. This is because not only the corpus callosum, but as well some subcortical comissures serve for interhemispheric transfer. In general both can simultaneously contribute to performance, since they use complement roles in processing.

A digression on handedness

An important issue, when exploring the different brain organization in the two hemispheres, is handedness, which is the tendency to use the left or the right hand to perform activities. Throughout history, left-handers, which only comprise about 10% of the population, have often been considered being something abnormal. They were said to be evil, stubborn, defiant and were, even until the mid 20th century, forced to write with their right hand.

One most commonly accepted idea, as to how handedness affects the hemispheres, is the brain hemisphere division of labour. Since both speaking and handiwork require fine motor skills, the presumption here is that it would be more efficient to have one brain hemisphere do both, rather than having it divided up. Since in most people, the left side of the brain controls speaking, right-handedness predominates. The theory also predicts that left-handed people have a reversed brain division of labour.

In right handers, verbal processing is mostly done in the left hemisphere, whereas visuospatial processing is mostly done in the opposite hemisphere. Therefore, 95% of speech output is controlled by the left brain hemisphere, whereas only 5% of individuals control speech output in their right hemisphere. Left-handers, on the other hand, have a heterogeneous brain organization. Their brain hemisphere is either organized in the same way as right handers, the opposite way, or even such that both hemispheres are used for verbal processing. But usually, in 70% of the cases, speech is controlled by the left-hemisphere, 15% by the right and 15% by either hemisphere. When the average is taken across all types of left-handedness, it appears that left-handers are less lateralized.

After, for example, damage occurs to the left hemisphere, it follows that there is a visuospatial deficit, which is usually more severe in left-handers than in right-handers. Dissimilarities may derive, in part, from differences in brain morphology, which concludes from asymmetries in the planum temporale. Still, it can be assumed that left-handers have less division of labour between their two hemispheres than right-handers do and are more likely to lack neuroanatomical asymmetries.

There have been many theories as to find out why people are left-handed and what its consequences may be. Some people say that left-handers have a shorter life span or higher accident rates or autoimmune disorders. According to the theory of Geschwind and Galaburda, there is a relation to sex hormones, the immune system, and profiles of cognitive abilities that determine, whether a person is left-handed or not. Concludingly, many genetic models have been proposed, yet the causes and consequences still remain a mystery (M.T.Banich, "Neuropsychology", ch.3, pg. 119).

The right hemisphere

The role of the right hemisphere in text comprehension

The experiments with "split-brain" patients and evidence that will be discussed soon suggest that the right hemisphere is usually not (but in some cases, e.g. 15% of left handed people) dominant in language comprehension. What is most often ascribed to the right hemisphere is cognitive functioning. When damage is done to this part of the brain or when temporal regions of the right hemisphere are removed, this can lead to cognitive-communication problems, such as impaired memory, attention problems, and poor reasoning (L. Cherney, 2001). Investigations lead to the conclusion that the right hemisphere processes information in a gestalt and holistic fashion, with a special emphasis on spatial relationships. Here, an advantage arises for differentiating two distinct faces because it examines things in a global manner and it also reacts to lower spatial, and also auditory, frequency. The former point can be undermined with the fact that the right hemisphere is capable of reading most concrete words and can make simple grammatical comparisons (M. T. Banich,“Neuropsychology“, ch.3, pg.97). But in order to function in such a way, there must be some sort of communication between the brain halves.

Prosody - the sound envelope around words

Consider how different the simple statement "She did it again" could be interpreted in the following context taken from Banich: LYNN: Alice is way into this mountain-biking thing. After breaking her arm, you'd think she'd be a little more cautious. But then yesterday, she went out and rode Captain Jack's. That trail is gnarly - narrow with lots of tree roots and rocks. And last night, I heard that she took a bad tumble on her way down. SARA: *She did it again* Does Sara say that with rising pitch or emphatically and with falling intonation? In the first case she would ask whether Alice has injured herself again. In the other case she asserts something she knows or imagines: That Alice managed to hurt herself a second time. Obviously the sound envelope around words - prosody - does matter.

Reason to belief that recognition of prosodic patterns appears in the right hemisphere arises when you take into account patients

that have damage to an anterior region of the right hemisphere. They suffer from **aprosodic** speech, that is, their utterances are all at the same pitch. They might sound like a robot from the 80ties. There is another phenomena appearing from brain damage: **dysprosodic** speech. In that case the patient speaks with disordered intonation. This is not due to a right hemisphere lesion, but arises when damage to the left hemisphere is suffered. The explanation is that the left hemisphere gives ill-timed prosodic cues to the right hemisphere, thus proper intonation is affected.

Beyond words: Inference from a neurological point of view

On the word level, the current studies are mostly consistent with each other and with findings from brain lesion studies. But when it comes to the more complex understanding of whole sentences, texts and storylines, the findings are split. According to E. C. Ferstl's review "The Neuroanatomy of Text Comprehension. What's the story so far?" (2004), there is evidence for and against right hemisphere regions playing the key role in pragmatics and text comprehension. On the current state of knowledge, we cannot exactly say how and where cognitive functions like building situation models and inferencing work together with "pure" language processes.

As this chapter is concerned with the neurology of language, it should be remarked that patients with right hemisphere damage have difficulties with inferencing. Take into account the following sentence:

With mosquitoes, gnats, and grasshoppers flying all about, she came across a small black bug that was being used to eavesdrop on her conversation.

You might have to reinterpret the sentence until you realize that "small black bug" does not refer to an animal but rather to a spy device. People with damage in the right hemisphere have problems to do so. They have difficulty to follow the thread of a story and to make inferences about what has been said. Furthermore they have a hard time understanding non-literal aspects of sentences like metaphors, so they might be really horrified when they hear that someone was "Crying her eyes out".

The reader is referred to the next chapter for a detailed discussion of Situation Models

The left hemisphere

Further evidence for left hemisphere dominance: The Wada technique

Before concerning concrete functionality of the left hemisphere, further evidence for the dominance of the left hemisphere is provided. Of relevance is the so-called Wada technique, allowing testing which hemisphere is responsible for speech output and usually being used in epilepsy patients during surgery. It is not a brain imaging technique, but simulates a brain lesion. One of the hemispheres is anesthetized by injecting a barbiturate (sodium amobarbital) in one of the patient's carotid arteries. Then he is asked to name a number of items on cards. When he is not able to do that, despite the fact that he could do it an hour earlier, the concerned hemisphere is said to be the one responsible for speech output. This test must be done twice, for there is a chance that the patient produces speech bilaterally. The probability for that is not very high, in fact, according to Rasmussen & Milner 1997a (as referred to in Banich, p. 293) it occurs only in 15% of the left-handers and none of the right-handers. (It is still unclear where these differences in left-handers' brains come from.)

That means that in most people, only one hemisphere "produces" speech output – and in 96% of right-handers and 70% of left-handers, it is the left one. The findings of the brain lesion studies about asymmetry were confirmed here: Normally (in healthy right-handers), the left hemisphere controls speech output.

Explanations of left hemisphere dominance

Two theories why the left hemisphere might have special language capacities are still discussed. The first states that dominance of the left hemisphere is due to a specialization for **precise temporal control of oral and manual articulators**. Here the main argument is that gestures related to a story line are most often made with the right and therefore by the left hemisphere controlled hand whilst other hand movements appear equally often with both hands. The other theory says that the left hemisphere is dominant because it is specialized for **linguistic processing** and is due to a single patient - a speaker of American Sign Language with a left hemisphere lesion. He could neither produce nor comprehend ASL, but could still communicate by using gestures in non-linguistic domains.

How innate is the organizational structure of the brain?

Not only cases of left-handers but also brain imaging techniques have shown examples of bilateral language processing:

According to ERP studies (by Bellugi et al. 1994 and Neville et al. 1993 as cited in E. Dabrowska, "Language, Mind an Brain" 2004, p. 57), people with the Williams' syndrome (WS) also have no dominant hemisphere for language. WS patients have a lot of physical and mental disorders, but show, compared to their other (poor) cognitive abilities, very good linguistic skills. And these skills do not rely on one dominant hemisphere, but both of them contribute equally. So, whilst the majority of the population has a dominant left hemisphere for language processing there are a variety of exceptions to that dominance. That there are different "organization possibilities" in individual brains Dabrowska (p. 57) suggests that the organizational structure in the brain could be less innate and fixed as it is commonly thought.

Auditory Language Processing

This section will explain where and how language is processed. To avoid intersections with visual processes we will firstly concentrate on spoken language. Scientists have developed three approaches of conceiving information about this issue. The first two approaches are based upon brain lesions, namely aphasia, whereas the recent approach relies on results of on modern brain-image techniques.

Neurological Perspective

The Neurological Perspective describes which pathways language follows in order to be comprehended. Scientists revealed that there are concrete areas inside the brain where concrete tasks of language processing are taking place. The most known areas are the Broca and the Wernicke Area.

Broca's aphasia

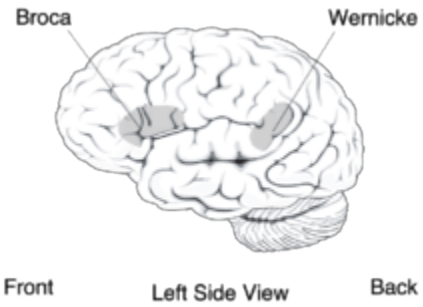

Figure 4.3.3.5: Broca's and Wernicke's area (Image from Wikimedia Commons; File:BrocasAreaSmall.png; https://commons.wikimedia.org/wiki/F...sAreaSmall.png; **public domain** in the United States because it is a work prepared by an officer or employee of the United States Government as part of that person's official duties.

One of the most well-known aphasias is Broca's aphasia that causes patients to be unable to speak fluently. Moreover they have a great difficulty producing words. Comprehension, however, is relatively intact in those patients. Because these symptoms do not result from motoric problems of the vocal musculature, a region in the brain that is responsible for linguistic output must be lesioned. Broca discovered that the brain region causing fluent speech is responsible for linguistic output, must be located ventrally in the frontal lobe, anterior to the motor strip. Recent research suggested that Broca`s aphasia results also from subcortical tissue and white matter and not only cortical tissue.

Example of spontaneous Speech - Task: What do you see on this picture?
„O, yea. Det's a boy an' girl... an' ... a ... car ... house... light po' (pole). Dog an' a ... boat. ‚N det's a ... mm ... a ... coffee, an' reading. Det's a ... mm ... a ... det's a boy ... fishin'." (Adapted from „Principles of Neuroscience" 4th edition, 2000, p 1178)

Wernicke's aphasia

Another very famous aphasia, known as Wernicke`s aphasia, causes opposite syndromes. Patients suffering from Wernicke`s aphasia usually speak very fluently, words are pronounced correctly, but they are combined senselessly – "word salad" is the way it is most often described. Understanding what patients of Wernicke`s aphasia say is especially difficult, because they use paraphasias (substitution of a word in verbal paraphasia, of word with similar meaning in semantic paraphasia, and of a phoneme in phonemic paraphasia) and neologisms. With Wernicke`s aphasia the comprehension of simple sentences is a very difficult

task. Moreover their ability to process auditory language input and also written language is impaired. With some knowledge about the brainstructure and their tasks one is able to conclude that the area that causes Wernicke`s aphasia, is situated at the joint of temporal, parietal and occipital regions, near Heschl`s gyrus (primary auditory area), because all the areas receiving and interpreting sensory information (posterior cortex), and those connecting the sensory information to meaning (parietal lobe) are likely to be involved.

Example of spontaneous Speech - Task: What do you see on this picture?
„Ah, yes, it‘s ah ... several things. It‘s a girl ... uncurl ... on a boat. A dog ... ‘S is another dog ... uh-oh ... long‘s ... on a boat. The lady, it‘s a young lady. An‘ a man a They were eatin‘. ‘S be place there. This ... a tree! A boat. No, this is a ... It‘s a house. Over in here ... a cake. An‘ it‘s, it‘s a lot of water. Ah, all right. I think I mentioned about that boat. I noticed a boat being there. I did mention that before ... Several things down, different things down ... a bat ... a cake ... you have a ...“ (adapted from „Principles of Neuroscience“ 4th edition, 2000, p 1178)

Conduction aphasia

Wernicke supposed that an aphasia between Broca‘s area and Wernicke‘s area, namely conduction aphasia, would lead to severe problems to repeat just heard sentences rather than having problems with the comprehension and production of speech. Indeed patients suffering from this kind of aphasia show an inability to reproduce sentences since they often make phonemic paraphasias, may substitute or leave out words, or might say nothing. Investigations determined that the "connection cable", namely the arcuate fasciculus between Wernicke‘s and Broca‘s area is almost invariably damaged in case of a conduction aphasia. That is why conduction aphasia is also regarded as a disconnection syndrome (the behavioural dysfunction because of a damage to the connection of two connected brain regions).

Example of the repetition of the sentence „The pastry-cook was elated“:
„The baker-er was /vaskerin/ ... uh ...“ (adapted from „Principles of Neuroscience“ 4th edition, 2000, p 1178)

Transcortical motor aphasia and global aphasia

Transcortical motor aphasia, another brain lesion caused by a connection disruption, is very similar to Broca`s aphasia, with the difference that the ability to repeat is kept. In fact people with a transcortical motor aphasia often suffer from echolalia, the need to repeat what they just heard. Usually patients` brain is damaged outside Broca`s area, sometimes more anterior and sometimes more superior. Individuals with transcortical sensory aphasia have similar symptoms as those suffering from Wernicke`s aphasia, except that they show signs of echolalia. Lesions in great parts of the left hemisphere lead to global aphasia, and thus to an inability of both comprehending and producing language, because not only Broca`s or Wenicke`s area is damaged. (Barnich, 1997, pp. 276–282)

Type of Aphasia	Spontaneous Speech	Paraphasia	Comprehension	Repetition	Naming
• Broca`s • Wernicke`s • Conduction • Transcortical motor • Transcortical sensory • Global	• Nonfluent • Fluent • Fluent • Nonfluent • Fluent • Nonfluent	• Uncommon • Common (verbal) • Common (literal) • Uncommon • Common • Variable	• Good • Poor • Good • Good • Poor • Poor	• Poor • Poor • Poor • Good (echolalia) • Good (echolalia) • Poor	• Poor • Poor • Poor • Poor • Poor • Poor

Overview of the effects of aphasia from the neurological perspective

(Adapted from Benson, 1985,p. 32 as cited in Barnich, 1997, p. 287)

Psychological Perspective

Since the 1960‘s psychologists and psycholinguists tried to resolve how language is organized and represented inside the brain. Patients with aphasias gave good evidence for location and discrimination of the three main parts of language comprehension and production, namely phonology, syntax and semantics.

Phonology

Phonology deals with the processing of meaningful parts of speech resulting from the mere sound. More over there exists a differentiation between a phonemic representation of a speech sound which are the smallest units of sounds that leads to different meanings (e.g. the /b/ and /p/ in bet and pat) and phonetic representation. The latter means that a speech sound may be produced in a different manner at different situations. For instance the /p/ in pill sounds different than the /p/ in spill since the former /p/ is aspirated and the latter is not.

Examining which parts are responsible for phonetic representation, patients with Broca`s or Wernicke`s aphasia can be compared. As the speech characteristic for patients with Broca`s aphasia is non-fluent, i.e. they have problems producing the correct phonetic and phonemic representation of a sound, and people with Wernicke`s aphasia do not show any problems speaking fluently, but also have problems producing the right phoneme. This indicates that Broca`s area is mainly involved in phonological production and also, that phonemic and phonetic representation do not take place in the same part of the brain. Scientists examined on a more precise level the speech production, on the level of the distinctive features of phonemes, to see in which features patients with aphasia made mistakes.

A distinctive feature describes the different manners and places of articulation. /t/ (like in touch) and /s/ (like in such) for example are created at the same place but produced in different manner. /t/ and /d/ are created at the same place and in the same manner but they differ in voicing.

Results show that in fluent as well as in non-fluent aphasia patients usually mix up only one distinctive feature, not two. In general it can be said that errors connected to the place of articulation are more common than those linked to voicing. Interestingly some aphasia patients are well aware of the different features of two phonemes, yet they are unable to produce the right sound. This suggests that though patients have great difficulty pronouncing words correctly, their comprehension of words is still quite good. This is characteristic for patients with Broca`s aphasia, while those with Wernicke`s aphasia show contrary symptoms: they are able to pronounce words correctly, but cannot understand what the words mean. That is why they often utter phonologically correct words (neologisms) that are not real words with a meaning.

Syntax

Syntax describes the rules of how words must be arranged to result in meaningful sentences. Humans in general usually know the syntax of their mother tongue and thus slip their tongue if a word happens to be out of order in a sentence. People with aphasia, however, often have problems with parsing of sentences, not only with respect to the production of language but also with respect to comprehension of sentences. Patients showing an inability of comprehension and production of sentences usually have some kind of anterior aphasia, also called agrammatical aphasia. This can be revealed in tests with sentences. These patients cannot distinguish between active and passive voice easily if both agent and object could play an active part. For example patients do not see a difference between “The boy chased the girl” and “The boy was chased by the girl”, but they do understand both “The boy saw the apple” and “The apple was seen by the boy”, because they can seek help of semantics and do not have to rely on syntax alone. Patients with posterior aphasia, like for example Wernicke`s aphasia, do not show these symptoms, as their speech is fluent. Comprehension by mere syntactic means would be possible as well, but the semantic aspect must be considered as well. This will be discussed in the next part.

Semantics

Semantics deals with the meaning of words and sentences. It has been shown that patients suffering from posterior aphasia have severe problems understanding simple texts, although their knowledge of syntax is intact. The semantic shortcoming is often examined by a Token Test, a test in which patients have to point to objects referred to in simple sentences. As might have been guessed, people with anterior aphasia have no problems with semantics, yet they might not be able to understand longer sentences because the knowledge of syntax then is involved as well.

	anterior Aphasia (e.g. Broca)	posterior Aphasia (e.g. Wernicke)

Phonology	phonetic and phonemic representation affected	phonemic representation affected
Syntax	affected	no effect
Syntax	no effect	affected

Overview of the effects of aphasia from the psychological perspective

In general studies with lesioned people have shown that anterior areas are needed for speech output and posterior regions for speech comprehension. As mentioned above anterior regions are also more important for syntactic processing, while posterior regions are involved in semantic processing. But such a strict division of the parts of the brain and their responsibilities is not possible, because posterior regions must be important for more than just sentence comprehension, as patients with lesions in this area can neither comprehend nor produce any speech. (Barnich, 1997, pp. 283–293)

Evidence from Advanced Neuroscience Methods

Measuring the functions of both normal and damaged brains has been possible since the 1970s, when the first brain imaging techniques were developed. With them, we are able to "watch the brain working" while the subject is e.g. listening to a joke. These methods (further described in chapter 4) show whether the earlier findings are correct and precise.

Generally, imaging shows that certain functional brain regions are much smaller than estimated in brain lesion studies, and that their boundaries are more distinct (cf. Banich p. 294). The exact location varies individually, therefore bringing the results of many brain lesion studies together caused too big estimated functional regions before. For example, stimulating brain tissue electrically (during epilepsy surgery) and observing the outcome (e.g. errors in naming tasks) led to a much better knowledge where language processing areas are located.

PET studies (Fiez & Petersen, 1993, as cited in Banich, p. 295) have shown that in fact both anterior and posterior regions were activated in language comprehension and processing, but with different strengths – in agreement with the lesion studies. The more active speech production is required in experiments, the more frontal is the main activation: For example, when the presented words must be repeated.

Another result (Raichle et al. 1994, as referred to in Banich, p. 295) was that the familiarity of the stimuli plays a big role. When the subjects were presented well-known stimuli sets in well-known experimental tasks and had to repeat them, anterior regions were activated. Those regions were known to cause conduction aphasia when damaged. But when the words were new ones, and/or the subjects never had to do a task like this before, the activation was recorded more posterior. That means, when you repeat an unexpected word, the heaviest working brain tissue is about somewhere under your upper left earlap, but when you knew this word that would be the next to repeat before, it is a bit nearer to your left eye.

Visual Language Processing

The processing of written language is performed when we are reading or writing and is thought to happen in a distinct neural processing unit than auditory language processing. Reading and writing respectively rely on vision whereas spoken language is first mediated by the auditory system. Language systems responsible for written language processing have to interact with a sensory system different from the one involved in spoken language processing.

Visual language processing in general begins when the visual forms of letters ("c" or "C" or "c") are mapped onto abstract letter identities. These are then mapped onto a word form and the corresponding semantic representation (the "meaning" of the word, i.e. the concept behind it). Observations of patients that lost a language ability due to a brain damage led to different disease patterns that indicated a difference between perception (reading) and production (writing) of visual language just like it is found in non-visual language processing.

Alexic patients possess the ability to write while not being able to read whereas patients with agraphia are able to read but cannot write. Though alexia and agraphia often occur together as a result of damage to the angular gyrus, there were patients found having alexia without agraphia (e.g. Greenblatt 1973, as cited in M. T. Banich, "Neuropsychology", p. 296) or having agraphia without alexia (e.g. Hécaen & Kremin, 1976, as cited in M. T. Banich, "Neuropsychology", p. 296). This is a double dissociation that suggests separate neural control systems for reading and writing.

Since double dissociations are also found in phonological and surface dyslexia, experimental results support the theory that

language production and perception respectively are subdivided into separate neural circuits. The two route model shows how these two neural circuits are believed to provide pathways from written words to thoughts and from thoughts to written words.

Two routes model

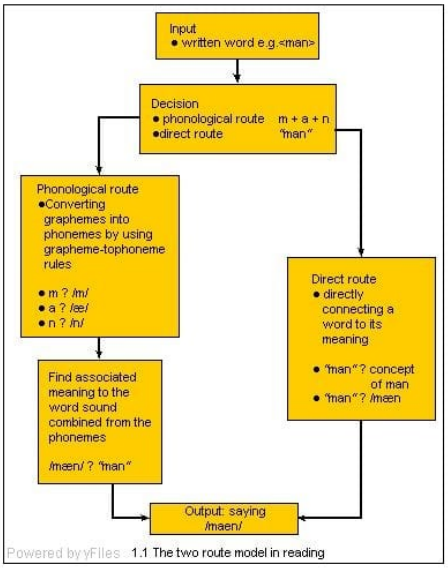

Figure 4.3.3.6: Each route derives the meaning of a word or the word of a meaning in a different way, depending on word familiarity. (Image from Wikimedia Commons; File:1 1 twoRouteModelInReading.JPG; https://commons.wikimedia.org/wiki/F...lInReading.JPG; by TilmanATuos at en.wikibooks; licensed under *GNU Free Documentation License*.).

In essence, the two routes model contains two routes. Each of them derives the meaning of a word or the word of a meaning in a different way, depending on how familiar we are with the word.

Using the **phonological route** means having an intermediate step between perceiving and comprehending of written language. This intermediate step takes places when we are making use of grapheme-to-phoneme rules. Grapheme-to-phoneme rules are a way of determining the phonological representation for a given grapheme. A grapheme is the smallest written unit of a word (e.g. “sh” in “shore”) that represents a phoneme. A phoneme on the other hand is the smallest phonological unit of a word distinguishing it from another word that otherwise sounds the same (e.g. “bat” and “cat”). People learning to read or are encountering new words often use the phonological route to arrive at a meaning representation. They construct phonemes for each grapheme and then combine the individual phonemes to a sound pattern that is associated with a certain meaning (see 1.1).

The **direct route** is supposed to work without an intermediate phonological representation, so that print is directly associated with word-meaning. A situation in which the direct route has to be taken is when reading an irregular word like “colonel”. Application of grapheme-to-phoneme rules would lead to an incorrect phonological representation.

According to Taft (1982, as referred to in M. T. Banich,“Neuropsychology“, p. 297) and others the direct route is supposed to be faster than the phonological route since it does not make use of a “phonological detour” and is therefore said to be used for known words (see 1.1). However, this is just one point of view and others, like Chastain (1987, as referred to in M. T. Banich, “Neuropsychology“, p. 297), postulate a reliance on the phonological route even in skilled readers.

The processing of written language in reading

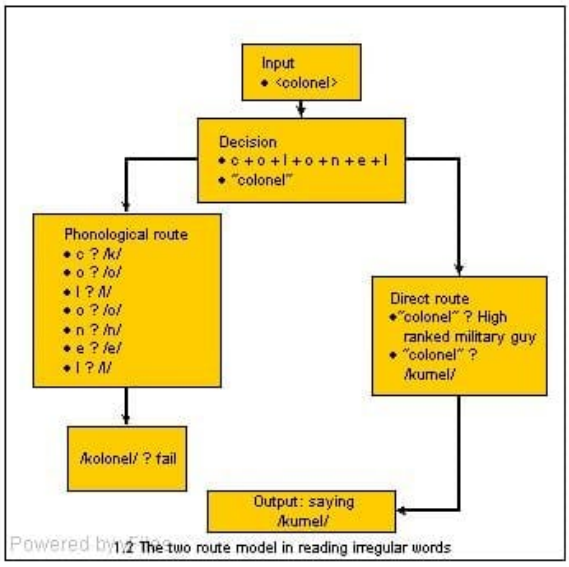

Figure 4.3.3.7: Regularity effects are common in cases of surface alexia. (Image from Wikimedia Commons; File:1 2 TwoRouteModelIrregularWords.JPG; https://commons.wikimedia.org/wiki/F...gularWords.JPG; by TilmanATuos at en.wikibooks; licensed under *GNU Free Documentation License*.).

Several kinds of alexia could be differentiated, often depending on whether the phonological or the direct route was impaired. Patients with brain lesions participated in experiments where they had to read out words and non-words as well as irregular words. Reading of non-words for example requires access to the phonological route since there cannot be a “stored” meaning or a sound representation for this combination of letters.

Patients with a lesion in temporal structures of the left hemisphere (the exact location varies) suffer from so called **surface alexia**. They show the following characteristic symptoms that suggest a strong reliance on the phonological route: Very common are regularity effects, that is a mispronunciation of words in which the spelling is irregular like "colonel" or "yacht" (see 1.2). These words are pronounced according to grapheme-to-phoneme rules, although high-frequency irregularly spelled words may be preserved in some cases, the pronunciation according to the phonological route is just wrong.

Furthermore, the would-be pronunciation of a word is reflected in reading-comprehension errors. When asked to describe the meaning of the word “bear”, people suffering from surface alexia would answer something like “a beverage” because the resulting sound pattern of “bear” was the same for these people as that for “beer”. This characteristic goes along with a tendency to confuse homophones (words that sound the same but are spelled differently and have different meanings associated). However, these people are still able to read non-words with a regular spelling since they can apply grapheme-to-phoneme rules to them.

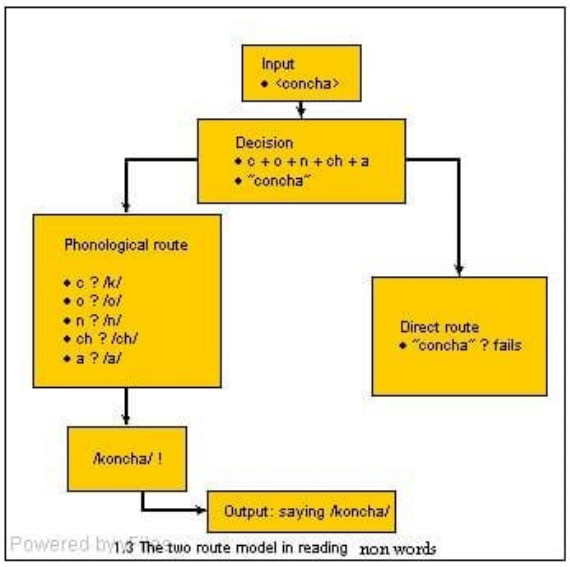

Figure 4.3.3.8: Patients with phonological alexia have to rely on the direct route. (Image from Wikimedia Commons; File:1 3 TwoRouteModelNonWords.JPG; https://commons.wikimedia.org/wiki/F...elNonWords.JPG; by TilmanATuos at en.wikibooks; licensed under *GNU Free Documentation License*.).

In contrast, **phonological alexia** is characterized by a disruption in the phonological route due to lesions in more posterior temporal structures of the left hemisphere. Patients can read familiar regular and irregular words by making use of stored information about the meaning associated with that particular visual form (so there is no regularity effect like in surface alexia). However, they are unable to process unknown words or non-words, since they have to rely on the direct route (see 1.3).

Word class effects and morphological errors are common, too. Nouns, for example, are read better than function words and sometimes even better than verbs. Affixes which do not change the grammatical class or meaning of a word (inflectional affixes) are often substituted (e.g. “farmer” instead of “farming”). Furthermore, concrete words are read with a lower error rate than abstract ones like “freedom” (concreteness effect).

Deep Alexia shares many symptomatic features with phonological alexia such as an inability to read out non-words. Just as in phonological alexia, patients make mistakes on word inflections as well as function words and show visually based errors on abstract words (“desire” → “desert”). In addition to that, people with deep alexia misread words as different words with a strongly related meaning (“woods” instead of “forest”), a phenomenon referred to as semantic paralexia. Coltheart (as referred to in the “Handbook of Neurolinguistics”, ch.41-3, p. 563) postulates that reading in deep dyslexia is mediated by the right hemisphere. He suggests that when large lesions affecting language abilities other than reading prevent access to the left hemisphere, the right-hemispheric language store is used. Lexical entries stored there are accessed and used as input to left-hemisphere output systems.

	Ability to read non-words	Ability to read irregular words	Ability to read regular words	Rely on	Disruption in	Other symptoms
Surface alexia	Ok	No	Ok	Phonological route	Direct route	-Confuse homophones - errors in word inflection
Phonological alexia	No	Ok	Ok	Direct route	Phonological route	-word class effects -morphological errors (e.g. farmer- farming) - concretness effect
Deep alexia	No	Ok	Ok	Direct route	Phonological route	-Confuse Homophones (e.g. pane -pain) -semantic paralexia (e.g. woods -forest)

Figure 4.3.3.9: Overview of alexia. (Image from Wikimedia Commons; File:Overview alexia.JPG; https://commons.wikimedia.org/wiki/F...iew_alexia.JPG; by TilmanATuos at en.wikibooks; licensed under *GNU Free Documentation License*.).

The processing of written language in spelling

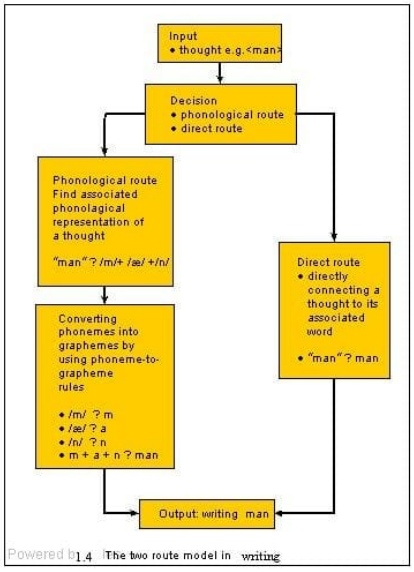

Figure 4.3.3.10: The phonological route is supposed to make use of phoneme-to-grapheme rules while the direct route links thought to writing without an intermediary phonetic representation. (Image from Wikimedia Commons; File:1 4 TwoRoutesModelWritig.JPG; https://commons.wikimedia.org/wiki/F...odelWritig.JPG; by TilmanATuos at en.wikibooks; licensed under *GNU Free Documentation License*).

Just like in reading, two separate routes –a phonological and a direct route- are thought to exist. The phonological route is supposed to make use of phoneme-to-grapheme rules while the direct route links thought to writing without an intermediary phonetic representation (see 1.4).

It should be noted here that there is a difference between phoneme-to-grapheme rules (used for spelling) and grapheme-to-phoneme rules in that one is not simply the reverse of the other. In case of the grapheme “k” the most common phoneme for it is /k/. The most common grapheme for the phoneme /k/, however, is “c”. **Phonological agraphia** is caused by a **lesion in the left supramarginal gyrus**, which is located **in the parietal lobe above** the **posterior** section of the **Sylvian fissure** (M. T. Banich,

"Neuropsychology", p. 299). The ability to write regular and irregular words is preserved while the ability to write non-words is not. This, together with a poor retrieval of affixes (which are not stored lexically), indicates an inability to associate spoken words with their orthographic form via phoneme-to-grapheme rules. Patients rely on the direct route, which means that they use orthographic word-form representations that are stored in lexical memory. **Lesions at** the **conjunction of the posterior parietal lobe** and the parieto-occipital junction cause so called **lexical agraphia** that is sometimes also referred to as **surface agraphia**. As the name already indicates, it parallels surface alexia in that patients have difficulty to access lexical-orthographic representations of words. Lexical agraphia is characterized by a poor spelling of irregular words but good spelling for regular and non-words. When asked to spell irregular words, patients often commit regularization errors, so that the word is spelled phonologically correct (for example, "whisk" would be written as "wisque").

	Ability to write non-words	Ability to write irregular words	Ability to write regular words	Rely on	Disruption in	Other symptoms
Phonological agraphia	No	Ok	Ok	Direct route	Phonological route	poor retrieval of affixes
Lexical agraphia	Ok	No	Ok	Phonological route	Direct route	

Figure 4.3.3.11: Overview of agraphia. (Image from Wikimedia Commons; File:Overview agraphia.JPG; https://commons.wikimedia.org/wiki/F...w_agraphia.JPG; by TilmanATuos at en.wikibooks; licensed under *GNU Free Documentation License*).

Evidence from Advanced Neuroscience Methods

How can we find evidence for the theory of the two routes. Until now neuroscientific research is not able to ascertain that there are neural circuits representing a system like the one described above. The problem of finding evidence for visual language processing on two routes in contrast to one route (as stated by e.g. from Seidenberg & McClelland as referred to in M. T. Banich,"Neuropsychology", p. 308) is that it is not clear what characteristic brain activation would indicate that it is either happening on two or one routes. To investigate whether there are one or two systems, neuroimaging studies examine correlations between the activations of the **angular gyrus**, which is thought to be a crucial brain area in **written language processing**, and other brain regions. It was found out that during reading of non- words (which would strongly engage the phonological route) the activation is mostly correlated with brain regions which are involved in phonological processing e.g. **superior temporal regions** (BA 22) and **Broca's area**. During reading of normal words (which would strongly engage the direct route) the highest activation was found in **occipital and ventral cortex**. That at least can imply that there are two distinct routes. However, these are conclusions drawn from highest correlations which do not ensure this suggestion. What neuroimaging studies do show is that the usage of a phonological and a direct route strongly overlap, which is rather unspectacular since it is quiet reasonable that fluent speakers mix both of the routes. Other studies additionally provide data in which the activated brain regions during reading of non-words and reading of normal words differ. ERP studies suggest that the left hemisphere possesses some sort of mechanism which responds to combinations of letters in a string, or to its orthography and/or to the phonological representation of the string. ERP waves differ, during early analysis of the visual form of the string, if the string represents a correct word or just pronounceable nonsense (Posner & McCandliss, 1993 as referred in M.T. Banich, "Neuropsychology," p. 307-308). That indicates that this mechanism is sensitive to correct or incorrect words.

The opposite hemisphere, the **right hemisphere**, in contrast to the left hemisphere, is not involved in abstract mapping of word meaning but is rather responsible for **encoding word specific visual forms**. ERP and PET studies provide evidence that the right hemisphere responds in a stronger manner than the left hemisphere to letter-like strings. Moreover divided visual field studies reveal that the right hemisphere can better distinguish between different shapes of the same letter (e.g. in different handwritings) than the left hemisphere. The contribution of visual language processing by both hemispheres is that the **right hemisphere first recognizes** a **written word as letter sequences**, no matter how exactly they look like, **then the language network in the left hemisphere builds** up an **abstract representation** of the word, **which is the comprehension of the word**.

Other symbolic systems

Most neurolinguistic research is concerned with production and comprehension of English language, either written or spoken.

However, looking at different language systems from a neuroscientific perspective can substantiate as well as differentiate acknowledged theories of language processing. The following section shows how neurological research of three symbolic systems, each different from English in some aspect, has made it possible to distinguish - at least to some extent - between brain regions that deal with the modality of the language (and therefore may vary from language to language, depending on whether the language in question is e.g. spoken or signed) from brain regions that seem to be necessary to language processing in general - regardless whether we are dealing with signed, spoken, or even musical language.

Kana and Kanji

Kana and Kanji are the two writing systems used parallel in the Japanese language. Since different approaches are used in them to represent words, studying Japanese patients with alexia is a great possibility to test the hypothesis about the existence of two different routes to meaning, discussed in the previous section.

The English writing system is phonological – each grapheme in written English roughly represents one speech sound – a consonant or a vowel. There are, however, other possible approaches to writing down a spoken language. In syllabic systems like the Japanese kana, one grapheme stands for one syllable. If written English were syllabic, it could e.g. (for example) include a symbol for the syllable “nut”, appearing both in the words “donut” and “peanut”. Syllabic systems are sound-based – since the graphemes represent units of spoken words rather than meaning directly, an auditory representation of the word has to be created in order to arrive at the meaning. Therefore, reading of syllabic systems should require an intact phonological route. In addition to kana, Japanese also use a logographic writing system called kanji, in which one grapheme represents a whole word or a concept. Different from phonological and syllabic systems, logographic systems don’t comprise systematical relationships between visual forms and the way they’re pronounced – instead, visual form is directly associated with the pronunciation and meaning of the corresponding word. Reading kanji should therefore require the direct route to meaning to be intact.

The hypothesis about the existence of two different routes to meaning has been confirmed by the fact that after brain damage, there can be a double dissociation between kana and kanji. Some Japanese patients can thus read kana but not kanji (surface alexia), whereas other can read kanji but not kana (phonological alexia). In addition, there is evidence that different brain regions of Japanese native speakers are active while reading kana and kanji, although like in the case of English native speakers, these regions also overlap.

Since the distinction between direct and phonological route also makes sense in case of Japanese, it may be a general principle common to all written languages that reading them relies on two independent (at least partially) systems, both using different strategies to catch the meaning of a written word – either associating the visual form directly with the meaning (the direct route), or using the auditory representation as an intermediary between the visual form and the meaning of the word (the phonological route).

The Japanese Kana sign for the syllable "mu"

The Japanese Kanji sign for the concept "Book", "writing", or "calligraphy

Figure 4.3.3.12: Two forms of Japanese writing elicit activity in different regions of the brain in native speakers.

Sign Language

From a linguistic perspective, sign languages share many features of spoken languages – there are many regionally bounded sign languages, each with a distinct grammar and lexicon. Since at the same time, sign languages differ from spoken languages in the way the words are “uttered”, i.e. in the modality, neuroscientific research in them can yield valuable insights into the question whether there are general neural mechanisms dealing with language, regardless of its modality.

Structure of SL

Sign languages are phonological languages - every meaningful sign consists of several phonemes (phonemes used to be called cheremes (Greek χερι: hand) until their cognitive equivalence to phonemes in spoken languages was realized) that carry no meaning as such, but are nevertheless important to distinguish the meaning of the sign. One distinctive feature of SL phonemes is the place of articulation – one hand shape can have different meanings depending on whether it’s produced at the eye-, nose-, or chin-level. Other features determining the meaning of a sign are hand shape, palm orientation, movement, and non-manual markers (e.g. facial expressions).

To express syntactic relationships, Sign Languages exploit the advantages of the visuo-spatial medium in which the signs are produced – the syntactic structure of sign languages therefore often differs from that of spoken languages. Two important features of most sign language's grammars (including American Sign Language (ASL), Deutsche Gebärdensprache (DGS) and several other major sign languages) are directionality and simultaneous encoding of elements of information:

- Directionality

The direction in which the sign is made often determines the subject and the object of a sentence. Nouns in SL can be 'linked' to a particular point in space, and later in the discourse they can be referred to by pointing to that same spot again (this is functionally related to pronouns in English). The object and the subject can then be switched by changing the direction in which the sign for a transitive verb is made.

- Simultaneous encoding of elements of information

The visual medium also makes it possible to encode several pieces of information simultaneously. Consider e.g. the sentence "The flight was long and I didn't enjoy it". In English, the information about the duration and unpleasantness of the flight have to be encoded sequentially by adding more words to the sentence. To enrich the utterance "The flight was long” with the information about the unpleasantness of the flight, another sentence (“I did not enjoy it") has to be added to the original one. So, in order to convey more information, the length of the original sentence must grow. In sign language, however, the increase of information in an utterance doesn’t necessarily increase the length of the utterance. To convey information about the unpleasantness of a long flight experienced in the past, one can just use the single sign for "flight" with the past tense marker, moved in a way that represents the attribute "long", combined with the facial expression of disaffection. Since all these features are signed simultaneously, no additional time is needed to utter "The flight was long" as compared to "The flight was long and I didn't enjoy it".

Neurology of SL

Since sentences in SL are encoded visually, and since its grammar is often based on visual rather than sequential relationships among different signs, it could be suggested that the processing of SL mainly depends on the right hemisphere, which is mainly concerned with the performance on visual and spatial tasks. However, there is evidence suggesting that processing of SL and spoken language might be equally dependent on the left hemisphere, i.e. that the same basic neural mechanism may be responsible for all language functioning, regardless of its modality (i.e. whether the language is spoken or signed).

The importance of the left hemisphere in SL processing indicated e.g. by the fact that signers with a damaged right hemisphere may not be aphasiacs, whereas as in case of hearing subjects, lesions in the left hemisphere of signers can result in subtle linguistic difficulties (Gordon, 2003). Furthermore, studies of aphasic native signers have shown that **damage to anterior portions of the left hemisphere (Broca’s area) result in a syndrome similar to Broca’s aphasia** – the patients lose fluency of communication, they aren’t able to correctly use syntactic markers and inflect verbs, although the words they sign are semantically appropriate. In contrast, patients with **damages to posterior portions of the superior temporal gyrus (Wernicke’s area)** can still properly inflect verbs, set up and retrieve nouns from a discourse locus, but **the sequences they sign have no meaning** (Poizner, Klima & Bellugi, 1987). So, **like in the case of spoken languages, anterior and posterior portions of the left hemisphere seem to be responsible for the syntax and semantics of the language respectively.** Hence, it’s not essential for the "syntax processing mechanisms" of the brain whether the syntax is conveyed simultaneously through spatial markers or

successively through word order and morphemes added to words - the **same underlying mechanisms might be responsible for syntax in both cases**.

Further evidence for the same underlying mechanisms for spoken and signed languages comes from studies in which fMRI has been used to compare the language processing of:

- 1. congenitally deaf native signers of British Sign Language,
- 2. hearing native signers of BSL (usually hearing children of deaf parents)
- 3. hearing signers who have learned BSL after puberty
- 4. non-signing subjects

Investigating language processing in these different groups allows making some distinctions between different factors influencing language organization in the brain - e.g. to what amount does deafness influences the organization of language in the brain as compared to just having SL as a first language(1 vs. 2), or to what amount does learning of SL as a first language differ from learning SL as native language (1,2 vs.3), or to what amount is language organized in speakers as compared to signers (1,2,3 vs.4).

These studies have shown that **typical areas in the left hemisphere** are activated in both native English speakers given written stimuli and native signers given signs as stimuli. Moreover, there are also areas that are equally activated both in case of deaf subjects processing sign language and hearing subjects processing spoken language – a finding which **suggests that these areas constitute the core language system regardless of the language modality** (Gordon, 2003).

Different from speakers, however, signers also show a strong activation of the right hemisphere. This is partly due to the necessity to process visuo-spatial information. Some of those areas, however (e.g. the **angular gyrus**) are only activated in native signers and not in hearing subjects that learned SL after puberty. This **suggests that the way of learning sign languages (and languages in general) changes with time:** Late learner's brains are unable to recruit certain brain regions specialized for processing this language (Newman et al., 1998).]

We have seen that evidence from aphasias as well as from neuroimaging suggest the **same underlying neural mechanisms to be responsible for sign and spoken languages.** It ‘s natural to ask whether these neural mechanisms are even more general, i.e. whether they are able to process any type of symbolic system underlying some syntax and semantics. One example of this kind of more general symbolic system is music.

Music

Like language, music is a human universal involving some combinatorial principles that govern the organizing of discrete elements (tones) into structures (phrases) that convey some meaning – music is a symbolic system with a special kind of **syntax and semantics**. It’s therefore interesting to ask whether music and natural language share some neural mechanisms: whether processing of music is dependent on processing of language or the other way round, or whether the underlying mechanisms underlying them are completely separate. By investigating the neural mechanisms underlying music we might find out whether the neural processes behind language are unique to the domain of natural language, i.e. whether language is modular. Up to now, research in the neurobiology of music has yielded contradicting evidence regarding these questions.

On the one hand, there is evidence that there is a double **dissociation of language and music abilities**. People suffering from **amusia** are unable to perceive harmony, to remember and to recognize even very simple melodies; at the same time they have **no problems in comprehending or producing speech**. There is even a case of a patient who developed amusia without aprosodia, i.e. although she couldn't recognize tone in musical sequences, she nevertheless could still make use of pitch, loudness, rate, or rhythm to convey meanings in spoken language (Pearce, 2005). This highly selective **problem in processing music (amusia)** can occur as a result of **brain damage**, or be inborn; in some cases it runs on families, suggesting a **genetic** component. The complement syndrome of amusia also exists – after suffering a **brain damage in the left hemisphere**, the Russian composer Shebalin **lost** his **speech** functions, **but** his **musical abilities remained** intact (Zatorre, McGill, 2005).

On the other hand, **neuroimaging** data suggest that **language and music** have a **common mechanism for processing syntactical structures**. The P600 ERP`s in the Broca area, measured as a response to ungrammatical sentences, is also elicited in subjects listening to musical chord sequences lacking harmony (Patel, 2003) – the expectation of typical sequences in music could therefore be mediated by the same neural mechanisms as the expectation of grammatical sequences in language.

A possible solution to this apparent contradiction is the dual system approach (Patel, 2003) according to which music and language share some procedural mechanisms (frontal brain areas) responsible for processing the general aspects of syntax, but

in both cases these mechanisms operate on different representations (posterior brain areas) – notes in case of music and words in case of language.

Summary

Many questions are yet to be answered. It is still unclear whether there is a distinct language module (that you could cut out without affecting anything in other brain functions) or not. As Evely C. Ferstl points out in her review, the next step after exploring distinct small regions responsible for subtasks of language processing will be to find out how they work together and build up the language network.

4.3.4: Handedness, Language, and Brain Lateralization

Learning Objectives

1. Describe hemispheric asymmetries
2. Describe the role of testosterone and stress in brain lateralization and handedness
3. Describe sex differences in brain lateralization and suggest an explanation
4. Describe lateralization in other species and briefly discuss implications for possible origins of human brain lateralization

Handedness, testosterone, and lateralization for language appear to be related. Approximately 10% of people are left-handed and 2/3 of left-handers are male. 95% of right handed men and women have language lateralized to the left hemisphere. The greatest asymmetries are in the posterior language areas including the temporal planum and angular gyrus. If the left hemisphere is damaged or defective prenatally the right hemisphere can acquire language functions.

Handedness, Language, and Lateralization

The brain's anatomical asymmetry, its lateralization for language, and the phenomenon of handedness are all clearly interrelated, but their influences on one another are complex. Though about 90% of people are right-handed, and about 95% of right-handers have their language areas on the left side of their brains, that still leaves 5% of right-handers who are either right-lateralized for language or have their language areas distributed between their two hemispheres. And then there are the left-handers, among whom all of these patterns can be found , including left-lateralization.

Some scientists suggest that the left hemisphere's dominance for language evolved from this hemisphere's better control over the right hand. The circuits controlling this "skillful hand" may have evolved so as to take control over the motor circuits involved in language. Broca's area, in particular, is basically a premotor module of the neocortex and co-ordinates muscle contraction patterns that are related to other things besides language.

Brain-imaging studies have shown that several structures involved in language processing are larger in the left hemisphere than in the right. For instance, Broca's area in the left frontal lobe is larger than the homologous area in the right hemisphere. But the **greatest asymmetries** are found mainly in the **posterior language areas**, such as the **temporal planum and the angular gyrus**.

Two other notable asymmetries are the larger protrusions of the frontal lobe on the right side and the occipital lobe on the left. These protrusions might, however, be due to a slight rotation of the hemispheres (counterclockwise, as seen from above) rather than to a difference in the volume of these areas. These protrusions are known as the **right-frontal and left-occipital petalias** ("petalias" originally referred to the indentations that these protrusions make on the inside of of the skull).

The **structures involved in producing and understanding language** seem to be laid down in accordance with **genetic instructions** that come into play as **neuronal migration** proceeds in the **human embryo**. Nevertheless, the two hemispheres can remain just about equipotent until language acquisition occurs. Normally, the language specialization develops in the left hemisphere, which matures slightly earlier. The earlier, more intense activity of the neurons in the left hemisphere would then lead both to right-handedness and to the control of language functions by this hemisphere. But **if the left hemisphere is damaged or defective**, **language** can be **acquired by** the **right hemisphere**. An **excess** of **testosterone** in newborns due to stress at the time of birth might well be one of the most common causes of **slower development in the left hemisphere** resulting in **greater participation by the right.**

This hypothesis of a central role for testosterone is supported by experiments which showed that **in rats, cortical asymmetry** is **altered** if the rodents are injected with **testosterone at birth**. This hormonal hypothesis would also explain why **two-thirds of all left-handed persons are males**.

Interindividual variations, which are essential for natural selection, are expressed in various ways in the **human brain**. **Volume and weight can vary by a factor of two** or even more. The **brain's vascular structures are extremely variable**; the deficit caused by an obstruction at a given point in the vascular system can vary greatly from one individual to another. At the macroscopic anatomical level, the **folds and grooves in the brain also vary tremendously from individual to individual**,

especially in the areas associated with language . **Variability in** the language areas can also be observed at the microscopic level, for example, in the **synaptic structure** of the **neurons in Wernicke's area.**

Interindividual variability is also expressed in the brain's functional organization, and particularly in the phenomenon of hemispheric asymmetry. For instance, some data indicate that **language functions may be more bilateral in women than in men**. The percentage of **atypical lateralization for language** also varies with handedness: it is considerably **higher among left-handers** than among right-handers.

Lastly, as if all this were not enough, there is also such a thing as intraindividual variability. In the same individual, a given mental task can sometimes activate different neuronal assemblies in different circumstances—for instance, when the individual is performing this task for the first time, as opposed to when he or she has already performed it many times before.

Even in many species that are quite distant from humans in evolutionary terms (frogs, for example), the brain is left-lateralized for the vocalization function.

In chimpanzees, lateralization for the anatomical areas corresponding to Broca's and Wernicke's areas already exists, even though it does not yet correspond to the language function. And like the majority of humans, the majority of chimpanzees use their right hand in preference to their left.

These asymmetries in the other primates represent persuasive evidence of the **ancient phylogenetic origin of lateralization** in the human brain. The expansion of the prefrontal cortex in humans might in part reflect its role in the production of language.

An asymmetrical lateralized brain may have evolved in order to reduce redundancy of information processing functions in favor of greater processing capacity in a brain whose volume is limited by the size of the human female birth canal (Corballis, 2017). To increase processing capacity if brain volume is fixed, lateralization of function may more efficiently utilize the processing resources available.

Women have the reputation of being able to talk and listen while doing all sorts of things at the same time, whereas men supposedly prefer to talk or hear about various things in succession rather than simultaneously. Brain-imaging studies may now have revealed an anatomical substrate for this behavioural difference, by demonstrating that language functions tend to place more demands on both hemispheres in women while being more lateralized (and mainly left-lateralized) in men. Women also have more nerve fibers connecting the two hemispheres of their brains (via a broader corpus callosum), which also suggests that more information is exchanged between them.

Summary

Most people are right-handed and language in most people is lateralized to the left hemisphere. Lateralization of the brain's functions may have been one way to increase the brain's processing capacity by reducing redundant usage of available processing resources. Vocalization is left-lateralized in species ranging from frogs to chimpanzees, suggesting ancient evolutionary origins of brain lateralization in humans.

4.3.5: The Right Hemisphere's Contribution to Language

Learning Objectives

1. Describe the cause and symptoms of hemineglect (unilateral neglect)
2. Describe the primary contributions of the right hemisphere to human language expression and comprehension
3. Identify and describe language pragmatics and its disorders
4. Describe theory of mind and how it is related to autism

Overview

Hemineglect, also known as unilateral neglect, following damage in the right parietal cortex is characterized by inability to attend to sensory inputs on the left side of the body leading to lack of awareness and emotional indifference to these inputs. Because of the disorder, such patients can "lose track" of the left side of their body and limbs because of the lack of attention to inputs from the left side of space including the left side of their own bodies. Some of these patients may fail to understand that the left side of their bodies belong to them. Right hemisphere damage can disrupt the emotional and contextual aspects of language use, suggesting that the right hemisphere is more emotional than the left and that normally the right hemisphere contributes the emotional aspects of human speech.

The Role of the Right Hemisphere in Language

To follow a conversation, a written document, or an exchange of witticisms, you must be able not only to understand the syntax of sentences and the meanings of words, but also to interrelate multiple elements and interpret them with respect to a given context. While various types of damage to the left hemisphere produce the many documented forms of aphasia, right hemisphere damage (RHD) causes a variety of communication deficits involving the interpretation of context. These deficits can be divided into two main categories.

The first category of RHD-induced deficits affect communication indirectly, by disrupting people's ability to interact effectively with their environment. One example of a deficit that can be caused by RHD is **hemineglect (unilateral neglect)**, in which an individual pays no attention to stimuli presented to the various sensory modalities on the left side of the body. The individual may also suffer from **anosognosia**: unawareness of such deficits. For instance, some people who have damage just posterior to the central sulcus in their **parietal lobe** in their **right** hemispheres cannot even recognize certain parts of their own bodies as being their own. Thus this type of RHD produces a kind of indifference that is the opposite of the minimum emotional investment required to establish harmonious communication.

The other major family of RHD-induced deficits affect communication and cognition directly. These deficits can be grouped under the heading of pragmatic communication disorders, pragmatics being the discipline that studies the relationships between language and the way that people use it in context. **Pragmatic disorders can be subdivided into disorders in prosody, discourse organization, and understanding of non-literal language.**

Prosody refers to the **intonation and stress** with which the phonemes of a language are **pronounced**. People with **aprosodia**—**RHD** that **impairs** their use of **prosody—cannot use intonation and stress to effectively express** the **emotions** they actually feel. As a result, they speak and behave in a way that seems flat and emotionless.

The **second category of pragmatic communication disorders** that can be caused by RHD affect the organization of discourse according to the rules that govern its construction. In some individuals, these disorders take the form of a **reduced ability to interpret** the signs that establish the **context** for a communication, or the nuances conveyed by certain words, **or the speaker's intentions or body language**, or the applicable **social conventions**. With regard to social conventions, for example, people generally do not address their boss the same way they would their brother, but people with certain kinds of RHD have difficulty in making this distinction.

Last but not least among the **types of pragmatic communication disorders caused by RHD** are **disorders** in the **understanding of non-literal language**. It is estimated that fewer than half of the sentences that we speak express our meaning

literally, or at least they do not do so entirely. For instance, whenever we use **irony, or metaphors, or other forms of indirect language**, people's ability to understand our actual meaning depends on their ability to interpret our intentions.

To understand irony, for example, people must apply two levels of awareness, just as they must do to understand jokes. First, they must understand the speaker's state of mind, and second, they **must understand the speaker's intentions** as to how his or her words should be construed. Someone who is telling a joke wants these words not to be taken seriously, while someone who is speaking ironically wants the listener to perceive their actual meaning as the opposite of their literal one.

Metaphors too express an intention that belies a literal interpretation of the words concerned. If a student turns to a classmate and says "This prof is a real sleeping pill", the classmate will understand the implicit analogy between the pill and the prof and realize that the other student finds this prof boring. But someone with RHD that affects their understanding of non-literal language might not get this message.

Lastly, the various indirect ways that we commonly use language in everyday life can cause problems for people with RHD. In such cases, the speaker's actual intention underlies their oral statement as such. For example, someone who says "I wonder what the time is now " is indirectly asking for someone to tell them the time, but a person with RHD may not understand that.

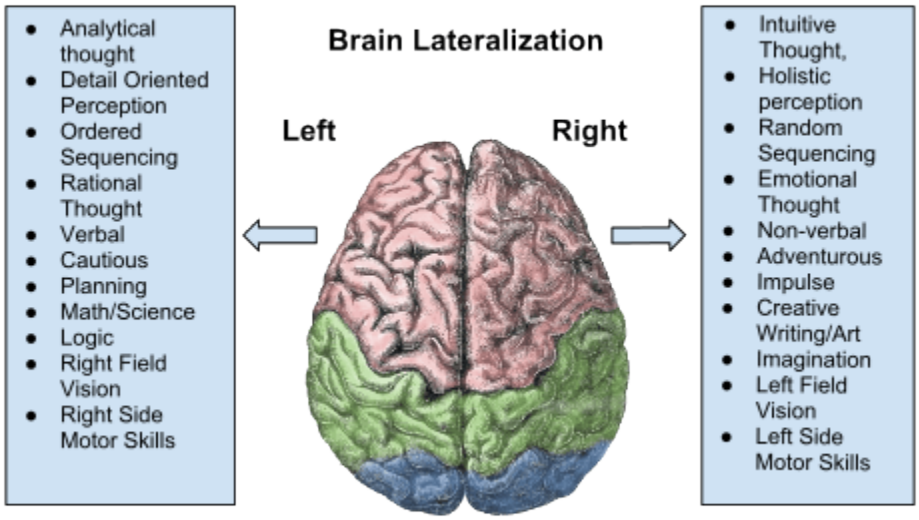

Figure 4.3.5.1: The oversimplification of lateralization in pop psychology. This belief was widely held even in the scientific community for some years. The left brain controls functions that have to do with logic and reason, while the right brain controls functions involving creativity and emotion. This simplified view of brain lateralization is no longer considered accurate by neuroscientists. Instead, new research using brain imaging shows that the two halves of the brain work together much more than earlier research had implied. (Image and first two sentences of caption from Wikimedia Commons, remainer of caption by Kenneth A. Koenigshofer, Ph.D.; File:Brain Lateralization.svg; https://commons.wikimedia.org/wiki/F...ralization.svg; by Chickensaresocute; licensed under the Creative Commons Attribution-Share Alike 3.0 Unported license).

Though the **left hemisphere** is still regarded as the **dominant hemisphere for language**, the role of the **right hemisphere** in understanding the **context** in which language is used is now well established. We know that in the absence of the left hemisphere (for example, when Wada's test is performed which temporarily inactivates targeted brain tissue), the **right hemisphere can produce some rudimentary language.** But lesion studies have shown that the right hemisphere's role in language appears to be far wider—so much so that it is now more accurate to think of the **two hemispheres' language specializations** not as separate functions, but rather as a variety of abilities that **operate in parallel** and whose interaction makes human language in all its complexity possible.

Many theories have been offered to explain people's ability to adapt their use of language to the interpersonal context. One of these is the theory of mind. According to Premack and Woodruff (1978), the **theory of mind is the ability that lets people ascribe mental processes to other people**, to reason on the basis of these ascribed processes, and to understand the behaviors that arise from them. Premack and Woodruff were the first authors to use the term "theory of mind". They did so in a study on the ability of chimpanzees to ascribe beliefs and intentions to human beings. Since the time of this study, the theory of mind has been applied mainly in studies comparing the cognitive development of normal children and **autistic children**, because the latter represent a population that is known to display **deficits in social reasoning** from the very earliest age. In normal children,

theory of mind (ToM) develops between 3 and 4 years of age and is fully developed by 5 years of age (Roth & Dicke, 2012).

When experimental subjects are asked to **identify the emotional content of recorded sentences** that are played back into only one of their ears, they perform **better if these sentences are played into their left ear (which sends them to the right hemisphere)** than into their right (which sends them to the left hemisphere). These results confirm that the right hemisphere has a role in processing the emotional content of speech.

Summary

Hemineglect, also known as unilateral neglect, caused by damage to the right parietal lobe, is a disorder of attention to sensory inputs from the left side of space including the left side of one's own body. Language in patients with this disorder, reflects indifference to sensory inputs from the left half of space. The right hemisphere is involved in understanding the speaker's intentions and the emotional components of language. Language pragmatics including prosody and indirect language appear to be at least in part dependent upon processing by the right hemisphere. Some researchers suggest that damage to the right hemisphere may interfere with theory of mind, the ability to understand that others have minds, beliefs and intentions, and that persons with autism may have impairments in theory of mind.

Picture the following scenario (Figure 12.1). Two students are jogging at dusk along a fire trail in the Berkeley, California hills. As they approach a small grove of trees, they spot a mountain lion lurking in the shadows. The students freeze. They can feel their hearts pounding, their breath quickening, their muscles are tense, their palms sweaty. All they can see is the mountain lion as it crouches and prepares to attack. The students turn towards the mountain lion, waving their arms and creating noise in an attempt to ward it off. They hurl strewn rocks until the mountain lion finally retreats.

Weeks later, one of the students keeps remembering the encounter and experiencing distress, is having trouble sleeping and no longer wants to jog in the hills. The other does not show signs of distress after the initial shock.

Encountering a mountain lion ready to attack would be a very stressful event for most people. A pounding heart, shallow breathing and sweaty palms are all part of the body's response to stress—an adaptive response which ensures our survival by preparing us to fight, flee or freeze in the face of threat. In the aftermath of this stressful encounter, why does one student experience lasting effects while the other has none?

In this chapter you will learn about stress and the stress response, the mechanisms regulating it, how stress affects brain circuits and behavior, and what sets up the variability between people in how they respond to stress.

4.5.2: What Is Stress?

Learning Objectives

By the end of this section, you should be able to

- 12.1.1 Define the concept of stress, a stressor, the stress response and describe the valence and nature of the stress response
- 12.1.2 Understand how stress research is carried out in both humans and animal models

Although colloquially we have an idea of what stress is, the aim of this section is to define and understand stress from a biomedical perspective. We will distinguish between stress, a stressor, the stress response, and the point at which we are 'stressed out.' We will learn about the different types of stressors and the nature and valence of the response. An interesting point to consider as you read ahead: is stress always bad?

Definition of stress

Most of us will never encounter a mountain lion, but we have all experienced stressful situations or the feeling of being 'stressed out'. Take a moment to think about a stressful situation you have experienced. How did it make you feel (physically, emotionally, cognitively)? (See Figure 12.2.) Because stress is 'personal' (i.e., a subjective experience), it can mean different things to different people. In order to study it from a biological perspective, however, we need a scientifically tractable definition to start from.

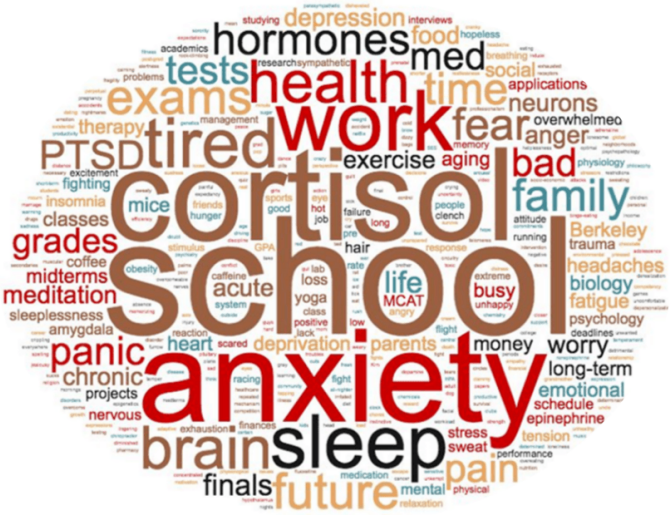

Figure 12.2 Stress associations "What does stress mean to you?" This word cloud shows responses of UC Berkeley students.

Biomedical perspective

Hans Selye—the founder of the field of stress research—defined stress from a physiological viewpoint as "the nonspecific response of the body to any demand made upon it." According to Selye, "anything that speeds up the intensity of life, causes a temporary increase in stress" (Selye, 1974). To fully understand this definition, we need to first define the concept of allostasis. Allostasis means "achieving stability through change." It includes the mechanisms that maintain life-sustaining functions (for example, body temperature, blood sugar levels, fluid balance, etc.) which must be kept within a pre-set range (see Chapter 16 Homeostasis). In addition, allostasis also includes processes that promote adaptation to challenge and expand our survival or coping capabilities. A classic example is fat accumulation in a bear preparing for hibernation. Fat accumulation is an anticipatory change that prepares the bear for survival during winter. Here, allostatic mechanisms accommodate this change, i.e., an expanded

physiological state to promote survival.

Based on Selye´s definition, any stimulus that speeds up the intensity of life (be it good or bad, pleasurable or painful, real or implied), and perturbs the physiological and psychological integrity of an organism is defined as a stressor. Interestingly, these can be deviations in variable, and even opposite directions: exposure to extreme heat or cold, starvation or obesity, injury, or threat to one's well-being, like when encountering a predator. Stress is the body's stereotyped physiological response to that stimulus. It is an evolutionarily conserved response and essential for survival. The stress response is orchestrated across all cells and tissues of the body to mobilize energy to support vital functions which are necessary to survive the immediate threat. For example, pumping glucose and oxygen to the heart, skeletal muscles and brain, and away from functions that are not pertinent to the immediate survival (e.g., digestion and reproduction).

Now that we've shifted our focus to the physiological response that occurs after exposure to a stressor, we notice that regardless of the specific stressor that initiated it, the broad physiological response will largely be the same. For example in our mountain lion scenario, both the students (i.e., potential prey), as well as the mountain lion itself, experience a stress reaction during the encounter. It is important to note that a similar physiological cascade of events can be initiated by an internal cue, in the absence of a physical threat. One can be sitting in a room, thinking about a fearful situation, and this may be sufficient to mount a full physiological response. Over decades of research, accumulating data has started to bridge our understanding of the physiological and psychological realms of stress, to create a unified picture. You will soon learn how the psychological appraisal of a situation influences the physiology of the stress response.

Now, most of us have probably experienced the feeling of being 'stressed out', the point at which a stressor becomes too much (i.e., it lasts too long, is too intense, or too much for a certain person to deal with) and leads to detrimental effects on the body. The term 'stressed out' was coined by another of the founders of the field of stress research, Bruce McEwen, to mean only the negative aspects of the response. We will revisit this idea of being 'stressed out'—a concept termed allostatic (over)load or toxic stress—in 12.4 Clinical Implications of Stress.

The stress response (aka the 'fight-or-flight' response)

Our working definition in this chapter for the stress response is: a physiological reaction that occurs in response to an actual or perceived harmful event, attack or threat to survival, which results from the coordinated action of the central and peripheral autonomic nervous systems and endocrine (hormonal) system; to generate physiological, cognitive, cardiovascular and metabolic changes that allow an organism to respond to a perturbance, promoting fitness and survival. We will explain this in detail throughout this chapter.

Generally, an event (stressor, stimulus) occurs, like a mountain lion appearing on our morning run. Or there is the perception that a threatening event might happen. This can be hearing a roar, or the thought that a mountain lion was spotted here last week. This is briefly followed by an appraisal of the threat. This appraisal relies on neural activation in the amygdala (the brain's alarm center), the prefrontal cortex (which regulates decision-making) and other circuits. And finally, there is a response to the threat (fighting, running away or freezing). The appraisal of the threat, the predictability of the stressor (whether you expected it or not) and sense of control over the situation (controllability) are 3 critical factors in mounting the stress response and in regulating its termination. We will discuss this in more depth in 12.3 Interindividual Variability and Resilience in Response to Stress .

Note that the focus of the field for many years has been on the 'fight-or-flight' response but there is also the freezing response. Freezing is a form of behavioral inhibition and functions to decrease the likelihood of detection since the visual cortex of many predators is programmed to detect moving objects. Freezing also reduces the chance that we make inadvertent sounds that other animals might detect (see discussion of cues in Chapter 7 Hearing and Balance). Freezing is not a passive state (i.e., the brain has not 'stopped working'). Rather it allows for perception and preparation of further defensive responses (Roelofs, 2017).

Functions that support the stress response

The stress response orchestrates all body systems so that they are primed and optimized to deal with the emergency situation at hand, many of which are diagrammed in Figure 12.3

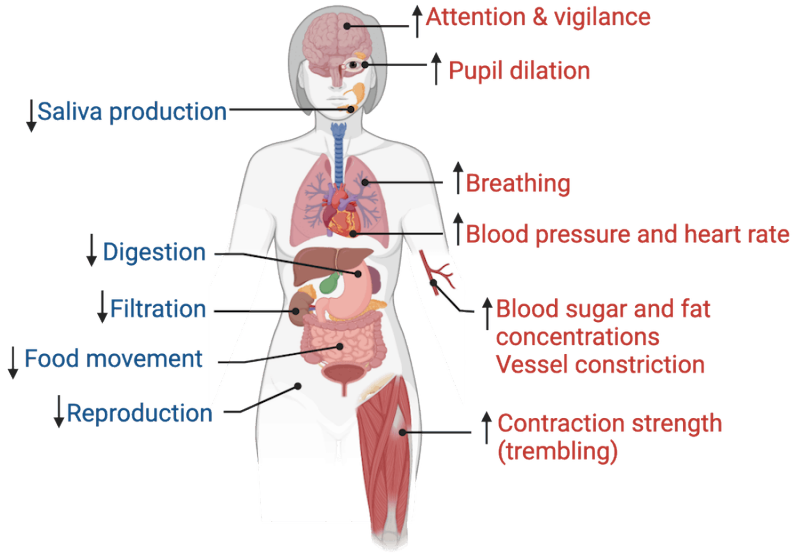

Figure 12.3 Major adaptive body responses to stress

If an individual needs to quickly run away from something, what functions would support this? *Attention* needs to be focused on the situation right now, so there are brain connectivity changes that occur to promote vigilance and sharpen attention. Pupils dilate to better detect even faint stimuli. Quick and deep *breathing* occurs to increase oxygen supply to the heart, skeletal muscles, and brain. Similarly, there are *metabolic changes* that increase the energy supply (increased blood sugar and fat concentrations) in the blood. *Blood pressure* and *heart rate* increase and blood flow is diverted away from other parts of the body and redirected to the muscles. As muscles become more tense, trembling can occur. Blood vessels in the skin constrict since blood flow is being diverted to muscles, resulting in chills or sweating. Everything else, that is, all *non-vital functions* like digestion, kidney filtration, and reproduction are slowed down. Thus, there is a decrease in saliva production (a person's mouth getting dry when they're nervous or anxious) and the output of digestive enzymes decreases. A slowdown of food movement through the bowels also occurs. One caveat, under situations of extreme stress, there might be a dumping of bowel contents. Similarly, because the absorption process through the bowels changes, 'stress diarrhea' can also occur. You may think back to a time when you were about to give a public speech—your mouth went very dry and you had a feeling that you needed to find the closest restroom ASAP. Now you know why.

Classification of stressors

Based on our definition of stress, stressors are anything that take an organism out of homeostatic range and thus can be a host of different stimuli/events. In this section, we will take a look at how stressors are classified and examples of each.

There are 3 main stressor domains:

1. Origin or type describes the modality a stressor comes in. These can be physical, psychological, or social
2. Duration describes how long a stressor lasts. Acute stressors generally range from minutes to hours. Subchronic stressors can last for days and chronic stressors range from weeks to years. Note that the initial stress response to an acute, subchronic or chronic stressor is the same, but differences arise once the stressor becomes a sustained event.
3. Severity describes whether it's a minor, moderate or major life-threatening event. These range on a scale from mild to moderate to severe to traumatic.

These domain divisions are not mutually exclusive, rather a specific type of stressor will range in both duration and severity. Below, we discuss further the 3 types (or origins) of stressors.

Physical stressors

Acute physical stressors include physical exertion or exposure to extreme environmental conditions (e.g., participating in a competitive cycling race, or acute exposure to extreme heat or cold). In the animal world, a classic example is a predator-prey interaction. Another is sustaining an acute injury (e.g., a broken arm). Chronic physical stressors include chronic illness and

obesity/starvation (i.e., moving away from the homeostatic body weight set point). Prolonged exposure to extreme environments is also a form of chronic physical stress. For example, staying at high altitude where the body needs to cope with decreased oxygen availability. Figure 12.4 shows examples of physical stressors, both acute and chronic.

Psychological stressors

Psychological stressors are the most common types of stressors for us modern humans, and what most people think of when asked to give examples of stress. These can also be classified as acute or chronic and range in severity. Figure 12.5 shows examples of psychological stressors. Interestingly, these stressors typically originate from thoughts of a potential perceived threat or worry, yet elicit the same physiological sequela aimed at facilitating the optimal function of the organism as it faces the need to fight, flee or freeze. This stressor category includes mundane events like arguing with a coworker or sitting in traffic, to more notable events like getting divorced, experiencing grief or financial and career worries.

Social stressors

For highly social species, including us humans, social interactions can provide a potent source of stressors, while supportive social bonds can act as an effective buffer of stress responses. Figure 12.6 shows examples of social and societal stressors, both acute and chronic. These can also range in severity. Much of the research on social stress in animal models has focused on social isolation or social hierarchy and its negative effects on wellbeing. In humans, there is also compelling data that demonstrates that social rejection is a potent cue activating the stress response (Dickerson and Kemeny, 2004). Social belonging was critical for survival success in primal societies and hence our brains are particularly sensitive to cues of social exclusion. In fact, the social environment interacts with stress on almost every front: social interactions can be potent stressors, they can buffer the response to an external stressor, and social behavior often changes in response to stressful life experiences. The next frontier in the interaction of the social world and stress is looking at the physiological and psychological effects of virtual social environments, as these take center stage in our daily realities.

Finally, we must consider societal stressors. Societal issues such as poverty, racism and inequality are particularly important to discuss because they have a considerable impact on health and well-being. Growing up in or living in poverty, or experiencing racism or inequality can change the pattern of the stress response throughout life and negatively impact health outcomes and health span. These are critical topics that need to be considered in medical and public health-level discussions.

Figure 12.6 Examples of social and societal stressors (credit: social isolation: "Lunch Guest" by Stephen Kelly/Wikimedia Commons, CC BY 2.0; societal stressors: "Homeless on Paulista Avenue" Wilfredo Rafael Rodriguez Hernandez/Wikimedia Commons, public domain; digital world related stress: Unsplash, public domain)

Valence of the stress response

We now know that the stress response is critical to survival but it has also garnered the reputation of being detrimental to health and wellbeing. This brings up the question of valence: is stress always a bad thing?

Inverted-U nature of the stress response

It turns out that some amount of stress is actually good and can enhance performance in the same domains where too much stress is detrimental (memory and executive function, for example). This type of relationship where increasing amounts of some factor (stress in our case) results first in an increase and then a decrease of a second factor (performance for example) is referred to as an inverted-U relationship (Yerkes-Dodson law). Figure 12.7 shows a typical inverted-U curve with increasing stress (stress/stimulation) on the x-axis and some measure of behavioral performance (e.g., memory function, decision-making, learning, playing an instrument, etc.) on the y-axis.

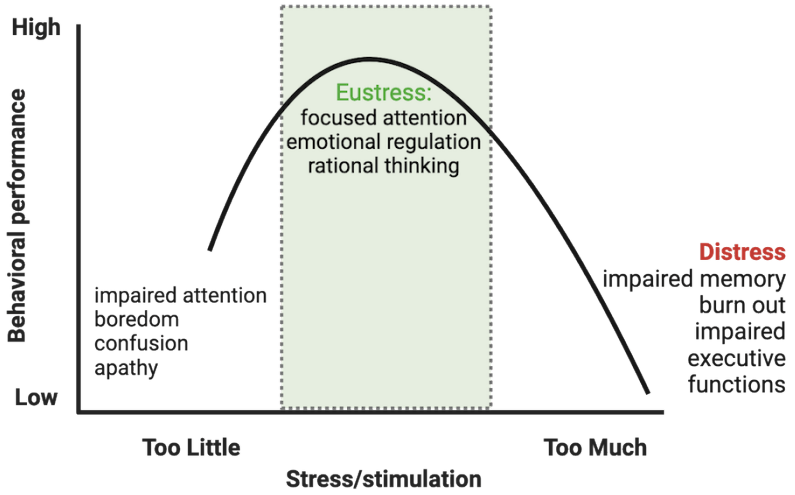

Figure 12.7 Inverted-U nature of the stress response

Notice that there is a point on the curve where performance reaches a peak, where attention gets very focused, rational thinking sharpens and emotional regulation is at its best: an optimal level of stress. This region of positive stress or eustress is defined as stress that is perceived as within an individual's coping abilities, motivates and focuses energy, may feel exciting, improves performance (Lazarus, 1998), and can protect against future stressors (a phenomenon termed 'stress inoculation').

Think about the functions that support the stress response: the sharpening of attention and focus, the increased energy supply in the bloodstream, and something that we didn't discuss but is also important, the mobilization of immune cells ready to protect against damage. This physiological state means that you're prepared and ready to tackle a challenge. For example, an upcoming final exam. You need to be focused, energized and cannot afford to get sick. Interestingly, viewing a challenge, for example, a slew of final exams or a tough new project at school or work as a positive thing can result in eustress. The key is not the stressor itself but how we perceive it. If we see it as an opportunity to learn new skills and showcase our abilities, we will feel energized and motivated to tackle it. On the other hand, if we perceive this as an obstacle or something beyond our coping capacity, we will not feel these positive effects of eustress and instead will likely feel signs of distress. Thus, the mindset with which we approach stress can have a significant impact on the outcome.

Finally, reframing stress-induced physiological reactions like a 'racing' heart as helpful and adaptive versus harmful has been shown to result in improved cognitive and physiological outcomes during/after a stressor (Jamieson et al., 2012). We will learn more about how stress perception, appraisal and reframing of stress-induced arousal can lead to positive outcomes in 12.3 Interindividual Variability and Resilience in Response to Stress.

Detrimental effects of stress exposure

When there is too little or too much stress (negative stress or distress), performance is decreased. With too little stress or stimulation, there might be impaired attention, boredom or even apathy. With too much stress (chronic or traumatic stress exposure), performance declines even further, resulting in impaired memory and executive functions or even burnout. Eventually, this could lead to the development of psychiatric disorders, for example, anxiety, depression, posttraumatic stress disorder (PTSD) or other stress-related pathologies (see Chapter 13 Emotion and Mood).

An important question, then, is when exactly does stress become detrimental? There is no exact answer because it differs from person to person based on an individual's genetics, epigenetics, life history, capabilities/resources at the moment the stressor occurs, appraisal of the situation and other factors. All of these vary amongst individuals (interindividual variability) and some factors will vary even for the same person at different times (intraindividual variability). You will learn more about this topic in 12.3 Interindividual Variability and Resilience in Response to Stress.

Status and stress in wild baboons

The work of primatologist and neuroscientist Robert Sapolsky examined the effects of stress and social hierarchy on the health and social behavior of a troop of wild baboons in Africa. He found that higher-ranking males had lower levels of stress (lower baseline levels of the stress hormone cortisol) when compared to lower-ranking males, differences that were largely due to better access to resources (food, mates). However, and particularly interesting, was the fact that stress levels were not wholly determined by social rank. For example, an individual´s perception of their social standing and ability to cope with disruptions also had a bearing: higher-ranking baboons could experience stress (significant spikes in cortisol levels) if they were constantly challenged within the troop´s social hierarchy.

Sapolsky also found that chronic exposure to stress had negative effects on the health of the baboons. Lower-ranking baboons exposed to chronic stressors (social subordination, lack of access to resources and constant social threat) had compromised immune function, increased rates of illness and were more vulnerable to cardiovascular disease and diabetes.

His work served to establish the link between social status, stress and health outcomes which has tremendous impact for understanding the role of socioeconomic status and stress-related health outcomes in humans (e.g., the detrimental impact of poverty on health).

Neuroscience across Species: Methods to study stress

To understand the nature, dynamics and outcomes of the stress response, we carry out research in humans and in a variety of

animal models, which we will discuss in this section.

Human research on stress

Research on the effects of stress in humans is largely correlational—that is, an investigator studies the relationship between two variables (for example, exposure to a traumatic stressor and the development of PTSD), as opposed to actually manipulating one of the variables. In these correlational designs, study participants are typically individuals with extreme exposure to stress or trauma (e.g., individuals that were in a severe car accident, experienced sexual abuse, participated in combat, experienced childhood maltreatment). Researchers use a cross-sectional study design, comparing those who experienced the extreme stressor(s) to a control group with similar demographics in order to understand the effects of stress exposure on different outcome variables. When studying stress-related pathologies, like anxiety, depression or PTSD, study participants will be individuals that meet the clinical criteria for diagnosis of those disorders and controls will be age and sex matched people who do not meet diagnostic criteria.

We can also study stress in humans in a laboratory setting where subjects are exposed to a stressful setting, and consequently, a stress response is induced. This design allows for better control over timing. This type of study is not correlational in nature as it involves manipulation of one of the variables, i.e., the stressor. For example, you can induce stress and then measure the dynamics of stress hormone concentration rising, and then resolving to baseline. The most common protocols are tasks that involve public speaking or scenarios that involve unpleasant social interactions. For example, a scenario using a virtual ball game where the study participant is purposely excluded (the ball is not passed to them). A widely used human laboratory stressor which reliably induces a stress response was developed at the University of Trier (Germany). It's called the Trier Social Stress Test (TSST). It combines elements of anticipatory stress, public speaking and performing mental mathematics before a panel of judges (Figure 12.8).

Figure 12.8 Trier social stress test The TSST is a psychosocial human laboratory stressor that reliably elicits a stress response. Image credit: John Coetzee/Wikimedia Commons, CC BY-SA 3.0

The TSST has been used in dozens of studies. It was used to: 1) map the magnitude and duration of neuronal and hormonal aspects of stress responses, 2) identify between-subject variability in the response, and 3) understand resilience and vulnerability to stress upon first exposure and repeated exposure.

Animal models of stress

Animal models enable us to study the molecular, cellular and physiological mechanisms underlying the body's response to stress. The stress response is conserved throughout evolution, and a similar response can be measured across taxa. This similarity across species has enabled the development of a variety of different animal models (monkeys, apes, chinchillas, mice, rats, fruit-flies, zebrafish) to examine stress-related effects through laboratory interventions and field studies. Lab studies take advantage of the fact that variables like timing and severity of the stressor, as well as environmental conditions (nutrition, type of housing, temperature, humidity, light-dark cycle, etc.) can be controlled. Other advantages to using lab-based models is that the responses

to stress can frequently be measured before and after a stressor in the same animal, and genetics and life history of individual animals are controlled for. Most stressors currently in use are social/psychological in nature and reflect the types of stressors most relevant to humans. Rodents are a widely used animal model and the following sections will focus on them. Figure 12.9 diagrams some of the common stress models in rodents that we will discuss below.

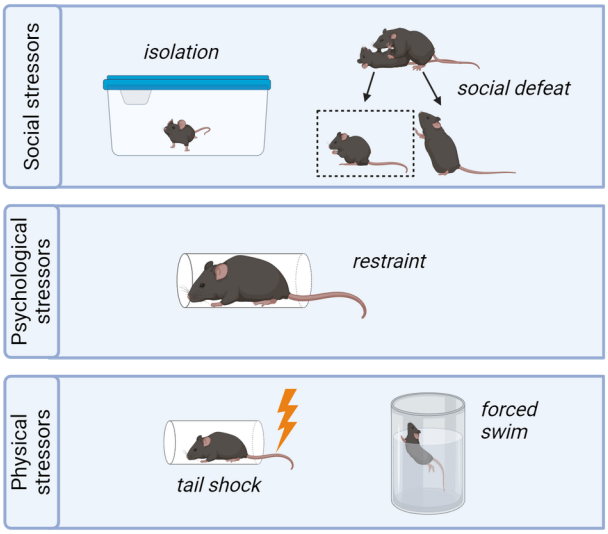

Figure 12.9 Stressor models in rodents

Social stress models

Social isolation: Like humans, rodents are social animals. Thus, social access or social interactions can be manipulated to activate a stress response. Social isolation is a moderate to severe stressor. It can be applied chronically, for example having a mouse live alone in a cage for a certain period of time (months) or grow up in cages where they're isolated from one another during a developmental period like childhood. Social isolation can also be an effective stressor acutely: removing a mouse from their home cage for ~24 hours can induce a stress response. Maternal separation is a specific type of social isolation during the developmental period that aims to model early-life adversity or neglect and how that influences stress responsivity throughout life.

Social defeat: Frequently implemented using a resident-intruder test, social defeat is a severe stressor which uses physical conflict between a smaller mouse (intruder) and an older, aggressive, dominant, male mouse (resident) in order to generate a stress response. After a brief physical confrontation, a plexiglass divider is inserted into the cage. This physically separates the mice but still allows the smaller mouse to see and smell the aggressor mouse, which serves as a further psychological stressor. This interaction repeats for 10-30 days. Social defeat has been used as a model for bullying and depression in humans.

Psychological stress models

Immobilization/restraint: In this widely used laboratory stressor, animals are placed in a restraining tube or bag so that they cannot move. It doesn't physically hurt them but rather serves as a psychological stressor since it prevents any movement or escape. Immobilization can be short (e.g., one 3-hour long session) or longer-term (e.g., 3 hours/day for 28 days) and can thus be used to model both acute and chronic stress. It can also be made more severe/traumatic if it is paired with exposure to predator odor, for example, fox urine or a collar worn by a cat.

Physical stress models

Tail shock: As the name implies, tail shock stress uses an electrical shock administered to the rodent's tail. Tail shock is generally used in studies aiming to investigate stress-induced anxiety/depression.

Forced swim: Rats or mice are made to swim in a tall cylinder without the possibility of escape for a set duration of time. This stressor can be both a source of stress and an assay for stress-induced changes in behavior that may be relevant to features of

depression. During forced swim, an animal will initially try to escape (show a burst of activity) and then become immobile, i.e., make only movements necessary to keep its head above water. Increased immobility is interpreted as a sign of behavioral despair or helplessness.

Validity of animal models for human disease

When establishing or utilizing an animal model for the purpose of developing insight relevant to human physiology, we need to ensure that the animal system is a valid model for the human system. Comparing animal models to humans can be especially challenging when we are interested in things like thoughts and feelings (i.e. more abstract functions of the brain). For example, we can determine that a person is depressed by asking them detailed questions and they can report back how/what they are feeling. This is, of course, impossible in a mouse (or other animal). Thus, we need to consider ways to 'interrogate' the mouse's behavior and figure out what aspects are meaningful or mimic the human disorder.

When modeling diseases in non-human animals, there are three criteria that must be taken into account for validation: 1) face validity (is the observable behavioral outcome similar to human symptoms; the behavior needs to be a good analog of the human behavior, not necessarily the same behavior), 2) construct validity (does the underlying mechanism reflect the cause of the disease in humans), and 3) predictive validity (are the same treatments effective). To learn more about how we assess animal models of stress-induced depression, see the Feature box on "How do we model depression?"

How do we model depression?

To model stress-related pathologies, such as anxiety or depression in rodents, selected stressors are generally either psychological or social. In addition, we need behavioral assays that can capture and allow us to quantify different aspects or symptoms of the disorder. Social defeat stress (SDS) is a relevant social/psychological stressor which reliably elicits depressive-like symptoms in rodents.

What does depression look like when you're a mouse? Figure 12.10 shows several common assays we use for behaviors that we interpret as relevant to core features of depression.

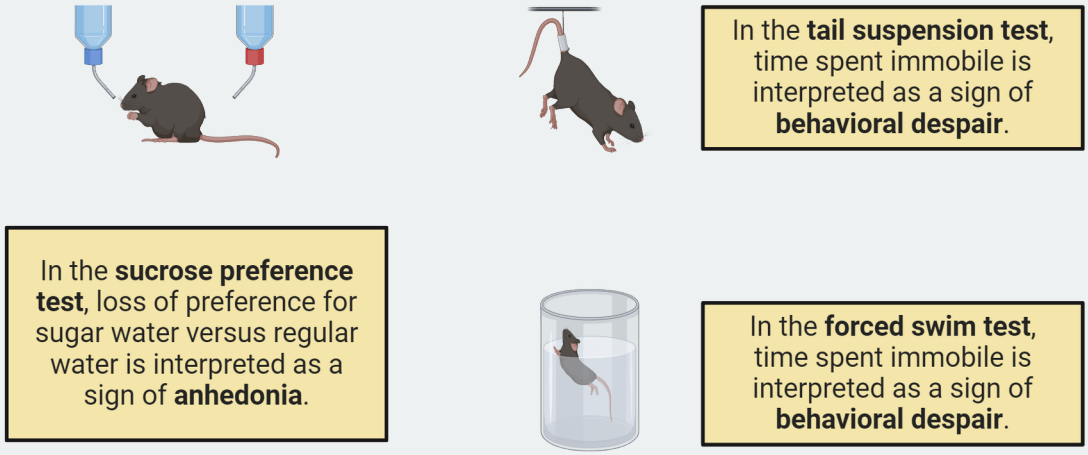

Figure 12.10 Depression assays in rodents

In the sucrose preference test, we measure whether a mouse has lost its preference for sweets (a rewarding treat). Rodents tend to prefer a sweet solution over plain water. Decreased preference for the sucrose solution indicates a loss of interest in pleasurable, rewarding stimuli. This mimics anhedonia—a decreased ability to experience pleasure from activities usually found enjoyable—which is a core symptom of depression in humans.

Two additional assays that measure the core depressive-like symptom of behavioral despair in rodents are the forced swim test (FST) and tail suspension test (TST). These 2 tests were both originally developed as screening tools for antidepressant drugs.

As described above, the FST measures time spent immobile as an indicator of behavioral despair. In the tail suspension test, a rodent is hung from a tube by its tail 10 cm above the cage floor for a brief period of time. After an initial struggle, the rodent will exhibit periods of immobility which are thought to reflect lack of active escape behavior. In both tests, increased immobility is interpreted as a sign of behavioral despair. Antidepressants shorten this immobility period, showing the key criterion of predictive validity. Notice that the FST and TST are stressors themselves. Thus, you can both induce stress and measure the behavioral response which make them convenient tools for quickly screening drugs. The FST in particular has excellent capacity to detect effective treatments. However, to model a disease, a panel of behavioral assays that measure different aspects of the disorder and capture the widest range of human symptoms should always be utilized. Can you think of any potential limitations in using tests like the FST or TST? How else could one interpret 'immobility' in these tests?

4.5.3: Neural Mechanisms and Circuitry of the Stress Response

Learning Objectives

By the end of this section, you should be able to

- 12.2.1 Describe the fast (millisecond) neural mechanisms that mediate the 'fight-or-flight' response
- 12.2.2 Understand the function of the endocrine system and its role in the stress response
- 12.2.3 Describe the circuitry of stress in the brain
- 12.2.4 Explain how stress modulates the function of stress-responsive regions of the brain
- 12.2.5 Identify the connection between the neural circuitry of stress and HPA axis function

Recall that the stress response consists of the following sequence of events. A threat cue arrives; for example, we spot a mountain lion during our morning run. Or we might *perceive* that such an event might occur (we hear a roar or we remember reading in the news that a mountain lion was sighted here last week). The brain's alarm center—the amygdala—is activated with input from other brain regions like the hippocampus which provides situational context information and the prefrontal cortex which regulates decision-making. The amygdala activates: 1) the sympathetic ('fight-or-flight') branch of the autonomic nervous system which mediates a fast (millisecond) neural response culminating in the release of epinephrine (also known as adrenaline) and 2) the hypothalamus, which initiates a slower, hormonal response (hypothalamic-pituitary-adrenal (HPA) axis response) that requires 3-4 minutes to start reaching the body's organ systems via circulating blood. These two systems (nervous and endocrine) are interconnected and work very tightly with one another to facilitate this response. We are now prepared to respond: fight, flee or freeze for further perception and defensive action planning. Termination of the stress response occurs later via engagement of the parasympathetic branch of the autonomic nervous system, which opposes sympathetic activation, and activation of allostatic mechanisms that restore homeostasis.

In this section, we will learn the steps of activation and deactivation in each of these systems and the neural circuitry (major stress-responsive brain regions) that both mediate and are in turn, modulated by stress exposure.

Sympathetic versus parasympathetic nervous system function

Recall from Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy that the autonomic nervous system (ANS), also known as the involuntary nervous system, regulates housekeeping or vegetative bodily functions. The ANS has two 'branches': the parasympathetic nervous system (PNS) and the sympathetic nervous system (SNS). Both systems innervate the same organs, but in an opposing manner. While the PNS mediates 'rest-and-digest' functions, the SNS is involved in the quick (millisecond) neural 'fight-or-flight' response as shown in Figure 12.11.

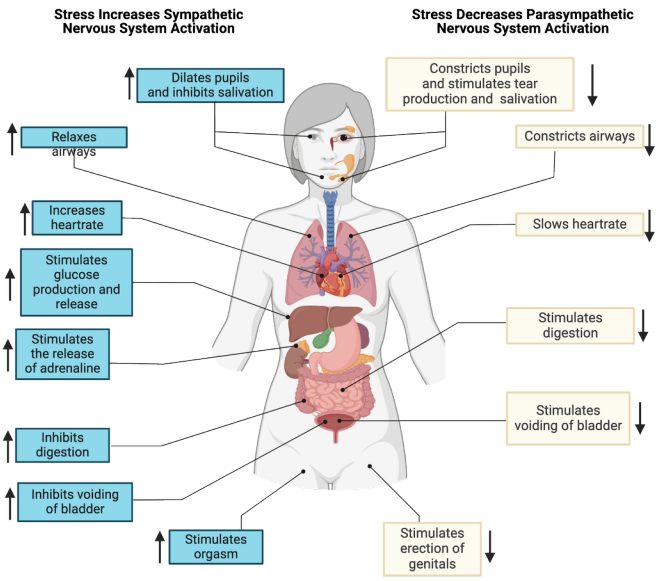

Figure 12.11 Stress and the autonomic nervous system

The SNS mediates this rapid neural response to stress in two ways:

1. Direct innervation of organs/tissues to effect changes through neural signaling (sympatho-neural system). This pathway originates in the hypothalamus and releases norepinephrine (noradrenaline) onto visceral effectors in target organs, e.g. the heart, lungs, stomach, liver, etc.
2. Through innervation of the adrenal gland medulla (sympatho-adrenomedullary system). This pathway synapses directly onto chromaffin cells of the adrenal medulla, triggering the release of epinephrine (adrenaline) into circulation. It mimics the hormonal response we will cover next to some extent because it results in hormonal release, but it is carried out via neuronal innervation of the adrenal medulla (not through a 2-step chain of hormones). The adrenal gland is also unique in that it does not receive PNS innervation like other glands/organs do.

Epinephrine and norepinephrine are very similar in structure and function. Their downstream effects are broadly to increase heartbeat resulting in increased blood pressure, shunt blood away from the skin and viscera to the skeletal muscles, create a rise in blood sugar, and increase metabolic rate, bronchodilation, and pupillary dilation.

HPA axis stress response

Coincident with the SNS activation upon perceiving a stressor, the hypothalamic-pituitary-adrenal axis (HPA axis) is also activated, leading to a chain of events involving multiple glands in order to produce powerful and sometimes long-lasting effects. While the SNS activation takes milliseconds, the sequence of steps in HPA activation take several minutes to be triggered one after the other. Like the SNS, though, the HPA axis is typically tightly regulated by multiple excitatory and inhibitory signaling inputs, ensuring a rapid response to stressful events, and a timely shut down of the response and return to equilibrium.

The HPA axis consists of the tiered release of 3 hormones from the 3 structures/glands that comprise it (the hypothalamus, the pituitary and the adrenal glands). The sequence of steps is diagrammed in Figure 12.12.

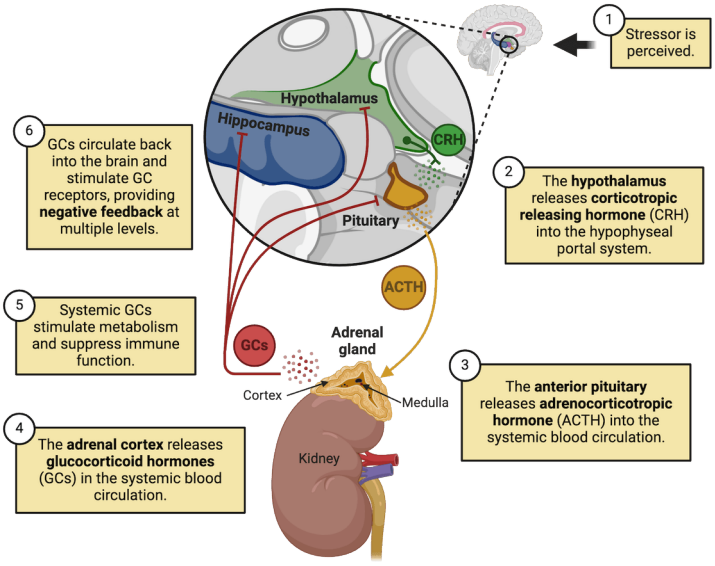

Figure 12.12 HPA axis

A stressor is perceived and corticotropin releasing hormone (CRH) is released from the hypothalamus into the hypophyseal portal system, a small blood network that connects the hypothalamus to the anterior pituitary (step 2 in Figure 12.12). As shown in Figure 12.13, the pituitary gland is comprised of two distinct anatomical parts: the anterior pituitary and posterior pituitary. The anterior pituitary produces and secretes various hormones in response to signals from the hypothalamus. Most relevant to the stress response, CRH from hypothalamic neurons stimulates the anterior pituitary gland to produce and secrete adrenocorticotropic hormone (ACTH) into the systemic bloodstream (step 3 in Figure 12.12).

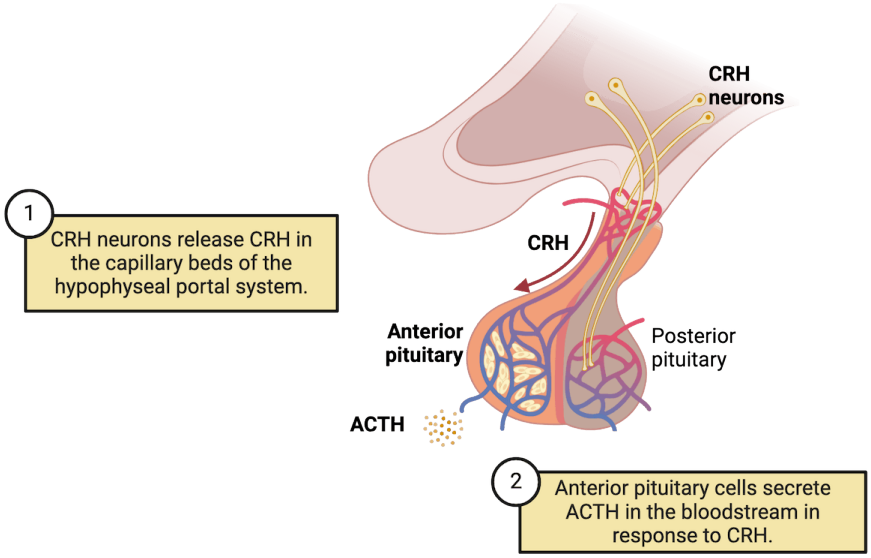

Figure 12.13 Microcircuit of the pituitary gland

ACTH circulates throughout the body, eventually reaching the adrenal glands, which sit on top of the kidneys. ACTH then induces the synthesis and release of the glucocorticoid hormone cortisol (cortisol in most mammals including humans; corticosterone in most laboratory rodents) from the cortex (outer shell) of the adrenal glands (step 4 in Image Figure 12.12). Glucocorticoids have massive and far-reaching effects on the body and brain, including increases in blood pressure, increased glucose circulation, decreased reproductive axis output, complex effects on immune functions and various other effects (step 5 in Figure 12.12). In addition to glucocorticoids, the adrenal gland also produces epinephrine and various other hormones from cells in the adrenal medulla (inner core) in response to the fast neural stress response described above. The adrenals are therefore a convergence location for HPA and neural components of the stress response, albeit via separate parts of the gland.

Feedback mechanisms

Glands of the endocrine system not only secrete hormones, but they respond to them as well. These responses allow for tight regulation of the amount of hormones in the bloodstream. One of the ways it achieves this is through feedback to the original gland. Negative feedback in an endocrine system like the HPA axis occurs when a hormone feeds back to some level of its activating system in order to inhibit further secretion.

There are several classifications of feedback in endocrine systems, diagrammed in Figure 12.14.

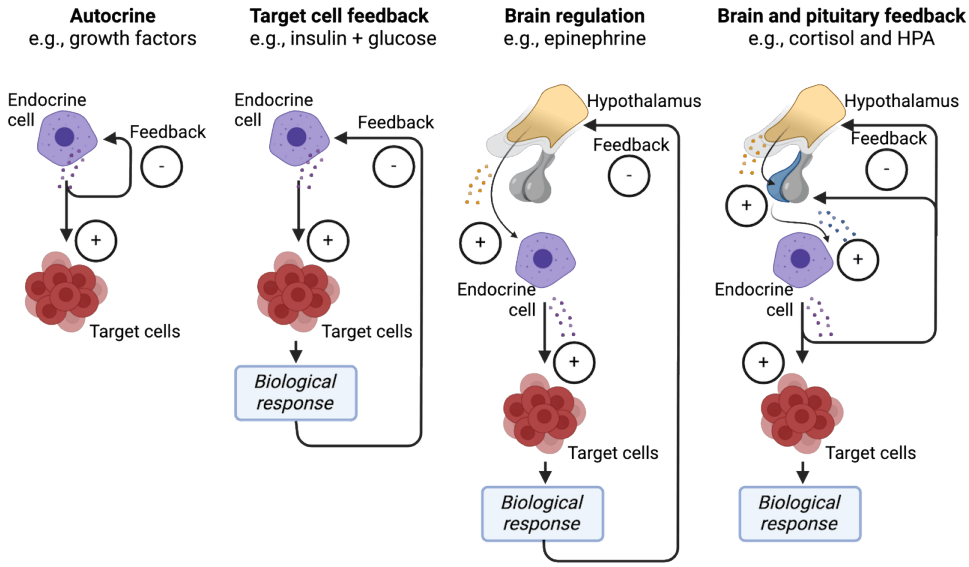

Figure 12.14 Feedback mechanisms

When a hormone binds to receptors on its originating cell to change hormone secretion levels, it is called autocrine feedback. Another mechanism, called target cell feedback, occurs when a hormone binds a target cell and elicits a biological response that feeds back to the original driver and inhibits further secretion. Feedback mechanisms can get complex and involve regions of the brain in addition to glands. Negative feedback involving the brain can look like an endocrine response that feeds back to the brain region that initiated hormone secretion (often the hypothalamus) in order to shut that brain region activity down (brain regulation). Sometimes the pituitary also gets involved, working as an intermediary between the higher brain region and the endocrine cells (brain and pituitary feedback).

HPA axis negative feedback fits the 'brain and pituitary' model, occurring at multiple levels, shown in Figure 12.14. The major negative feedback targets of glucocorticoids released by the adrenals is shown as step 6 in Figure 12.12. Most proximate to the adrenals, the pituitary gland responds directly to glucocorticoids, shutting down production of ACTH in response to high glucocorticoid levels. When pituitary function is impaired, it can impact the homeostasis of the HPA axis and potentially cause other neuropsychiatric symptoms by altering the function of other brain regions. For instance, Cushing's syndrome is a type of pituitary adenoma (benign tumor) that produces too much ACTH, resulting in overflowing glucocorticoids in the body. Patients with Cushing's syndrome not only exhibit impaired body metabolism, but also display comorbidity with various psychiatric conditions, for example personality disorders, psychosis, depression, and anxiety disorders. Although the exact mechanisms underlying the link between Cushing's syndrome and psychiatric disorders are unknown, it is likely that the high glucocorticoid levels may directly impact other brain regions expressing glucocorticoid receptors or indirectly impact overall brain function at a circuit level.

The hypothalamus is also an important regulator of the pituitary and serves as a site for glucocorticoid feedback resulting in inhibition of CRH secretion. Several other brain regions also participate in glucocorticoid negative feedback to the HPA. The hippocampus has direct connections with the hypothalamus, and these inhibit the hypothalamus when the hippocampus is exposed to high levels of glucocorticoids. Receptors for glucocorticoids are also expressed in other areas of the limbic system, such as the prefrontal cortex, amygdala, and thalamus. Negative feedback through these indirect pathways to the hypothalamus shuts down the response elicited by the HPA axis. These areas of the limbic system contribute to control of the HPA axis and create more complex feedback mechanisms. We will learn more about these higher brain regions' roles in the stress response in later sections.

Stress hormone cortisol receptor signaling

Both negative feedback and the effects of glucocorticoids on body organ systems rely on these hormones binding to receptors expressed on target cells. Glucocorticoids, like cortisol, can bind to receptors expressed by cells all over the body. In fact, every cell in our body expresses at least one type of glucocorticoid receptor. While most neurotransmitter receptors we have learned about are present on the cell surface (see Chapter 3 Basic Neurochemistry), glucocorticoid receptors are found mainly inside the cell, floating in the cytoplasm. Glucocorticoids like cortisol, the main stress-related glucocorticoid in humans, are steroid hormones, which are lipid-based. Being small fatty molecules, they diffuse freely through the cell membrane to bind intracellular glucocorticoid receptors. When the ligand cortisol binds to a glucocorticoid receptor, there is a conformational change in the receptor itself that leads to dimerization with another activated receptor, and exposure of a nuclear localization signal that directs it to the nucleus. In the nucleus, the dimerized complex acts as a transcription factor, and modulates the transcription of thousands of genes (Figure 12.15). This mechanism of action is global to all cells, but different cell types respond with a unique pattern of gene expression changes, which arises from the specific array of receptor and transcription factors expressed in each cell.

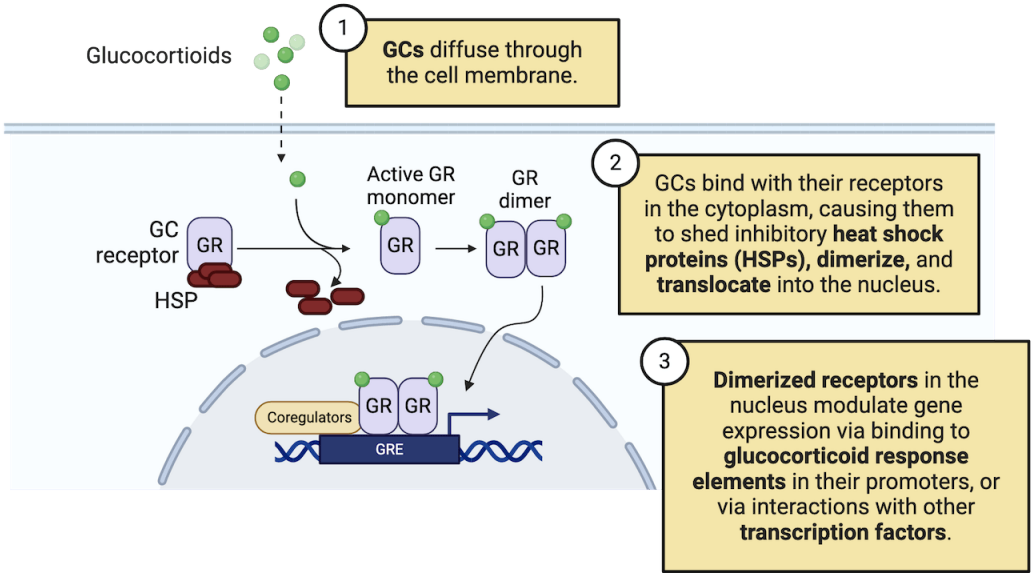

Figure 12.15 Glucocorticoid receptor action

There are two different receptors for glucocorticoids, called glucocorticoid receptor (GR) and mineralocorticoid receptor (MR). Cells can have one or both. MRs are expressed in the kidney, colon, heart, adipose tissue, sweat glands, and central nervous system. They bind aldosterone and cortisol with high affinity. In vivo, MRs are 80-100% occupied at normal levels of cortisol. GRs, on the other hand, are expressed everywhere in the body and bind cortisol with lower affinity. GRs range from 10-80% occupancy. At normal cortisol levels, there is lower GR occupancy and at high levels there is higher occupation, making GR the stress-responsive receptor (Figure 12.16).

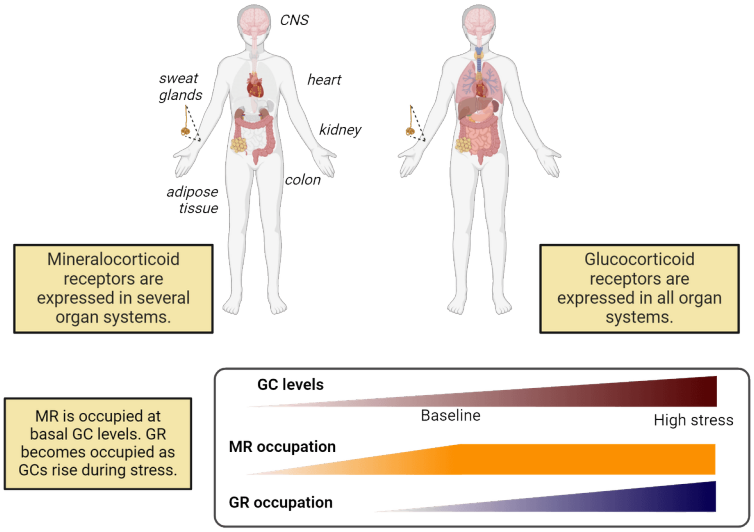

Figure 12.16 Glucocorticoid receptor (GR) and mineralocorticoid receptor (MR) expression and occupancy

SNS and HPA axis effects on the body and restoring balance

Do epinephrine/norepinephrine and cortisol have the same physiological effects? Mostly yes. This is because the rapid neural response and slower HPA endocrine response converge on the same organ systems. At first glance, this seems redundant. This convergence, however, means that there are numerous spots for regulation such that if a particular mechanism fails, there is a backup mechanism that can orchestrate the same alarm response.

We've learned throughout this topic that there are negative feedback loops that can stop the stress response at discrete points, for example, during HPA axis activation. But how is balance restored to the whole organism after this type of massive activation? Clearly, the SNS must be de-activated and the PNS must be activated. One of the ways of engaging PNS function is through deep breathing. This expands the diaphragm which stimulates the vagus nerve. The vagus (cranial nerve X) supplies parasympathetic information to visceral organs of the cardiovascular, respiratory, digestive and urinary systems and vagal stimulation activates the PNS. Termination or the 'end' of the stress response is not a clear-cut event, however. Cortisol, for example, can remain elevated for hours.

How stress affects the brain and behavior

We know that stress affects all organs throughout the body. However, the effects of stress on cells and circuitry of the brain are critical, because the brain regulates both arms of the response—the nervous and endocrine systems. In this section, we will move beyond the HPA axis and learn how connections between individual brain regions shape information and ultimately behavior. The brain regions we will discuss are summarized in Figure 12.17.

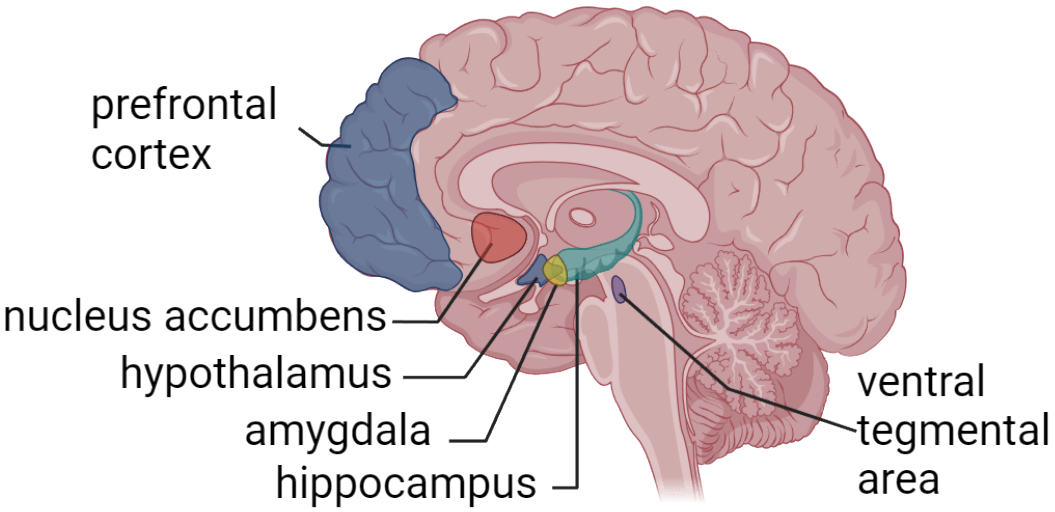

Figure 12.17 Major stress-sensitive brain regions

Amygdala

The amygdala is an almond-shaped cluster of nuclei located in the medial temporal lobe and is comprised of several subregions that are interconnected in a microcircuit. There are 2 amygdalae, one in each cerebral hemisphere. The amygdala as a whole helps coordinate emotional responses such as anxiety and fear to aversive stimuli (see Chapter 13 Emotion and Mood). It plays a major role in the processing of physiological and behavioral responses to stress and is characterized by high inhibitory tone under resting state conditions. Exposure to stress, through threat-related input from the thalamus or high levels of glucocorticoids, leads to hyperactivity of the amygdala and is accompanied by the removal of this inhibitory control. The prefrontal cortex (PFC; discussed below), which mediates executive function, can balance amygdala activity by providing part of this inhibitory tone. The amygdala, in turn, sends outputs to the paraventricular nucleus of the hypothalamus (where CRH is synthesized), as well as several other brain regions that help coordinate fear and anxiety responses.

As a result of its role in emotion coordination, amygdala activity can potently modulate learning and memory, particularly fear learning induced by stress (see Chapter 18 Learning and Memory). For example, disrupting or blocking basolateral and central amygdala GRs attenuates fear conditioning in rodents (Donley et al., 2005, Kolber et al., 2008). Some of the stress-related regulation of learning also appears to rely on the direct actions of CRH, released by hypothalamic neurons directly onto neurons of the central nucleus of the amygdala which express CRH receptors (Haubensak et al., 2010; Gilpin et al., 2015; Tovote et al., 2015). Additionally, inhibition of central amygdala-CRH neurons disrupts the extinction of conditioned fear memories, indicating a potential role for this subpopulation of neurons in stress-associated fear learning (Jo et al., 2020).

The function of the amygdala in response to stress has been well documented in studies that utilized functional magnetic resonance imaging (fMRI) which measures small changes in blood flow as a proxy for brain activity (see Methods: fMRI). It is notable that patients with PTSD exhibit exacerbated amygdalar responses to emotional stress compared to healthy individuals (Morey et al., 2012). Thus, while some stress may enhance fear learning, too much can be detrimental (the inverted U). Stress-reduction interventions such as mindfulness-based training are correlated with decreases in the amygdala structure density (Holzel et al., 2010), underscoring the importance of the amygdala in the stress response and as a target for stress-reduction interventions.

Hippocampus

The hippocampus, located in the medial temporal lobe of each cerebral hemisphere, is an integral brain region for stress responses. It is highly sensitive to stress due to the abundant expression of GR and MR stress hormone receptors (Sapolsky et al., 1984). As we learned earlier in this section, the hippocampus plays a role in negatively regulating HPA axis activity, particularly in the shutdown of the HPA axis following activation. The hippocampus also mediates stress effects on several forms of learning and memory in complex ways. Stress can have both enhancing and impairing effects on hippocampal memory depending on the severity, length, and the stage that is affected (memory formation, consolidation, or retrieval). Generally, emotionally arousing

events are very well remembered, a process mediated via GR signaling and amygdala input. Experiencing moderate or severe levels of stress, for example, may boost memory formation (a traumatic event tends to be very strongly encoded). However, because stress exposure can also modulate other stages like memory consolidation and retrieval, severe stress may also lead to impaired memory function.

The hippocampal response to stress involves several cell types, including neurons and glia, both of which may contribute to stress-related pathology or resilience in the hippocampus (Figure 12.18). Mature neurons in the hippocampus are highly sensitive to steroid stress hormones. Activation of MR/GR-expressing hippocampal neurons is a critical part of the HPA axis negative feedback loop to the hypothalamus. Hippocampal neurons also change how they function in response to stress, particularly if the stressor is chronic. For example, a series of studies revealed that stress-associated neurosteroids can impact long-term potentiation (see Chapter 18 Learning and Memory) or neurotransmitter release from the presynaptic terminals in hippocampal neurons (Venero and Borrell, 1999; Karst et al., 2005; Groeneweg et al., 2011; Popoli et al., 2011).

One relatively unique (and stress-sensitive) aspect of the hippocampus is that it is one of very few regions in the adult brain that can generate new functional neurons in most mammalian species that have been studied to date. Integration of new neurons to existing neural circuitry has been implicated in spatial and emotional learning and memory functions, and in the regulation of the HPA axis. For example, increased neurogenesis in the ventral region of the dentate gyrus can reduce responses to anxiogenic (stress-inducing) stimuli (Anacker et al., 2018), indicating that neurogenesis may serve as a potential mechanism for resilience to stress. In addition to mediating responses to stress, adult neurogenesis is also regulated by exposure to stress. Chronic or traumatic stress exposure is a strong suppressor of hippocampal neurogenesis (Snyder et al., 2011; Cameron and Glover, 2015; Anacker et al., 2018; Cope and Gould, 2019). Acute moderate stress, in contrast, can promote adult hippocampal neurogenesis and is correlated with increased fear extinction (Kirby et al., 2013). The neurogenic response to stress, therefore, also shows the inverted-U pattern that is common to stress responses.

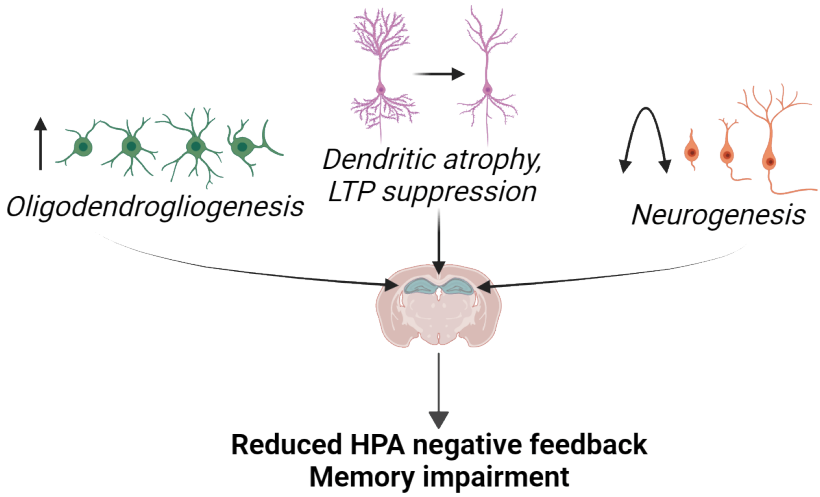

Figure 12.18 Hallmarks of stress in the hippocampus

In addition to neurons, other supporting cells (glial cells) can respond to stress and play a role in stress integration. For example, a series of recent studies have highlighted a role for oligodendrocytes in response to stress. Chronic stress can promote the generation of oligodendrocyte precursor cells via glucocorticoid exposure and susceptibility to acute stress is linked to increases in myelin plasticity in the rat hippocampus (Chetty et al., 2014; Long et al., 2021). These findings indicate a potential role for hippocampal myelin and oligodendrocyte plasticity in stress susceptibility and resilience.

Prefrontal cortex

The cortex is comprised of multiple complex brain structures that play a key role in cognitive and executive functions. In this section, we will learn about a key cortical area, the PFC, and projection areas such as the ventral tegmental area (VTA) and nucleus accumbens (NAc) in HPA axis integration and the stress response.

The PFC is located in the anterior part of the frontal lobe and occupies one third of the frontal lobe in the human cerebral cortex

(see Chapter 19 Attention and Executive Function). Through its interaction with other brain regions, the PFC orchestrates complex cognitive tasks requiring attention, planning, reasoning, and decision-making and exerts top-down or high-order control of other brain regions. Part of that function, which we discussed above, is providing inhibitory input to the amygdala, thereby helping to prevent, reduce or terminate stress responses.

Catecholamines play an important role in stress regulation of PFC function (see Chapter 3 Basic Neurochemistry). Dopamine, in particular, modulates PFC function and PFC function modulates dopaminergic function. Figure 12.19 diagrams these two types of pathways (DA to PFC and PFC to DA).

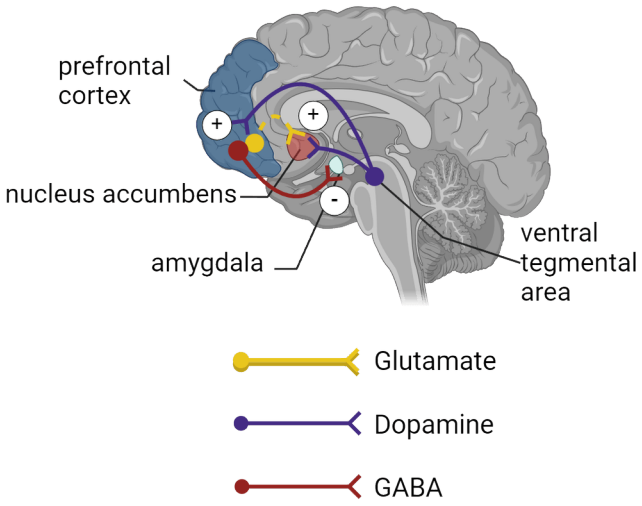

Figure 12.19 PFC dopamine interactions during stress

First, a large group of dopamine neurons in the VTA are known to project their axons to the PFC (Guiard et al., 2008) (see Chapter 14 Psychopharmacology). These dopaminergic neurons fire in response to stressful stimuli. Thus, when exposed to stress, a subset of VTA dopamine neurons is activated (Brischoux et al., 2009), and the activated dopamine neurons in the VTA projecting to the PFC increase dopamine neurotransmitter levels in the PFC (Holly and Miczek, 2016). Small amounts of dopaminergic stimulus in the PFC will acutely increase PFC functions like working memory but if the stressor is more severe, it can flip to causing deficits in working memory (i.e., an inverted-U relationship).

The PFC feeds back onto the dopaminergic system via its projections to the NAc, converging there to modulate dopamine input from the VTA onto the NAc neurons (see Figure 12.19). The NAc is well-known for reward learning behavior, but recent studies point to a role in negative prediction error—predicting negative outcomes based on previous learning experience—as part of a coping mechanism for inescapable stress (Cui et al., 2020). The NAc receives glutamatergic inputs from the medial PFC (mPFC) and stimulation of mPFC has been shown to stimulate dopamine release in the NAc (Quiroz et al., 2016). This signaling supports the negative prediction error coping mechanism.

Neurochemical balance often plays a key role in the high-order control mediated by the PFC. As noted above, some dopaminergic input in the PFC promotes function while too much impairs it. Both acute or chronic stress can lead to neurochemical imbalances in the PFC (for example, increase in catecholamine neurotransmitter release (Finlay et al., 1995)). Long-term or severe shifts in dopamine input (and other neurotransmitters) result in dysregulation of other brain regions while eliciting susceptibility towards various neuropsychiatric disorders including PTSD, mood disorders, and attention deficit and hyperactivity disorders (ADHD).

Hypothalamus

As we saw previously, the HPA axis is critical for maintaining endocrine homeostatic balance, but more recent studies have also provided circuit-based evidence that hypothalamic CRH neurons (which release the first of the HPA axis trio of hormones) serve as a key component for proper behavioral responses to acute stress in rodents. We've previously mentioned how CRH input in the amygdala seems to directly support fear extinction, but CRH has other direct behavioral effects and may be particularly important for stress coping behaviors. Upon exposure to acute foot-shock stress, for example, mice exhibit distinct behaviors such as grooming, walking, and rearing. When hypothalamic CRH neurons are inhibited via optogenetic silencing (see Methods:

Optogenetics), these behaviors are not displayed, indicating that hypothalamic CRH neuronal activation is important as part of stress-coping mechanisms (Fuzesi et al., 2016).

4.5.4: Interindividual Variability and Resilience in Response to Stress

Learning Objectives

By the end of this section, you should be able to

- 12.3.1 Describe the factors that influence interindividual variability in the stress response
- 12.3.2 Explain the concept of resilience and describe some of the beneficial effects of stress
- 12.3.3 Describe some useful strategies to optimize the stress response

Not surprisingly, individuals vary greatly in their response to stress due to factors like genetics, epigenetics, biological sex, developmental and later life history, and even preconceptional and transgenerational influences. Additionally, factors like how a stressor is perceived, whether it's predictable or controllable and the social milieu can dramatically alter an individual's response. The good news is that not all stress is bad—moderate stressors have beneficial effects. In addition, multiple interventions including physical exercise, breathing exercises, meditation, and mindfulness-based stress reduction are proven techniques that can help not just mitigate but optimize one's response to stress.

Factors that influence interindividual variability in response to stress

So far, we have described the generic response that is activated by stress—a response that is similar between many different manifestations of stress (physical, social or psychological) and evolutionarily conserved across taxa. This response involves the stereotypical neural and endocrine axis activation, but it can vary greatly between individuals. Biological, life history and psychological factors all contribute to this interindividual variability. For example, an individual's genetic and epigenetic makeup, biological sex, and stress exposure during critical periods (e.g., *in utero*, neonatal and early life, adolescence, and exposure during aging later in life) all impact their response to stress. Recent evidence suggests that preconceptional and transgenerational mechanisms are also involved in setting up or shaping this interindividual variability. Finally, factors like an individual's physiological and emotional state (are they hungry, tired), psychological differences in how a person perceives/appraises a stressor, whether the stressor is deemed as predictable or controllable, the availability of social resources, and specific characteristics of the encountered stressor can all lead to a more heterogeneous and fine-tuned response.

Genetic factors

Genetic factors that influence the stress response include polymorphisms in genes involved in glucocorticoid signaling and HPA axis regulation, monoamine neurotransmitter function, and regulation of brain plasticity. For example, the gene encoding FK506-binding protein 51 (FKBP5/FKBP51) is an important modulator of stress responses. FKBP5 acts as a co-chaperone for the glucocorticoid receptor. Specific alleles of the FKBP5 gene (e.g. T allele) are associated with blunted GR-dependent feedback inhibition of the HPA axis, resulting in dysregulated axis function (e.g. prolonged cortisol responses). In other words, people with certain genetic forms of the FKBP5 protein will take longer to turn off the HPA axis (and get their circulating cortisol levels back to normal) after a stressor because of impaired GR function compared to people with more typical forms of FKBP5.

These mutations in FKBP5 (and the chronically impaired shutdown of stress responses) have clinically relevant effects on behavior. For example, the T allele is associated with increased anxiety, attentional bias towards threat, hippocampal activation after fear/threat induction, and changes in amygdala volume which can predispose to development of stress-related pathology. In fact, alleles associated with greater FKBP5 induction and longer cortisol responses are associated with higher risk for Major Depressive Disorder, Posttraumatic Stress Disorder, suicidality, psychosis, aggression and violent behavior (for review see Zannas et al., 2016).

Developmental Perspective: Critical periods for stress exposure

Just like there are critical periods for learning and development, there are critical periods for stress exposure (see Chapter 5

Neurodevelopment). During periods of our development, the brain is especially plastic, allowing for changes that can translate to risk or resilience in the face of stress later in life. During these periods, factors in the environment combine with those of our genetics to influence neurodevelopment. These effects can persist into adulthood, influence the trajectory of our lives, and manifest as vulnerabilities to mental health.

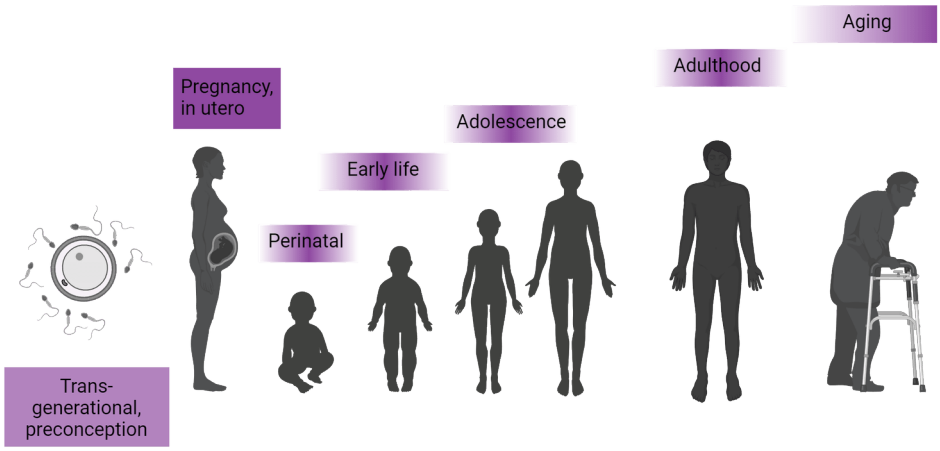

Figure 12.20 Stress-critical periods

In utero

Before birth, our neurodevelopment is already being influenced by the world around us. Many studies of prenatal stress come from retrospective studies where a mother has experienced a disaster, for example war, malnutrition, hardship in personal relationships, or tensions in their everyday environment. Many of these retrospective studies have focused on historical events, for example, a year of extreme food shortage in the Netherlands during World War II, known as the Dutch famine, or more recently the events in New York City on September 11, 2001, also known as the 9/11 attacks, which affected women at different stages of pregnancy.

As we know, stress exposure elicits an HPA axis and neural response. Although the placenta acts as a selective barrier, some stress hormones produced by the mother can cross through the placenta and reach the fetus, triggering release of additional stress hormones (Weinstock, 2005). Evidence suggests that maternal stress exposure is associated with shorter gestational age, increase in preterm births, low birthweight, and small size for gestational age (Class et al., 2011). This exposure to maternal stress and high cortisol levels can also lead to deficits in mental development scores and cognitive ability once a fetus matures into childhood (Brouwers et al., 2001; Bergman et al., 2010). It is also associated with autistic traits and ADHD behaviors (Ronald et al., 2011), emotional problems (O'Connor et al., 2002), and higher cortisol response to a stressor (Davis et al., 2011). Animal models show that maternal stress alters HPA axis function, cortisol, and CRH levels throughout the lifetime of the offspring (Weinstock, 2008). Thus, the effects of maternal stress hormones can alter neurodevelopment in the fetus and contribute to adverse consequences throughout life.

Early life stress

Exposure to stress that occurs in the timeframe from infancy to adolescence, can also have a major impact on the trajectory of development. During this period, stress can come from maltreatment, neglect, or exposure to trauma or stressful life events (see Chapter 5 Neurodevelopment). Early life stress can increase the risk of developing psychiatric disorders in adulthood (Carr et al., 2013), for example depression and anxiety (Heim and Nemeroff, 2001). It can also increase the likelihood of developing alcohol or drug dependence (Enoch, 2011). In rodents and primates, early life stress can evoke depression-like behaviors and altered HPA axis responsiveness that lasts into adulthood (Pryce et al., 2005).

Epigenetics, the chemical modification of DNA without a change in nucleotide sequence, can account for a major part of the developmental trajectory following stress. To understand this idea of epigenetic modification, we first need to appreciate how

DNA is packed into the nucleus. The DNA contained in each cell's nucleus is not lying about like loose spaghetti. It is actually packed together quite purposefully, folded and wrapped around on itself and around proteins called histones so that the ~3 billion nucleotide base pairs that make up the human genome can fit into the cramped quarters of the nucleus. Epigenetic changes are chemical modifications attached to the DNA itself or to the histones that the DNA wraps around. These modifications change how loosely or tightly the DNA is packed. Genes that are in stretches of DNA that are packed up especially tightly are less readily expressed (transcribed into RNA) while genes in segments of DNA that are packed more loosely are accessible and more easily transcribed.

Early life stress has been shown to induce changes in the epigenome, specifically in genes that regulate the HPA axis, which persist throughout life and can modulate HPA axis and stress reactivity. For example, the quality of maternal care during the neonatal period—modeled in rodents as increased pup licking and grooming by rat mothers—results in epigenetic modifications that enhance feedback sensitivity and efficient HPA axis shutdown following stress. See Feature Box on the persistent effect of maternal care on stress vulnerability and resilience. Similarly, early life stress (duration of maternal separation, for example) has been shown to induce changes in the epigenome that persist throughout life and can confer either vulnerability or resilience to stress. Additionally, recent research is beginning to uncover how transgenerational effects (i.e., events experienced by previous generations) can modulate individual variability in stress responses. See Feature Box on preconceptional, historical and transgenerational effects of stress.

Adolescence

The transition from childhood to adolescence represents another vulnerable period to stress exposure. Internally, dramatic physiological and hormonal changes occur (see Chapter 11 Sexual Behavior and Development). At the same time, the development of complex behaviors, including a notable dependence on peer relationships, as opposed to parental ones, emerges. These intense changes combined with high brain plasticity makes adolescence a crucial period in development where vulnerability is heightened. Exposure to stress during this period has been shown to increase the risk for depression and is associated with social and educational impairments (Fletcher, 2010).

Aging

In aging populations, changes in the brain and in the endocrine system occur in some, but not all individuals. A particularly vulnerable part of the brain to the aging process is the hippocampus. During aging, a decrease in hippocampal function and reactivity to cortisol leads to a decrease in the efficient shut down of HPA axis activation. This is seen in some aged individuals as hyper-reactivity to stress, resulting in higher levels of baseline and stress-related cortisol, and a deficient shutdown of activation. This is a vicious cycle for the aging hippocampus, as the increased levels of cortisol lead to increased neurodegeneration, cellular vulnerability and memory decline, which contributes to greater effects from stressors and could be at least partially responsible for aging the hippocampus (Miller and O'callaghan, 2005).

People behind the science: The persistent effect of maternal care on stress vulnerability and resilience

How a mother cares for their child can vary widely. There are variations in social, emotional, and socio-economic contexts. If these variations result in neglect or abuse towards a child, they can lead to persistent negative effects on stress reactivity (vulnerability to stress). Drs. Darlene Francis, Frances Champagne, Michael Meany, and Moshe Szyf have made significant contributions to our understanding of the long- term effects of maternal care on stress reactivity. Through their work with rodents, initiated primarily at McGill University and subsequently pursued at other institutions, they showed that early experiences can translate into later life behaviors via epigenetic mechanisms. They studied this phenomenon using rats as a model. Rats, it turns out, can be very caring mothers and one of the main ways they care for their pups is by regularly licking and grooming them. Through observations of rat maternal behaviors like pup licking, grooming, and nursing, this team of researchers found that a greater frequency of these behaviors resulted in increased numbers of hippocampal GRs, enhanced glucocorticoid feedback sensitivity and more modest HPA axis responses to stress in the adult offspring of high maternal care mothers. Furthermore, their work showed that GR gene expression is controlled by epigenetic modifications (altered chromatin structure and DNA methylation of a promoter region for the GR gene) which can persist into adulthood (Liu et al., 1997; Weaver et al., 2004). Ultimately, their work provided valuable insight into the epigenetic processes behind transmission of individual variabilities in stress reactivity.

Preconceptional, historical and transgenerational effects of stress

Stress has obvious effects on one's own body and offspring, but there can be detrimental effects on subsequent generations as well. Ancestral environments and behaviors can create lasting beneficial or detrimental effects. One way in which the effects of stress can be transferred to a future generation is through biological inheritance. For example, when a mother conceives a female embryo, that offspring creates all the eggs she will have throughout her lifetime before she even leaves the womb. Any experiences of the grandmother then could have some effect on the granddaughter. Another mechanism of transmission is social inheritance. Maternal care is an excellent example of this: here a mother's care for their child can affect emotional outcomes later in life. Lastly, ecological inheritance or the shared experience of trauma at a community level can also be a mechanism of transmission. Survivors of the Holocaust and Native American experiences of genocide and oppression provide evidence that effects of trauma and stress can extend beyond the generation directly exposed and contribute to the development of depression, anxiety and PTSD in offspring that themselves were not exposed. These transgenerational effects most likely also rely on epigenetic modification of DNA. Evidence suggesting this ecological inheritance is seen in the offspring of trauma survivors, where low cortisol levels are associated with parental PTSD (Yehuda & Bierer., 2007; Perroud et al., 2014). Epigenetic modifications in the FKBP5 gene, a co-chaperone for the glucocorticoid receptor (discussed above under genetic factors affecting interindividual variability), have also been observed in both Holocaust survivors (mothers) and their offspring (Yehuda et al., 2016).

Transgenerational transmission is not only seen in humans, it applies to other species as well. *Caenorhabditis elegans* (nematode worms), for example, show altered gene expression in response to temperature changes for at least 14 generations (Klosin et al., 2017). They also show changes in small RNAs (regulators of gene expression) if ancestors were starved for extended periods (Rechavi et al., 2014). *Drosophila melanogaster* (fruit flies) also show an obesity phenotype for two generations if an ancestor was placed on a high-calorie diet (Buescher et al., 2013). In rodents, work by Dr. Brian Dias is revealing the epigenetic mechanisms involved in transgenerational inheritance of fear learning. You can learn more about Dr. Dias' innovative work and his path in research in the talk "Great Scientists, Great Failures".

Biological sex differences

Sex differences in stress responses have garnered significant attention within the field of neuroscience and psychology. Numerous studies have demonstrated that males and females exhibit distinct patterns of physiological and behavioral responses when faced with stressful situations. These differences extend to both acute and chronic stressors, with variations in stress hormone secretion, neural activation, and coping strategies. For example, rodent studies have shown that females exhibit unique patterns in the number, distribution, membrane trafficking, and signaling of CRH receptors (Bangasser and Wiersielis, 2018) - patterns which are affected by estrogen. Similarly, female rats are known to release higher levels of glucocorticoids after acute restraint stress (Goel et al., 2014). These differences point to nuanced, sex-specific HPA axis function in response to stress.

At the behavioral level, studies have shown, for example, that female rodents generalize fear responses more than males (see Chapter 18 Learning and Memory). Fear generalization occurs when conditioned fear responses 'spread' (or generalize) to new stimuli. This effect is dependent upon estrous cycle phase and thus has been linked to sex hormone, specifically estrogen signaling. Although stress is thought to affect fear learning-related brain regions similarly in males and females, distinct molecular and gene expression profiles at the synaptic level are sex-specific. Understanding these types of differences will allow us to develop more tailored and effective interventions. Women, for example, have higher prevalence of PTSD which involves aberrant fear conditioning, fear generalization and a lack of proper fear-extinction. For review, see Fleischer and Frick, 2023.

A main challenge in the field is the difficulty of setting up experimental designs that represent true sex differences using animal models. For example, some rodent models like social defeat stress are based on behaviors mainly exhibited by males. Thus, it has been challenging to examine stress responses using the same set of stressors and behavioral assays in animals of different sexes.

Stress perception, appraisal, and reappraisal

Appraisal of a stressor, whether a person perceives it as harmful or a positive, challenging experience, can dramatically change the stress response. Interestingly, an individual's response to stress seems to have a strong inherent or innate component. In humans, for example, an individual's genetic and environmental/epigenetic makeup affects their processing and perception of stress (i.e., positive or negative valence attributed to a stressor) such that individuals respond differently to the same stressor.

A study by Forkosh et al., 2019 identified four stable 'personality types' in mice (termed identity domains) based on unbiased behavioral tracking which persisted through time, developmental stages and stressful changes in their social environment. These 'personality types' corresponded to specific patterns of gene expression in the insular cortex, mPFC and amygdala.

Numerous studies have found that individuals who perceive stress as having a negative impact on their health suffer more serious health problems, including premature death (Keller et al., 2012; Nabi et al., 2013). Not surprisingly, abnormal patterns of appraisal are seen in various stress-related psychopathologies. The good news is that the stress response can be changed by reframing it as helpful. As mentioned in 12.1 What Is Stress?, a study by Jamieson et al. (Jamieson et al., 2012) tested whether reappraisal of stress-induced arousal (for example, a 'racing' heart) as helpful and adaptive, as opposed to harmful, could improve physiological and cognitive outcomes. The results showed that participants in the reappraisal group displayed a more adaptive physiological response (improved cardiovascular functioning), reported higher levels of perceived resources and showed decreased attentional bias for emotionally negative information. That is, they dealt much better with the stressful situation even when the reappraisal training consisted of brief instructional materials. Notice that the reappraisal intervention did not change the actual increased physiological arousal caused by the stressor; it is not an intervention aimed at decreasing or dampening arousal. What changed was the 'rethinking' of what that arousal means (whether it's positive versus negative) and that is what ultimately influenced the measured outcomes. Neuroimaging studies have shown that reappraisal is associated with activation of frontal cortical areas (i.e., regions regulating executive functions) like the dorsal anterior cingulate cortex and medial PFC (Kalisch, 2009).

Stress predictability and controllability in animal models

To understand the molecular mechanisms underlying appraisal, we must turn to animal models. However, animals cannot report if they are 'reappraising' a stressful situation, thus, we must examine whether things like predictability or controllability over the stressor can change their response. Experiments have shown that rodents exposed to stressors that were not predictable had significantly higher and longer glucocorticoid responses than those presented with a regularly scheduled stressor. Similarly, the work of Steven Maier's group at the University of Colorado Boulder has shown that controllability (a rat controls the cessation of a presented stressor by turning a wheel, for example) alters the neural and behavioral response, but doesn't change the HPA axis output. Animals receiving the exact same stressor (i.e., amount, intensity, and duration of an electrical shock) but who differed on whether they could terminate the shock or not, displayed similar HPA axis activation but dramatically different behavioral responses. Animals that could not stop the shock (uncontrollable stress) later failed to learn to escape in a different context, were afraid of new things, were less dominant, showed less social interactions, and had exaggerated responses to drugs of abuse (see Figure 12.21).

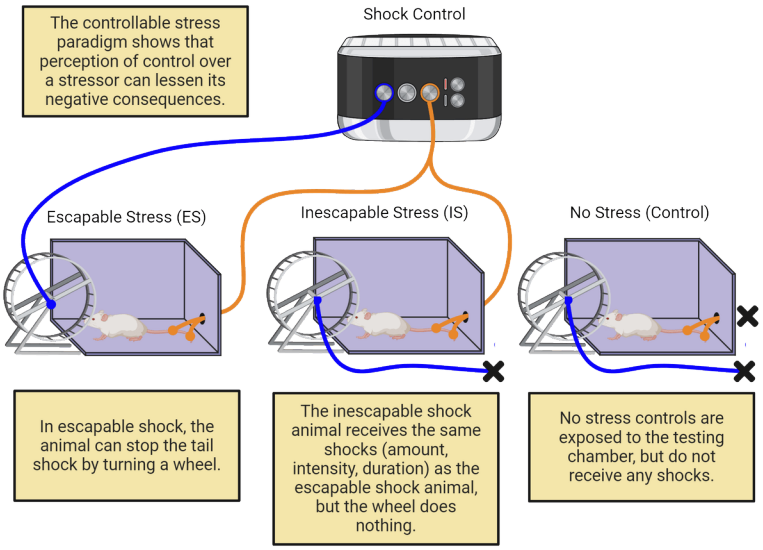

Figure 12.21 Controllable stress in rodents

A large amount of work has gone into understanding the neural circuitry of this behavioral difference. Studies have found that uncontrollable stress produces robust activity in the dorsal raphe nucleus which increases release of serotonin, amygdala activation, and development of learned helplessness. Exposure to controllable stress, however, activates the medial PFC which inhibits dorsal raphe nucleus activation and blocks the negative behavioral outcomes (Amat et al., 2005; Amat et al., 2006).

Social support and buffering of the stress response

Many social animals display an interesting characteristic: when together with a conspecific they show dampened stress responses and better recovery from stressful experiences. This phenomenon is called social buffering and it has been observed in numerous species including rodents, felines, birds, nonhuman primates and humans.

Candidate molecular mediators of social buffering

Not much is known about the molecular mechanisms or neural pathways mediating the effects of social buffering. A candidate molecular mediator is the neuropeptide oxytocin—which is known for its role in social affiliative behaviors in many mammalian species.

Although no direct mechanism has been established, evidence suggests that oxytocin is released in response to stress, is associated with social/affiliative interactions after stress and can decrease HPA axis activation (via inhibition of CRH activation and ACTH and corticosteroid release), as well as SNS responses (Taylor, 2002). Additional mediators involved in stimulating and regulating the effects of social support include norepinephrine/noradrenaline, prolactin, vasopressin, serotonin and endogenous opioids.

Brain regions involved in social buffering

In humans, a study by Eisenberger et al., (Eisenberger et al., 2007) found that greater social support and decreased cortisol responses to a social stressor were associated with decreased activity in the dorsal anterior cingulate cortex (dACC) and prefrontal cortex (PFC)—brain regions that have been linked to social distress. A recent study in adolescent mice also points to a role for the PFC. In this study, social support (the presence of a mouse attempting to free a restrained mouse) blocked the negative effects of restraint stress on working memory, memory consolidation and retrieval. These stress-alleviating effects were dependent upon inhibition of stress-induced signaling cascades and normalization of stress-induced gene expression changes in the PFC (Kim et al., 2018).

Stress drives social affiliation

Social buffering is encouraged by the fact that, in many social species, stress directly promotes behaviors that will increase social interaction. Thus, stress and social buffering can form a loop, where stress drives affiliative behaviors, which in turn reduce the experience of stress (see Figure 12.22). For example, moderate stress is associated with increased affiliative behaviors in rats. A study by Muroy et al (Muroy et al., 2016) found that moderate stress exposure increased affiliative behaviors (huddling/affiliative contact, better sharing of a water resource, improved homecage stability (dominance rank) and oxytocin signaling). When the stress was made more severe by addition of predator odor, however, oxytocin signaling was reduced and the positive social effects were eliminated. These findings suggest that even the drive for affiliation by stress may follow an inverted-U pattern.

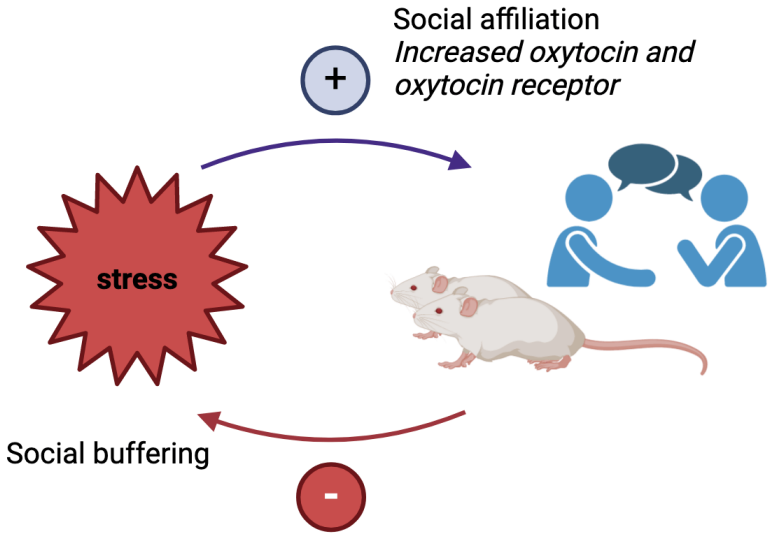

Figure 12.22 Stress-social behavior interaction Stress stimulates social affiliative behaviors, which lead to social buffering to reduce the impact of the stressor.

In humans, acute stress has also been shown to increase affiliative interactions and prosocial behavior. For example, increased time interacting and higher group cohesion were observed in study participants awaiting an electrical shock versus groups awaiting a mildly embarrassing or ambiguous stimulus (Morris et al., 1976). In terms of prosocial behavior, participants exposed to a socioevaluative stressor (the TSST) showed greater trust and sharing in interactive games with monetary stakes (von Dawans et al., 2012). Importantly, affiliative social interactions, for example, contact with a friend or other supportive person during times of stress can decrease sympathetic reactivity and cortisol levels, facilitating recovery. This, in turn, can positively influence health and life expectancy (for review see House et al., 1988; Taylor, 2011). Lack of social connection (e.g. social isolation), on the other hand, can increase HPA axis and SNS activity and is a major risk factor for stress-related psychiatric conditions like depression and anxiety.

Summary of factors affecting interindividual variability in the stress response

Figure 12.23 shows a summary of the factors discussed in this section. Factors and their associated brain regions are displayed at the top. Some brain regions are attuned to various factors. For example, the reward system is sensitive to predictability (i.e., novelty), controllability and duration of a stressor. The frontal cortex is similarly attuned to duration, controllability and stressor predictability, and additionally mediates stressor appraisal; the stress dampening effects of social support are integrated here as well. Brainstem regions, the circumventricular organs and the limbic system are attuned to stressor type and the physiological state of the organism (metabolic, inflammatory state, for example), which can influence an individual's perception of stress.

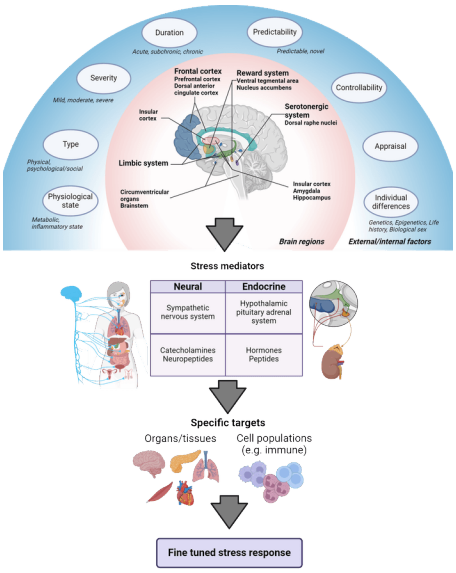

Figure 12.23 Summary of factors affecting interindividual variability in the stress response

The brain assimilates both external and internal inputs and constructs a 'grid' of brain activity specific for each stressor. This pattern of brain activity varies 1) between individuals (due to individual differences based on genetics, epigenetics, life history events, biological sex, emotional and physiological state, etc.) and 2) between different stressors. The response is then integrated at the level of the hypothalamus and specific brainstem nuclei to produce fine-tuned neural and endocrine outputs that are designed to deal with the specific challenge. For example, stressors that exert metabolic pressure (hypoglycemia) induce secretion of growth hormone from the pituitary gland (Jezova et al., 2007) while stressors that elicit pain activate pain relief pathways. The severity of the painful stressor further fine-tunes which type of pain relief pathway is activated: opioid versus non-opioid. Exposure to heat or cold stress requires activation of brown fat to restore internal body temperature, while encountering a mountain lion requires priming of the immune system in case of injury. For the latter two examples, specificity is mediated by differential activation of sympathetic fibers in adipose tissue and the spleen (an immune organ) respectively, in response to different types of physical stressors (Iriki and Simon, 2012). SNS peripheral nerve terminals can also co-secrete various neuropeptides that further fine tune the generic stress response.

Thus, the type of neural activation (e.g., which SNS fibers), variety of secreted factors, their concentration and different combinations diversify the stereotypical neural and endocrine stress response. Moreover, even secretion of the canonical stress hormones ACTH and corticosterone depend on the stressor context. For example, lactating female rats caring for a litter generally show blunted ACTH and glucocorticoid responses to common laboratory stressors. However, if the stressor involves danger to the pups (inclusion of predator odor or a male intruder in the home cage), then plasma levels of ACTH and glucocorticoids rise significantly (Deschamps et al., 2003). In this example, the organism's physiological state is also an important factor. For in depth review, see Haykin and Rolls, 2021.

Resilience

Resilience is the capacity to adapt following adversity. It is not a fixed trait—it can change throughout life and is multidimensional: for example, a person can be resilient to injury but not to psychological stress. The inverted-U curve can be used to understand how stress responsivity (vulnerability or resilience) varies between individuals (Sapolsky, 2015). For example, the curve can be right- or left-shifted along the x-axis (see the blue and orange curves in Figure 12.24).

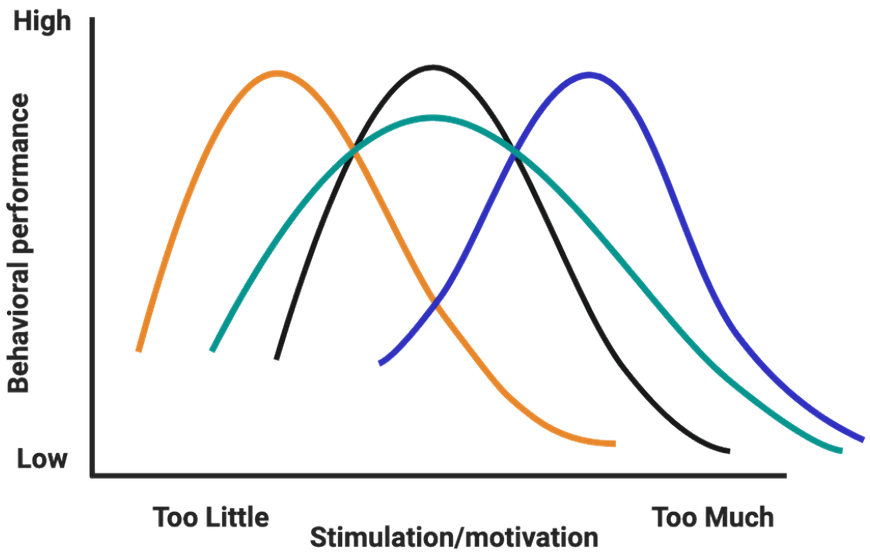

Figure 12.24 Interindividual variability in the stress response Different individuals can show different inverted-U curves of reponse to stressors.

The 'right' amount of stress (eustress) that yields optimum function for the person with the blue curve is much higher than that for the person with the orange curve. This optimal level will also vary in different domains for the same person and for the same person at different points in time (intraindividual variability). Curves could also be flattened (wider; see green curve). The individual with the green curve would require really low or really high HPA axis activation for it to be detrimental to their function.

Little is known about the mechanisms that shift inverted-U curves to the right, that is, towards resilience. Most resilience studies have been done at the group level and few have focused on individuals, i.e., those who respond (are vulnerable) versus those that don't respond (are resilient) to stress. Additionally, does resilience mean that there was no change or a lack of molecular response? Or was there a protective response that helped resilient individuals bounce back? The answer seems to point to the latter, but the mechanisms are yet mostly unknown.

How to optimize the stress response

How can we optimize our response to stress? That is, modulate it towards eustress versus distress? As mentioned before, reappraisal of a (mild-moderate) stressor as an adaptive challenge can improve physiological and cognitive stress outcomes. We can also engage in *exercise*—a physical stressor—which can enhance our adaptive capacity and has been shown to have numerous beneficial effects on stress responses. Exercise produces in the short-term feelings of calmness and reduced anxiety and can lead to long-lasting adaptations in neuroendocrine/HPA axis function after chronic training. It has reported antidepressant effects and has been shown to increase overall resilience, well-being and healthspan. Acute vigorous exercise increases levels of endogenous cannabinoids in the bloodstream (see Chapter 3 Basic Neurochemistry). These neurotransmitters are similar to compounds found in cannabis (marijuana) and may mediate post-exercise feelings of calm, reduced anxiety and sometimes euphoria, colloquially referred to as a 'runner's high' (Raichlen et al., 2013; Volkow et al., 2017). Training over several weeks attenuates resting/basal levels of stress hormones (Hackney, 2006). Furthermore, the stress-attenuating effects of chronic exercise training seem to carry over into reduced stress responses to other life stressors (Traustadóttir et al., 2005).

Meditation is an Eastern spiritual-associated practice that has been adapted for stress reduction and is currently a very active area of study. Research into meditation seems to point to enhanced executive control of attention (Tang et al., 2007), reduced cortisol levels (Tang et al., 2007; Fan et al., 2014) and improvements in mood (Basso et al., 2019). Note that research is limited to human subjects and correlational studies. Please see the demonstration video for an example of a short, guided meditation. To learn more about meditation research, see the work of Richard Davidson (University of Wisconsin-Madison; current leader in the field) and the Mind & Life Institute.

Finally, there are interventions like Mindfulness-based stress reduction (MBSR) (Kabat-Zinn, 2013) - an evidence-based program that combines mindfulness meditation, body awareness and examination of patterns of thought, emotion, behavior/action as tools for effectively coping with stress. MBSR has been shown to enhance attention skills, increase emotional regulation and significantly reduce rumination and worry. It has been very successfully utilized as an intervention for ameliorating anxiety, depression, and pain.

4.5.5: Clinical Implications of Stress

Learning Objectives

By the end of this section, you should be able to

- 12.4.1 Define allostatic (over)load and explain its consequences
- 12.4.2 Describe the pathological effects of stress exposure and some of its clinical implications
- 12.4.3 Describe the role of microglia in stress-related mood and neurodegenerative disorders

The cumulative 'wear and tear' from prolonged or severe stress exposure can tax our adaptive systems predisposing us to pathology and stress-related disorders. In this section, we will learn more about the concept of allostatic (over)load, which describes what can happen when stress becomes 'too much'. We will also discuss common stress-related nervous system disorders and the role of microglia, the brain's resident immune cells.

Allostasis vs. allostatic (over)load

We now know that the stress response is a necessary, survival-promoting response that allows us to adapt to challenges. What happens, however, if this response is activated for too long or too often, as a result of repeated exposure to stressors, or lack of proper shut down?

Well, it's very much the continuation of the beneficial, life-saving aspects of stress that become detrimental when they are prolonged or chronic (inverted-U nature of the response). Think about the acute effects of stress. For example, you are confronted with a stressor and your blood pressure increases because that is what's needed in order to run away from the threat. But, if your blood pressure is increased constantly, that becomes your new set point and now you have hypertension. Hypertension is a disease that affects most organ systems in the body. In the long-term, it increases wear and tear on many systems and accelerates the aging process. Other bodily systems are similarly affected. The immune and reproductive systems are turned down leading to immune suppression and reproductive distress/dysfunction. In the digestive tract, you can develop ulcers and decreased nutrient absorption. If the excessive stress exposure came early on in life, it can result in stunted growth. In terms of metabolism, glucose thrown into the bloodstream helps the muscles in the short run (escaping the threat) but can lead to diabetes if chronic. Similarly, in the brain, prolonged or severe stress exposure can lead to regional changes in brain structure (dendritic hypo/hypertrophy, remodeling, circuit plasticity) that can alter brain function and lead to pathologies such as anxiety, depression, and PTSD.

Recall that allostasis refers to the processes that restore homeostasis and also allow us to adapt through change. Our body's activation of the nervous, endocrine (and immune) systems during a stress response, for example, are allostatic mechanisms that allow us to adjust and increase our resilience in the face of stress. Allostatic (over)load, on the other hand, is the physiological cost of that adaptation to our body, i.e., the 'wear and tear' that accumulates after repeated or chronic stress exposure (see Figure 12.25).

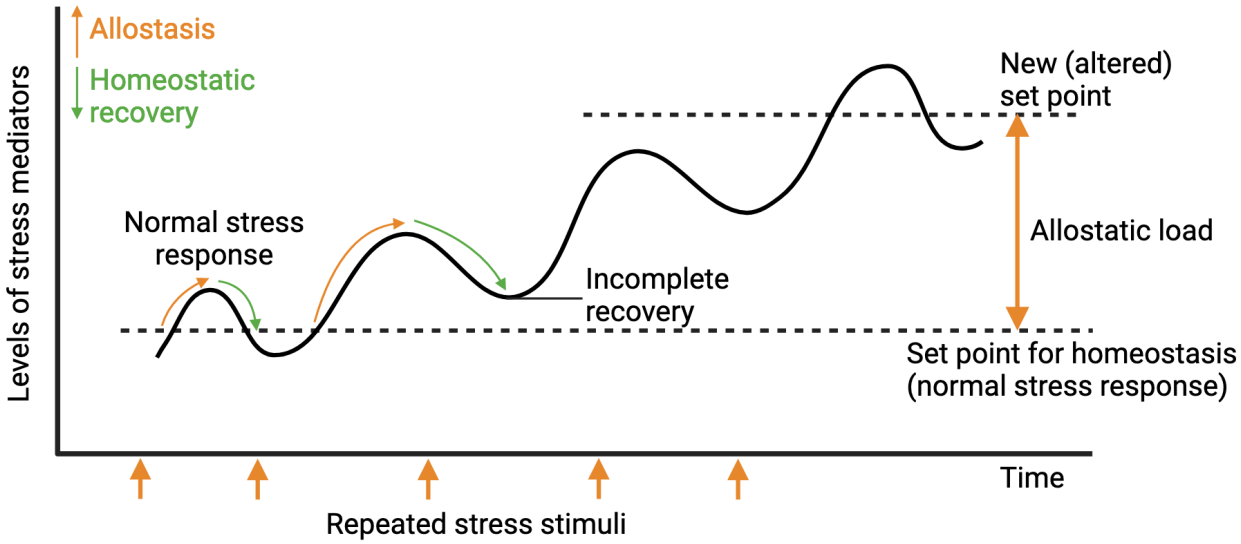

Figure 12.25 Allostatic overload Allostatic load is the difference between new and old set points that arises due to a cumulative burden of adaptation to stress.

Types of allostatic (over)load include:

1. Frequent activation of allostatic systems: e.g., repeated hits from multiple stressors resulting in overexposure to stress hormones.
2. Lack of adaptation to a repeated stressor: e.g., not getting used to public speaking.
3. Failure to shut off stress response activation after the stressor has passed: i.e., the inability to efficiently shutoff the stress response resulting in overexposure to stress hormones.
4. Failure to adequately activate the stress response: e.g., an inability to mount the proper HPA activation.

These aren't mutually exclusive. There can be combinations of these occurring at the same time.

Ultimately, continual or chronic stress exposure results in allostatic (over)load. Allostatic (over)load serves no useful function and can predispose individuals to stress-related disorders and pathology. Some of the clinical consequences are discussed below.

Mood disorders

Mood disorders are often accompanied by a distorted or inconsistent emotional state that persistently interferes with the ability to function. The American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders Fifth Edition (DSM-5) categorizes several disorders as part of mood disorders including major depressive disorder (MDD), bipolar disorder, and others. Many studies have implicated that both acute and chronic stress are related to the onset of MDD (McEwen, 2004). One potential mechanism connecting stress and mood disorders is dysregulation of the neurotransmitter serotonin. Serotonin is a crucial neurotransmitter for mood regulation in the brain (see Chapter 13 Emotion and Mood). Chronic stress is known to modulate neurotransmitters linked to mood disorders and their receptors. For instance, chronic stress reduces 5-HT1A autoreceptor sensitivity in the dorsal raphe nucleus—the brainstem nucleus where serotonergic cell bodies are located (Chaouloff et al., 1999). Although 5-HT1A receptors are not actively engaged in anti-depressant drug effects, the receptors are well-known for regulating the entire serotonergic system. Furthermore, an increase in stress hormones due to hyperactivity of the HPA axis has been shown to elevate expression of the gene encoding the serotonin reuptake transporter—a main target of major anti-depressant drugs, which inhibit the transporter's ability to reuptake/remove serotonin from synapses (Tafet et al., 2001). It is notable that dysregulation of serotonin homeostasis during critical periods (in utero, childhood, adolescence) and adulthood via exposure to chronic stress and dysregulated HPA axis function may produce long-lasting changes in the brain and ultimately impact the development of (and affect treatments for) mood disorders including MDD.

Anxiety disorders

Anxiety disorders are often characterized by intense and excessive symptoms of anxiety and worry that last persistently.

According to the DSM-5, there are multiple types of anxiety disorders, diagnosed based on potential causes and symptoms such as generalized anxiety disorders, social anxiety disorders, phobias, and panic disorders. One of the risk factors for anxiety disorders includes exposure to chronic stress. Chronic stress is well known to enhance amygdala-mediated fear. For example, a study by Rosekranz et al. revealed that chronic stress can activate neural excitability in the lateral amygdala circuitry (Rosenkranz et al., 2010). The amygdala circuitry is particularly important in the regulation of emotion, anxiety, and fear. Thus, heightened amygdala activation mediated by stress plays a role in the development of anxiety disorders.

Repeated and chronic exposure to stress may also result in hyperactivity of the HPA axis, which can contribute to anxiety. A subgroup of patients with anxiety disorders often displays hyperactivity of the HPA axis (Tafet and Nemeroff, 2020). Furthermore, anti-anxiety drugs, such as benzodiazepines, tricyclic antidepressants (TCAs), and selective serotonin reuptake inhibitors (SSRIs), all modulate components of the HPA axis. For instance, some types of benzodiazepines have been shown to alleviate anxiety symptoms and reduce the activity of CRH neurons in the hypothalamus, indicating the potential impact of anti-anxiety drugs on HPA axis regulation.

Posttraumatic stress disorder (PTSD)

Posttraumatic stress disorder (PTSD) is a psychiatric disorder that can develop in a subset of individuals exposed to a traumatic event (e.g., severe car accident, combat, sexual assault, natural disaster). It is characterized by persistent reexperiencing of the trauma (e.g., intrusive memories and flashbacks), avoidance of stimuli associated with the trauma and numbing of general responsiveness (similar to symptoms of depression) (see Figure 12.26).

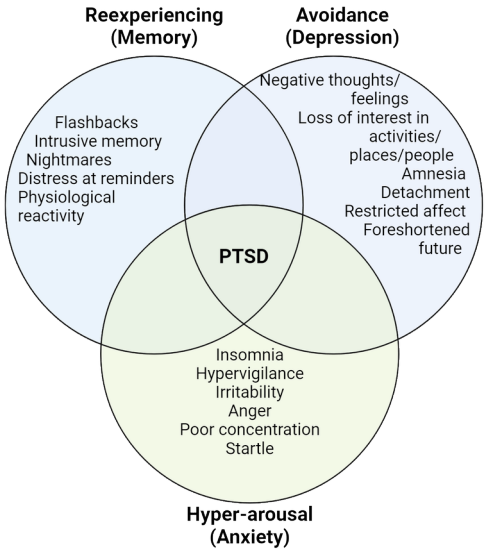

Figure 12.26 Core symptoms of PTSD

Women are twice as likely to have PTSD than men (Kessler, 1995). Immediately following exposure to severe trauma, most individuals will present with a collection of these symptoms (i.e., will display an acute stress response). Yet, in most people, these symptoms will resolve within months. Only 15-25% of individuals will continue to show persistent symptoms a year after the traumatic event and meet the diagnostic criteria for PTSD (Yehuda et al., 1998). Thus, PTSD represents a physiological failure to recover from an acute stress response that is almost universal.

Not surprisingly, patients with PTSD display HPA axis dysregulation, but paradoxically, they show lower overall cortisol levels, especially in the hours immediately after the trauma (Mason et al., 1986; Yehuda, 2002). Additionally, they have an abnormally high noradrenaline/cortisol ratio which suggests a loss of coordinated activity between HPA axis and ANS function. Cortisol administration shortly after trauma (in ER patients exhibiting low cortisol levels) has been successful as a preventative intervention for PTSD (Zohar et al., 2011). Non-pharmacological interventions in the form of cognitive behavioral therapy, sometimes coupled with virtual reality scenarios, have also proven successful in treating the symptoms of PTSD.

Cognitive and memory disorders

Stress can affect multiple aspects of cognition including attention, learning, and memory. Some major cognitive/memory disorders in humans are Alzheimer's disease (AD), attention deficit disorder, and dementia. Each of these is affected by stress exposure. Stress exacerbates AD (Machado et al., 2014; Justice, 2018), there's a high comorbidity rate of PTSD with attention deficit disorder (Cuffe et al., 1994; Adler et al., 2004), and chronic stress is associated with dementia (Peavy et al., 2012) and increased risk for dementia later in life (Johansson et al., 2010). Stress-sensitive brain regions like the hippocampus and PFC likely contribute to these phenotypes.

Interestingly, PTSD can be viewed as a memory disorder, and it is easy to understand many of the symptoms via this lens. In addition to the strong recall of the traumatic event, PTSD patients report problems with declarative memory (remembering facts), fragmentation of memory and dissociative amnesia (not being able to recall important personal information). A salient feature of PTSD is an aberrant consolidation of the traumatic memory event (aberrant fear learning). It may manifest as a lack of fear extinction (new safety cues are not associated with the old memory) or a generalization of the fear response. For example, if the event was the experiencing of a bomb blast, then the result could be a sensitivity to other loud noises (Parsons and Ressler, 2013; Shalev et al., 2017; Fenster et al., 2018).

Addiction, compulsive and impulse disorders

Addiction is a compulsive behavior or use of a substance characterized by an inability to control consumption and withdrawal symptoms when unable to access it (see Chapter 14 Psychopharmacology). Gambling and shopping are examples of behaviors that can lead to a non-substance addiction. Substance abuse is highly studied and provides the basis for what we know about stress and addiction. Stress is a prominent risk factor for developing a substance use disorder or relapsing (Schmid et al., 2009; Enoch, 2011; Duffing et al., 2014; Tschetter et al., 2022). Stress and substance use both activate the HPA axis and connected amygdala, while down-regulating activation of the hippocampus and the PFC, leading to impaired decision making and impulsivity. These similarities suggest that stress may influence and further aggravate the effects of many drugs of abuse and contribute to addiction. Therefore, reducing stress could aid in efforts to treat addictions or prevent susceptibility.

Stress and (neuro)immune function

We all know that exposure to pathogens leads to characteristic changes in physiology and behavior. When we're sick, we feel tired and sleepy, lose motivation, withdraw socially, don't feel as hungry or thirsty, might have a fever and our brains might feel foggy. Sometimes we might also feel more sensitive to pain or more anxious and depressed. This constellation of symptoms is called the sickness response, and it is remarkably similar to endophenotypes that characterize stress-related mood disorders like MDD, anxiety and PTSD (see Chapter 17 Neuroimmunology). This intriguing observation hinted at the idea that neuropsychiatric conditions like mood disorders had an immune component. That is, the immune system might be involved in regulating an organism's motivational state. This idea led to intense interest in the role of the immune system in brain function and how it relates to stress.

As we know, stress can affect every cell and tissue in the body, hence it is no surprise that it has profound effects on immune system function. In general, following the inverted-U pattern, acute stress seems to enhance immune responses while chronic stress has a suppressive effect. However, both acute and chronic stress can generate anti-inflammatory and proinflammatory responses, leading to a more complex picture. In recent years, inflammation has garnered a negative reputation, but it is in fact a necessary and beneficial immune response after an acute stressor like an injury/infection: here the immune system attacks the invaders, clears the threat and helps to promote healing. Inflammation is deleterious, however, if it becomes prolonged. Studies have shown, for example, that chronic socio-environmental stressors (poverty, bereavement) are associated with increased expression of genes involved in inflammation and decreased expression of antiviral responses—the conserved transcriptional response to adversity. This transcriptional program is thought to promote a state of chronic, low-grade inflammation which can result in development of inflammation-related diseases.

Stress and microglia—the brain's resident immune cells

The brain, largely isolated from cells of the immune system due to the presence of the blood-brain-barrier, was long thought to be an immune-privileged organ; however, it contains its own tissue-resident immune cells: microglia. In recent years, there has been intense interest in understanding the crucial role of microglia in brain development and function.

As the resident phagocytes, microglia actively scan their environment for disruptions in homeostasis. They are first responders to threat (e.g., infection with a virus, tissue damage), play a critical role in neurodevelopment and perform numerous functions in the maintenance of the healthy adult brain. For example, they use their phagocytic activity to remove debris, dead/dying neurons and other cells. They also lend trophic (growth) support to neurons, modify synaptic connections and plasticity, and modulate neuronal activity. Additionally, because they are immunocompetent cells, microglia produce and release anti- and proinflammatory mediators (cytokines and chemokines), some of which have roles in synaptic plasticity and memory function. Figure 12.27 diagrams some of these cellular functions which impact brain function and development.

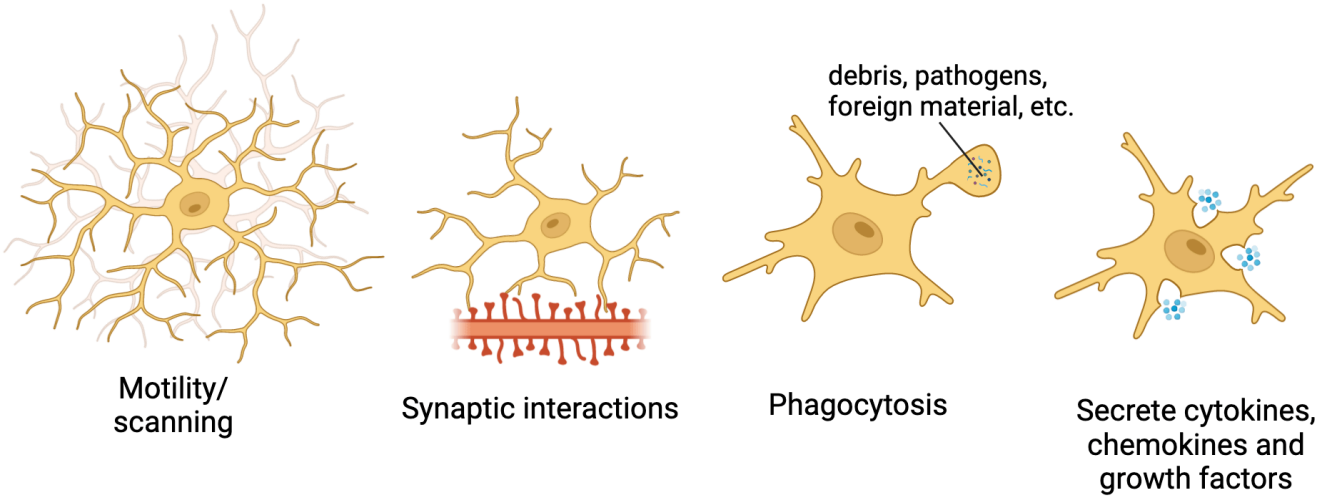

Figure 12.27 Microglial functions Through several cellular functions, microglia regulate injury/illness response, healthy brain function and neurodevelopment.

Homeostatic or surveilling microglia exhibit a highly branched morphology with a small cell body and unique transcriptional signature. This phenotype is suppressed when disruptions to CNS homeostasis occur (for example, during infection or aging). At the same time, microglia undergo changes in morphology, transcription and proinflammatory mediator profile (a spectrum of different functional states grouped under the umbrella term 'activation') which at the extreme becomes a phenotype characteristic of neurodegeneration. One of these activation states, termed 'primed', is seen in microglia under neuroinflammatory conditions like stress and aging. Microglia can also proliferate, increasing their numbers in response to homeostatic disruptions. Below, we will discuss more specifically the role of microglia in stress-related pathology with a focus on mood and cognitive dysfunction/ neurodegenerative disorders.

Inflammatory priming and mood disorders

Microglia can respond directly to key stress mediators, including glucocorticoids and the catecholamines epinephrine and norepinephrine. Although glucocorticoids are widely known for their immunosuppressive effects, they can also have a more permissive role. A number of studies have implicated glucocorticoids in stress-induced inflammatory priming—that is, a sensitization or heightened immune response in microglia to subsequent inflammatory stimuli—in stress-related brain regions like the hippocampus. In other words, glucocorticoid exposure can make microglia more susceptible to a second inflammatory stimulus, and this can then trigger an exaggerated or prolonged inflammatory response that can damage nearby neurons or other cells and negatively affect brain function.

Experiments have tested the causal role of glucocorticoids in this phenomenon. For example, exposure to tailshock stress in rats where glucocorticoids signaling was blocked (via application of GR antagonists or adrenalectomy, removal of the adrenal glands) blocked this type of exaggerated inflammatory response in hippocampal microglia when subsequently stimulated with a bacterial product. Other experiments using β-adrenergic receptor agonists or antagonists and repeated social defeat stress have shown that catecholamines are also implicated in stress-induced microglial priming in regions of the brain related to threat-appraisal. Additionally, they play a critical role in the mobilization and redistribution of specific types of inflammatory peripheral immune cells to the CNS (for review see Frank et al., 2019). This type of infiltration of peripheral immune cells into the brain, along with a greater overall local inflammatory microenvironment, lead to a full-blown state of neuroinflammation.

Inflammatory priming is thought to contribute to the development of a number of mood disorders and their related symptoms.

For example, microglia that have been primed by repeated stress exposure release several molecules that can directly impact emotion-related behaviors. IL-1β is one such molecule. It is a cytokine released by microglia that both contributes directly to further HPA axis activation and also drives sickness behaviors, like decreases in motivation to obtain a reward. Loss of motivation for previously rewarding stimuli is a core symptom of depressive disorders. Another protein released by stress-primed microglia, PGE2, stimulates increases in social avoidance and greater anxiety responses to stress (for review see Wolf et al., 2017). How this vicious cycle of stress and microglia function contributes to mood disorders is an active field of research which may yield new ways to treat depression and anxiety in the future.

Stress, microglia and neurodegeneration

Neurodegeneration is the age-related, progressive damage to neuronal structures and function in the CNS. It can result in disruptions to cognitive performance and is seen in disorders like Alzheimer's disease (AD) and other dementias. Notably, a life-long history of stress exposure is a risk factor for developing cognitive deficits, brain atrophy and AD (Gracia-Garcı ́a et al., 2015, Alkadhi, 2012) and psychosocial stress, in particular, is a risk factor for late-onset AD (LOAD). Chronic stress has also been shown to worsen neurodegeneration and cognitive impairments in rodent models of AD (Carroll et al., 2011; Srivareerat et al., 2009). As discussed previously, chronic stress can lead to neuroinflammation, one of the hallmarks of many neurodegenerative disorders including AD.

Microglia play a key role in the establishment and progression of neurodegenerative disorders. Microglial dysfunction is prominent in AD, for example, and several genetic risk factors associated with the disease are specifically or highly expressed by microglia (APOE and TREM2). It is worth noting that during normal aging, microglia lose some of their surveillance/homeostatic capacity and are thought to become more proinflammatory or reactive in general. Additionally, their phagocytic function is impacted.

During neurodegeneration, microglia react to age-related, accumulated debris/protein aggregates through their dedicated pathogen and damage-sensing receptors. They also adopt an 'extreme' activated, primed phenotype termed MGnD (neurodegenerative microglia) or DAM (disease-associated microglia) characterized by induction of genes associated with cellular damage and degeneration. This phenotype also includes higher expression of immune modulators that induce astrocyte activation and aid in recruitment of inflammatory and other specialized immune cells that further contribute to neuronal damage. Thus, chronic stress can exacerbate neurodegeneration by compromising microglial homeostatic support for neurons/synaptic function and sensitizing microglia towards a primed state which leads to neuroinflammation and neuronal dysfunction and death. Interestingly, regions like the frontal cortex and hippocampus which are particularly sensitive to the effects of stress are also amongst the first brain areas affected in AD.

The stress response is a non-specific physiological reaction to any event (stressor) that takes an organism out of homeostatic range. It is necessary for survival and to adapt to challenges. Stressors are classified by type, severity, and duration. The stress response follows an inverted-U pattern: too little or too much stress is deleterious to behavioral performance but there is an optimal level that is beneficial. Research on stress seeks to understand the mechanisms underlying both pathological and salutary effects of stress in humans and is carried out using humans and animal models.

12.2 Neural Mechanisms and Circuitry of the Stress Response

The stress response depends on multiple interconnected systems working on different timescales. The fast neural response is mediated by the SNS via the sympatho-neural system and sympatho-adrenomedullary system. The slower neuroendocrine response depends upon the HPA axis and is important for the long-term effects of the stress response as well as various other bodily functions. Activation of the HPA axis involves serial activation of the hypothalamus, pituitary gland, and adrenal gland to produce stress hormones. This in turn, produces changes in glucocorticoid levels with effects throughout the body. Termination of the stress response is not a clear-cut event, but vagal stimulation (through deep breathing) can engage the PNS and inhibit the SNS and help to restore homeostasis. Cortisol levels return more slowly to baseline with help from negative feedback mechanisms.

The brain orchestrates the body´s response to stress and stress, in turn, has major effects on brain circuitry, resulting in long-lasting changes in structure, function, and behavior. Major brain regions that are affected by stress and mediate behavioral responses include the prefrontal cortex, amygdala, hippocampus, and hypothalamus. These brain regions express stress hormone receptors and thus are directly stimulated by stress hormones. At the same time, they also receive signals via connections to other brain regions.

12.3 Interindividual Variability and Resilience in Response to Stress

Numerous factors (genetic, epigenetic, life history, biological sex, emotional and physiological state, as well as the characteristics of the specific stressor) are involved in determining interindividual variability in response to stress. Additionally, the perception, appraisal, and predictability/controllability of stressors can profoundly affect stress reactivity and stress outcomes. Not all stress is bad, however, and some types of stress can have salutary effects on brain function. Stress can also promote social affiliation which is associated with increased health and life expectancy.

12.4 Clinical Implications of Stress

Repeated or prolonged stress can lead to allostatic over(load) resulting in stress-related pathologies like mood, anxiety, cognitive, memory, impulse control and substance abuse disorders. Exposure to traumatic stress can lead to development of PTSD. Additionally, chronic stress can drive microglial priming and neuroinflammation which exacerbates mood and cognitive disorders and contributes to neurodegeneration.

4.5.7: Key Terms

12.1 What Is Stress?

stress, stressor, stress response, allostasis, stressor type (physical, psychological, social), stressor duration (acute, subchronic, chronic), stressor severity (mild, moderate, severe/traumatic), inverted-U curve, eustress, distress, animal model

12.2 Neural Mechanisms and Circuitry of the Stress Response

amygdala, hippocampus, prefrontal cortex, autonomic nervous system, parasympathetic nervous system, sympathetic nervous system, sympatho-neural system, sympatho-adrenomedullary system, hypothalamic-pituitary-adrenal (HPA) axis, corticotropin releasing hormone (CRH), adrenocorticotropic hormone (ACTH), glucocorticoid, cortisol, negative feedback, Cushing's syndrome, glucocorticoid receptor, mineralocorticoid receptor, ventral tegmental area (VTA), nucleus accumbens (NAc), top-down or high-order control

12.3 Interindividual Variability and Resilience in Response to Stress

interindividual variability, epigenetic, critical period, biological inheritance, social inheritance, ecological inheritance, appraisal/reappraisal, predictability, controllability, social buffering, resilience

12.4 Clinical Implications of Stress

stress-related disorders, allostatic overload, sickness response, inflammation, microglia, inflammatory priming, neuroinflammation, neurodegeneration

This page titled 4.5.7: Key Terms is shared under a CC BY-NC 4.0 license and was authored, remixed, and/or curated by Ivette Merced via source content that was edited to the style and standards of the LibreTexts platform.

4.5.9: Multiple Choice

12.1 What Is Stress?

1.
Hans Selye noticed that physiological responses to different stressors were:

a. similar.
b. dissimilar.
c. unpredictable.
d. absent.

2 .
Stress responses evolved to:

a. make you feel bad.
b. harm your body.
c. adapt to environmental demands.
d. make stressors more predictable.

3.
Stress is

a. bad.
b. good.
c. sometimes bad, sometimes good.
d. not a real thing.

4 .
Stress can be studied:

a. only in humans.
b. only in rodents.
c. in many animal species.
d. only in the lab.

5.
Chronic stress can negatively affect:

a. immune function.
b. cardiovascular health.
c. memory function.
d. All of these

6 .
A mouse who had been exposed to social defeat stress would show which of the following behaviors in a forced swim test?

a. Less movement
b. More movement
c. Sinking
d. None of these

12.2 Neural Mechanisms and Circuitry of the Stress Response

7.
What are the two major systems that mediate most components of the stress response?

a. Autonomic nervous system and mesolimbic dopaminergic system
b. Periaqueductal grey and anterior cingulate cortex
c. Hypothalamic pituitary gonadal (HPG) axis and corticolimbic system
d. Sympathetic nervous system and hypothalamic pituitary adrenal (HPA) axis

8 .
While walking to class one day, you encounter a squirrel in your path. You stare at the squirrel. It stares back. You walk forward one step. So does the squirrel. You step right, to go around the squirrel. It steps right also, blocking your path. Suddenly, the squirrel charges, a 2 pound blur of fur, teeth and claws. You scream and run away faster than you have ever run before. What part of your nervous system is most active to support your rapid flee for safety (i.e. your initial, rapid response to this stressor)?

a. Your parasympathetic nervous system
b. Your sympathetic nervous system
c. Your hypothalamic-pituitary-adrenal axis
d. Your mesolimbic dopaminergic system

9.
Which of the following are sites for negative feedback in the HPA?

a. Hippocampus
b. Hypothalamus
c. Pituitary
d. All of these

10 .
Negative feedback helps to

a. amplify the stress response.
b. turn off the stress response.
c. bring GRs to response elements.
d. dimerize glucocorticoid receptors.

11.
How does stress impact memory functions mediated by the hippocampus?

a. Stress improves memory
b. Stress impairs memory
c. Stress can improve or impair memory
d. Stress does not affect memory

12 .
The adult hippocampus is somewhat unique in its ability to generate new neurons in adulthood. How is this process affected by stress?

a. Stress increases neurogenesis
b. Stress decreases neurogenesis
c. Stress can increase or decrease neurogenesis
d. Stress does not affect neurogenesis

12.3 Interindividual Variability and Resilience in Response to Stress

13.
Which of the following can affect how an individual responds to stress?

a. Genetics
b. Previous stress experiences
c. Sex
d. All of these

14 .
How different individuals respond to the same stressor:

a. can be highly variable.
b. is pretty similar person to person.
c. cannot be measured in any meaningful way.
d. relies mostly on their genetics.

15.
The shared experience of trauma at a community level is called:

a. biological inheritance.
b. social inheritance.
c. ecological inheritance.
d. All of these

16 .
Transgenerational transmission of stress effects:

a. happens only via changes in parental care of offspring.
b. can be observed in worms.
c. only happens in humans with language and cultural transmission mechanisms.
d. None of these

17.
In a controllable stress paradigm, which group shows the most negative consequences of shock exposure?

a. The escapable stress group
b. The inescapable stress group
c. The no stress control
d. None of these

18 .
Which of the following can reduce the negative effects of a stressor?

a. Reappraisal
b. Social buffering
c. Controllability of the stressor
d. All of these

19.
The point of eustress on the stress inverted-U curve is:

a. different for different people.
b. the same throughout any one individual's life.
c. the same for all individuals.
d. the same for different types of stress within any one individual.

20 .
Which of these are strategies with evidence to support that they can help people optimize their stress response?

a. Reappraisal of a stressor as a challenge
b. Exercise
c. Meditation
d. All of these

12.4 Clinical Implications of Stress

21.

Which type of stress is key to developing allostatic overload?

a. Psychological
b. Physical
c. Acute
d. Chronic

22 .
Allostatic overload is:

a. bad.
b. good.
c. sometimes bad, sometimes good.
d. not a real thing.

23.
PTSD is a psychiatric disorder that:

a. is guaranteed to happen after a traumatic event.
b. is more prevalent in men than women.
c. is characterized by prolonging of the typical acute response to trauma.
d. is characterized by lower resting cortisol levels.

24 .
Which cells are the major mediators of immune responses in the brain?

a. Astrocytes
b. Oligodendrocytes
c. Microglia
d. Neurons

4.5.10: Fill in the Blank

12.1 What Is Stress?

1.
The three stressor domains are type, duration, and _____.
2 .
When evaluating animal models of human disease, _____ refers to whether the observable behavioral outcome is similar to human symptoms.

12.2 Neural Mechanisms and Circuitry of the Stress Response

3.
In the HPA axis, _____ is released by hypothalamic cells into the hypophyseal portal system.

12.3 Interindividual Variability and Resilience in Response to Stress

4 .
Early life stress can cause lifelong changes in gene expression through _____ changes to DNA.
5.
A period of development when the brain is especially plastic allowing for changes that can translate to risk or resilience in the face of stress would be called a _____.

12.4 Clinical Implications of Stress

6 .
_____ is the physiological cost of stress adaptation to our body.

Living organisms are exposed daily to a wide array of stimuli from the external environment. These external events have an incredible amount of power in heightening the activity of internal cognitive, physiological and behavioral reactions. When joined together, these three changes represent what is loosely referred to as “the emotions” that ultimately dictate the responses we exert on the environment. In essence, emotions are complex instinctive feelings produced by synthesizing environmental cues and external stimuli that alert an organism that some action may be required of them. A more comprehensive definition of emotions was provided by Klaus R. Scherer (2009) which states:

“Emotions are elicited when something relevant happens to the organism, having a direct bearing on its needs, goals, values and general well-being. Relevance is determined by the appraisal of events on a number of criteria, in particular the novelty or unexpectedness of a stimulus or event, its intrinsic pleasantness or unpleasantness and its motivational consistency, i.e. its conduciveness to satisfy a need, reach a goal, or uphold a value or its ‘obstructiveness’ to achieving any of those.”

The scenarios depicted in Figure 13.2 permit you to directly experience how external stimuli, scenes or scenarios are potent initiators of internal mechanisms that regulate our thought, mood and physiological disposition. The collection of images also permits you to witness the subtle, yet immediate, impact that external events may produce on your own private and very personal internal processes associated with emotion.

Figure 13.2 Introduction to emotions Do these images make you feel something? External stimuli, scenes or scenarios are potent initiators of internal mechanisms that regulate our thought, mood and physiological disposition. This chapter will guide you along a journey to understand the complexity of perceptual processes that allow stimuli from our immediate environment to impact physiological body states, cognition, mood and the behaviors that are initiated to respond adaptively to dynamic changes in the environment.

This chapter will present a comprehensive understanding of the global nature and broad category of factors involved in the development of emotions. We will first explore prominent theories that explain, through diverse viewpoints, the sequence of perceptual, neural and physiological processes that are thought to produce emotions. Following this theoretical framework is a discussion of the six categories of basic emotions, the external conditions associated with eliciting each, and the types of behavioral responses belonging to each classification. Once you have gained a foundation for understanding the impact of external stimuli in eliciting overt behavioral changes, the chapter will then take a deeper look at the internal mediators (*i.e. neural and circuit levels in the brain*) that play a dual role in: first registering within the brain the array of stimuli encountered externally, and second, forming internal computations of their significance to generate the appropriate physiological and interoceptive changes that are the basis for the labels and categories used to define individual emotions. We will conclude the chapter with discussions on the translational aspects of this field of study and the application of findings to understanding the etiology of mood and emotional disorders and the contemporary approaches to treat these conditions.

4.5.12: Foundational and Contemporary Theories of Emotion

Learning Objectives

By the end of this section, you should be able to

- 13.1.1 Discuss the similarities and differences between the early theories of emotion.
- 13.1.2 Understand the shortcomings of early theories of emotion and list some specific behavioral conditions that early theories cannot adequately explain.
- 13.1.3 .Describe how the shortcomings of early theories led to more contemporary theories of emotion that describe emotions as complex interactions between cognitive, neural and physiological changes to external events

Three interrelated variables are presented repeatedly throughout this chapter to discuss the most important factors underlying emotions. The first involves the environmental context we inhabit. The environmental context is the source of ever-changing external stimuli and events that are perceived by the organism. Second, stimuli encompassing a given context possess the capacity to elevate or reduce bodily or physiological states by their impact on sympathetic or parasympathetic divisions of the autonomic nervous system, respectively. Third, autonomic changes, in turn, influence brain systems that appraise environment-body interactions, and provide cognitive resources to generate the broad range of conscious emotions and the behavioral responses to adapt appropriately to environmental events. Although each variable is vital in the generation of emotions, we shall see below that the major theories differ in their explanations of how each component of this triad, contributes to the conscious development of feelings, mood and emotions.

James Lange

William James (1884) and Carl Lange (1885) independently proposed a theory to explain how the experience of emotion influences behavior. Their collective views became known as the James-Lange theory of emotion. According to their understanding, “the conscious experience of emotion develops, only after an organism’s perception of its body’s level of autonomic arousal” to some external stimulus or event (see Step #3 in Figure 13.3).

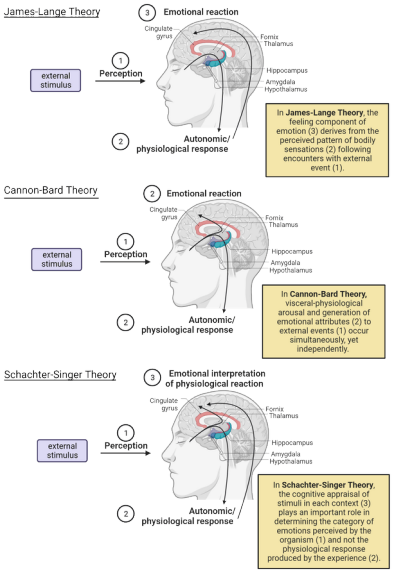

Figure 13.3 Theories of emotion

One common example to describe their theory concerns the cause of why fear is generated during an encounter with any of the three pictures in the second row of Figure 13.2. Contrary to common sense interpretations, the James-Lange theory posits that the emotion of fear is not developed because you are naturally afraid of any of the dangerous or threatening stimuli in those contexts. Rather, the feeling of fear is generated *after* an organism perceives the increased physiological and visceral changes generated

by the autonomic nervous system following direct experience with those events. Put simply, we become afraid not because of the stimulus, but because of the internal physiological changes the stimulus produces within us. *That is, the feeling component of emotion derives from the perceived pattern of bodily sensations following encounters with external events.*The James-Lange theory places an emphasis on autonomic specificity, which assumes that different patterns of physiological arousal shown as Step #2 in Figure 13.3 (e.g. elevations or reductions in heart rate, respiration, blood pressure, skin conductance, secretion of adrenal hormones, etc.) are the basis for the experience of distinct emotional states or feelings that are given the labels of fear, happiness, anger, sadness or the like. Several empirical studies report that discrete patterns of autonomic nervous system responses to a given external stimulus are correlated with the differentiation of separate emotion categories (Stephens, Christie and Friedman, 2010). For example, it is well-documented that the emotions of sadness or fear can be produced by exposing human participants to visual film clips or auditory stimuli. These types of experiments report that the emotion of fear is accompanied by predicted changes in heart rate acceleration, elevated blood pressure, increased skin conductance and faster respiration (Kreibig et al., 2007; Bosch et al., 2001). In contrast, laboratory conditions that induce the emotion of sadness produce consistent decelerations in cardiac functioning, deep and slow breathing and increased activation of the corrugator supercilii and zygomaticus facial muscles that have a dedicated role in producing frowning and other related facial expressions that correspond to suppressed mood states (Bosch et al., 2001; Ritz, et al., 2005).

The James-Lange theory is known as a bottom-up theory because, as Figure 13.3 illustrates, exposure to external stimuli (1) directly impacts physiological activity in the peripheral autonomic nervous system (2), that in turn is projected to the brain (3) to produce emotional reactions. Thus, the behavioral responses of fleeing from, or completely freezing to, some threatening stimulus will, according to James, elicit heightened visceral activity. Perception of these elevated bodily changes is the critical factor, James assumes, that leads to the direct *feeling of fear*. James supported his argument by stating that when emotions are stripped of their *bodily manifestations*, they are no longer emotions, but simply cold and neutral states of intellection perception (James, 1884, p. 193). Moreover, James suggested to imagine feeling sad without tears or sighing; feeling angry in the absence of muscle tension or heat in the face; experiencing fear when there is no racing of the heart or unsettling reactions in the stomach. Because this is not possible, James contends that *bodily responses* are necessary for the subjective feelings and play a causal role in generating those feelings that are commonly known as emotions.

Cannon-Bard

An extension of the James-Lange theory was proposed by Walter Cannon and his graduate student Philp Bard. Their theory came from observations of experiments in physiology and emotion in cats. The Cannon-Bard theory challenged James' initial propositions on three separate grounds. First, they asserted that autonomic and visceral changes that follow exposure to external stimuli develop much too slowly to generate the type of emotional feelings that occur almost instantaneously when organisms are exposed to emotion-provoking stimuli. Second, artificially generating visceral changes in the body by injecting the stress hormone adrenaline to increase sympathetic drive does not always induce discrete conscious emotions (Schachter and Singer 1962). Moreover, when visceral reactions are blocked pharmacologically with drugs, the perception and feeling of emotional reactions are not abolished (Reisenzein, 1983). The Cannon-Bard position was also strengthened by the finding that their cats continued to display species typical emotional reactions to threatening stimuli, even when signals representing heightened physiological states were blocked. They interrupted the flow of updated information from the viscera to the brain by severing visceral and spinal nerves that normally transmit important fluctuations in bodily states to discrete brain structures. Despite the absence of intact nerves to relay elevated changes in the viscera to the brain, Cannon and Bard observed that presentation of a threatening canine still elicited emotional reactions such as hissing, fighting responses or reflexive muscular responses leading to piloerection in their denervated cats. Similar findings are reported in humans who continue to display appropriate emotional reactions to events, even after spinal cord transections from accidents or surgery interrupt the flow of communication regarding changes in autonomic activity to the brain (Bermond, Niewenhuyse, Fasotti & Schuerman, 1991).

Cannon and Bard also noted the extensive number of visceral organs in the autonomic nervous system that show changes in activity to salient stimuli from the environment (e.g. heart, lungs, adrenals, stomach, liver, etc). As such, they concluded that the body's anatomy contains an insufficient number of nerves to convey the multiple changes across these organs to brain systems involved in generating conscious differences in emotional experiences. Based upon these limitations, the Cannon-Bard theory took issue with the neat sequential three-stage explanations of James-Lang and as depicted in Figure 13.3. They expanded this view by asserting that during an encounter with external stimuli (1), the thalamus is activated by the external event. The thalamus then sends the information in two simultaneous directions. It relays the specifics of the encounter to cerebral cortical structures (e.g. prefrontal, cingulate and insula cortex) to appraise the possible danger, safety or other emotional features of an experience (3). It also sends neural signals to subcortical structures such as the hypothalamus and amygdala to initiate physiological reactions in the body to adapt to the specific nature of the experience (2).

The Cannon-Bard theory of emotion introduces the idea that visceral-physiological arousal and generation of emotional

attributes to external events occur simultaneously, yet independently. Therefore, exposure to an alerting event such as a vicious canine or hissing snake will result in the feeling of fear during the same time that the body shows adaptive increases in sympathetic activation to initiate the behavioral response of fleeing or freezing to the external event. In contrast to the James-Lange theory, this viewpoint is considered a top-down theory since the initiation of emotional states are generated in cortical regions of the brain, and downstream projections from the thalamus to hypothalamus are attributed a role in producing the visceral physiological reactions in the organs of the body.

Schachter-Singer Two-Factor view

Stanley Schacter and Jerome Singer developed a theory of how human emotions evolve by incorporating the main premises from both Cannon-Bard and James-Lange. As such, it was named the two-factor theory since emotions were proposed to develop from interactions between autonomic physiological changes in the body with cognitive appraisals generated in the brain. According to the Two-Factor theory, (1) encounters with broad categories of external stimuli will (2) elicit increased autonomic activity within the body. However, (3) the brain plays an important role in *interpreting the context* in which the changes are elicited, before assigning a label or discrete emotion to the feelings that are experienced. This appraisal process involves obtaining knowledge regarding the nature of the immediate context and evaluating the personal significance (i.e. beneficial, harmful, rewarding, etc.) of what is happening in the environment. For example, encountering a hissing snake that jumps into the air will unmistakably evoke increased physiological arousal whether it is encountered in the woods, or while viewing an exhibit with a snake handler at a zoo. The Two-Factor theory proposes that although bodily changes are heightened in both circumstances, cognitive appraisal of the respective contexts will determine whether the emotion of fear and responses of startle and fleeing are generated in the woods, or the emotion of amazement or being astounded, surprised and entertained develops in the context of the zoo. Thus, cognitive interpretations of the actual items, events or stimuli in a context interact cooperatively with changes in body physiology to determine the exact label the brain assigns as a bona-fide emotion. It is these interactions that capture the true essence of any meaning we derive from a given experience.

The significance of cognitive processes and their importance in interpreting contextual attributes prior to assigning emotional labels was nicely illustrated in a well-cited study by the authors of this theory (Schacter & Singer, 1962). *Contextual influences* were assessed by assigning human participants to groups that completed a survey of subjective emotional reactions. Participants were assigned to either a pleasant context containing a euphoric actor or an unpleasant context where the actor was instructed to display a great deal of anger, pessimism, or discontent (Figure 13.4). *Physiological changes* were induced in participants by injecting either a placebo drug consisting of saline (0.9% NaCl) or the stress hormone epinephrine to produce arousal and physiological changes (i.e. increased heart rate, sweating, etc.) via the autonomic nervous system. The relative impact of *cognitive interpretive processing* on emotional perception was assessed by informing one group of the reactions to expect from the injection (i.e. you will experience a change in heart rate), while providing no information regarding the effects of the stress hormone to a second group.

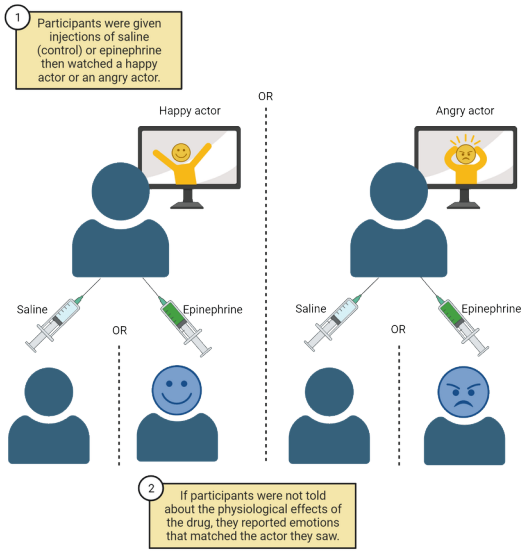

Figure 13.4 Schachter-Singer experiment

The most striking finding from this experiment is that the group given adrenaline and not informed about its effects reported

intense emotional reactions. This finding supports the James-Lange viewpoint. However, the specific emotion experienced (i.e. euphoria or anger) actually matched the *emotion displayed by the actor placed in the CONTEXT* where unsuspecting participants completed the subjective emotional questionnaires. Thus, epinephrine-injected participants placed with the euphoric actor reported intense pleasant feelings, whereas epinephrine-injected participants grouped with the angry actor experienced intense anger. It should be noted that only mild emotional responses were reported in participants *informed about the reactions of the adrenaline injection* and placed in either the happy or angry context. The authors noted that only mild responses were reported in these participants because they attributed the changes in physiological and emotional state directly to their knowledge (i.e. cognitive appraisal) regarding the actions of the injection *and not to the actors*. Taken together, both findings reveal that bodily/physiological changes may intensify any emotional experience but more importantly, *the cognitive appraisals of the context* in which these bodily changes occur has a direct impact on the type of emotion attributed to any given experience and the corresponding behaviors that are manifested therein.

To shed light on the distinctions between the Schachter-Singer and James-Lange models, consider how the experience of riding a thrilling roller coaster versus enduring extreme turbulence while flying in an airplane, may lead to completely opposing emotional reactions. Both conditions involve rapid changes in velocity or speed, unsteady elevated and dropping movements that lead to a bumpy uncomfortable ride. Both conditions also produce profound elevations in cardiac output, blood pressure and a number of other autonomic physiological variables. Despite the similarity in physiological changes produced by both conditions, most individuals experience emotions of joy, excitement and exhilaration after a roller coaster ride, while the emotions of fear, helplessness and worry are generally attributed to undergoing turbulence during an airplane flight. Notice that both experiences produce similar physiological outcomes. Yet, the emotions attributed to each are totally dependent on how the brain *interprets the context* that physiological changes occur in, prior to assigning labels to the conscious emotion that is experienced. In the context of the roller coaster, you are likely to view others laughing, raising their arms in excitement, and smiling widely. In contrast, the context of the turbulent flight may be filled with others displaying facial signs of distress and fear, as well as auditory signs such as sighs or moans, etc. This example reveals a shortcoming of the James-Lange theory of autonomic specificity that assumes specific categories of subjective emotions are produced by distinct physiological signatures. *According to the Schachter-Singer model, the cognitive appraisal of stimuli in each context, plays an important role in determining the category of emotions perceived by the organism and not the physiological response produced by the experience*.

Appraisal Theory Perspectives

There are several other viewpoints of emotion that belong to the category of appraisal-based theories. These theories are similar to the Schacter-Singer model in stressing that the same external event will not produce identical emotions across all individuals. Appraisal theories assert that emotional reactions are very different from one individual to another because of several complex processes that are initiated collectively to produce a final emotion. The foundation of these theories stress that what produces emotional reactions *is not the stimuli we encounter externally*, but how we *subjectively interpret or appraise* these stimuli relative to several personal variables. These variables include the meaning that external stimuli present in terms of our goals in life and concerns regarding our own well-being, as well as that of others, our job, country, etc.

Magda Arnold (1960) was one of the first Appraisal theorists who believed that physiological changes are not the only basis for emotional feelings. Rather, the act of cognitive appraisal of daily experiences is the defining feature and cause of emotional reactions. This view was later echoed by Richard Lazarus (1977) who also advanced the idea that appraisal *causes emotions*. The emotions are then ultimately expressed internally through physiological and motivational changes, and externally through behavioral responses. A defining feature of most of Appraisal theories is the insistence that emotions are not generated solely as reactions to events faced on a daily basis in the world. Instead, emotions are responses to our "ongoing relationships with the environment", that result in our evaluation of whether a given array of stimuli and events will serve to benefit or harm us (Lazarus, 1991). Lazarus viewed the Appraisal process in terms of two separate themes. The first identifies emotions as a consequence of forming evaluative judgments that renders meaning to our circumstances. The second concerns the role of emotions, as Appraisal theories provide a nice extension to the propositions developed by Schacter-Singer. They do so by defining the category or types of appraisals employed to evaluate the significance and relevance of circumstances we find ourselves in daily.

Here is how Lazarus describes these processes:

"This approach to emotion contains two basic themes: First, emotion is a response to evaluative judgments or meaning; second, these judgments are about ongoing relationships with the environment, namely how one is doing in the agenda of living and whether the encounter of the environment is one of harm or benefit."

The following list is not exhaustive but summarizes the types of appraisal dimensions organisms consider while appraising not only the context, but also the potential value any new experience presents to them. Appraisal theories assert that, for any

environmental encounter, the resulting emotion is a product of the individual evaluating the present situation relative to 1) *novelty*, or whether or not we have ever experienced this set of features before, 2) *expectedness*, is this event predictable based upon the configuration of environmental events, 3) *pleasantness*, is the circumstance one that will be positive and beneficial or aversive and bad for me, 4) *goal oriented*, is the situation congruent with my present goals or a distraction, 5) *fairness*, is the circumstance fair and just or dishonest and deceitful, 6) *control*, can I control the present events or is the locus of control outside of my responding, 7) *certainty*, which is similar to *expectedness* in being capable of predicting the outcome of this encounter, 8) *morality*, is the event in line with my concepts of what is or is not morally acceptable, and 9) *self-concept relevance*, will this event influence how I feel or view myself.

Answers derived from evaluating how new events rate on these, or a subset of these, dimensions determine how a given event will produce the emotion of happiness, sadness, fear, anger, same, disgust, or any combination of these states. Richard Lazarus (1991) categorized the list of appraisal dimensions into either primary appraisals or secondary appraisals. The former term is used to denote the type of assessments that directly influence an organism's well-being such as whether a given encounter is *goal oriented*, *pleasant*, *fair*, has *relevance to self-concept* or grouped collectively will impact how an organism will feel about itself. As such, primary appraisals determine the type of emotional response to any new encounter. *Secondary* appraisals assess how well one may be able to cope with a new encounter. These evaluations are derived by considering the appraisal dimensions of *expectedness*, *fairness* , *control* and *certainty*. Assessment of these dimensions allows organisms to reach the conclusion of whether they are competent enough to address the conditions of a new experience, or alternatively, if the present circumstances will require some form of emotion regulation to accept the lack of control of any given event.

Constructionist Theory view

Constructionist theories of emotion believe the memories representing your previous encounters with natural or inanimate objects, living organisms or personal episodes involving these events play an important role in generating emotions. According to this view, the vast reservoir of stored information regarding previously experienced stimuli, your reaction to these events, and the outcome of your responses is used by the brain to provide some of the conceptual meaning or perceptions to any new experiences an organism will face. The Constructionist's perspective is a bit different from those of previously discussed theories. Those viewpoints consider the brain as a passive medium to transduce or convert auditory, visual, tactile, etc. components of new events into neural activity. It is this constellation of inputs from various sensory modalities that provide an internal representation of what you are currently experiencing in the external or real world.

In contrast to these views, constructionist theory asserts a primary role of the brain in combining stimuli within your immediate context with past episodes saved in memory. These two sources of information are then used to construct a hypothesis or prediction of what an organism is experiencing. The point made with constructionist theories of emotion is that the brain itself, rather than individual features of environmental stimuli, is what *constructs* meaning to, or predictions of, what is occurring in our immediate circumstances. In essence, the brain is viewed as actively creating explanations for the sensory input it receives during new events, by generating internal models to infer the nature or causes of what we experience from the environment.

The merit of this concept explains why a single event may produce variations or totally different emotional reactions from one individual to the next. If the brain simply played a role in converting sound, sight, smells, taste and touch into neural patterns of activity to represent the features of environmental stimuli, then everyone would experience the same reactions. The constructionist's viewpoint readily accounts for why variations of emotional reactions occur to identical circumstances. Their premise is that the brain uses both previously stored knowledge, along with the configuration of newly imposed environmental stimuli, to create *simulations* or hypotheses about your immediate circumstances. Since the content of stored knowledge and memory varies from one individual to the next, it is conceivable that the actual perceptions everyone creates from environmental events will also vary.

This point is illustrated in Figure 13.5; where the same event (i.e. a funeral) creates opposing emotional reactions due to how the brain constructs the actual meaning to be attributed to any environmental encounter.

Celebration at a funeral

Sadness at a funeral

Figure 13.5 Differences in emotional reactivity to the same event, a funeral Constructionist theories assert the brain combines memory of previous events (we celebrate vs mourn death) with stimuli representing your immediate circumstances (funeral attendance) to construct emotions appropriate for honoring the death of a loved one at a funeral. Note the difference in emotional reactions to the same category of emotional experience. Image credit: Right: Picture provided by Carl and Lorraine Aveni and their world travels. From aveniadventure.weebly.com/blo...-jazz-funerals. CC BY NC SA 4.0; Left: By Eric Draper - White House Photo Essay, Public Domain, commons.wikimedia.org/w/inde...?curid=25500424

The image on the left depicts a traditional funeral in New Orleans, where many inhabitants have learned from an early age that death is actually celebrated. The response of celebration, rather than of mourning, evolves from learned *cultural beliefs or concepts*, that through death, their loved ones are advancing, graduating, or moving on to a much better place than the present earth. Contrast the emotions observed in this image with those in the image on the right, where individuals display sad and solemn emotions. Here, the *brain's learned concept* of funerals generates these opposing emotions because loved ones have learned that funerals are where you mourn the permanent loss or absence of the valuable roles they remember the deceased played in their lives. Thus, concepts learned through experience and embedded within memory are used by the brain as a foundation for guessing or predicting what is occurring in the world and in selecting the most appropriate behavioral responses to adapt flexibly to any given event.

4.5.13: What Category of Feelings Are Considered as the “Basic Emotions”?

Learning Objectives

By the end of this section, you should be able to

- 13.2.1 Describe the basic category of emotions that are generally accepted in this field.
- 13.2.2 Understand how complex interactions between the 6 basic emotions lead to subcategories of emotional reactions.
- 13.2.3 Use Plutchik’s “Wheel of Emotions” to discuss how extensions to the 6 basic emotions provide a more ecologically valid illustration of the complex range of emotions experienced by humans and animals.

Are there categories of basic emotions for all humans? The potential for contextual stimuli from the environment to signal opportunities for social engagement, rewards, safety or signs of danger are appraised by cognitive processes in the brain. The interpretations evolving from this process coordinate a range of appropriate behavioral reactions that fall into the class of either approach towards, or avoidance from, stimuli in the immediate environment. In essence, the collection of brain systems that contribute to the appraisal process allow organisms to learn what will work in a given context. Brain systems also encode in memory the environment-body-brain interactions and use these memories to guide behavior in a more automatic and seamless fashion when similar events arise in the future. As we have learned, the selection of either form of engagement with the environment (approach or withdrawal) is determined by both the level of physiological arousal elicited by the experience and the emotional labels assigned to the represent the subjective feelings created inwardly from that transient event. This framework of understanding leads to another important topic in the field of emotion research, *are there categories of basic emotions that are present across all human species*?

Answers to this question were not initially addressed through direct investigations. They evolved from studies questioning whether the same appraisal processes that generate subjective affective experiences (i.e. conscious awareness of a state of feeling) are also capable of interpreting the nature of emotions inferred in facial expressions that accompany different emotional states of others. For example, when we are enthralled in an emotionally-laden circumstance, a cascade of involuntary unconscious changes occur such as split second changes in body functions in the autonomic nervous system, the volume, pitch and rate of our speaking, as well as the generation of different expressions on our face. Expressions involving smiles, frowns, clinched eyebrows and other forms of facial utterances are overt expressions of the internal emotions humans and animals may experience. This observation implies that feelings and emotions can be inferred through body language and more specifically, facial expressions.

Paul Eckman.

Paul Eckman and Wallace Friesen (Eckman & Friesen, 1975) were the first researchers to provide empirical support that humans possess a core set of six or more fundamental emotions. Their initial research examined whether research participants could identify the emotion a person was experiencing in a series of photographs by paying attention to different cues among the facial expressions, similar to those shown in Figure 13.6:

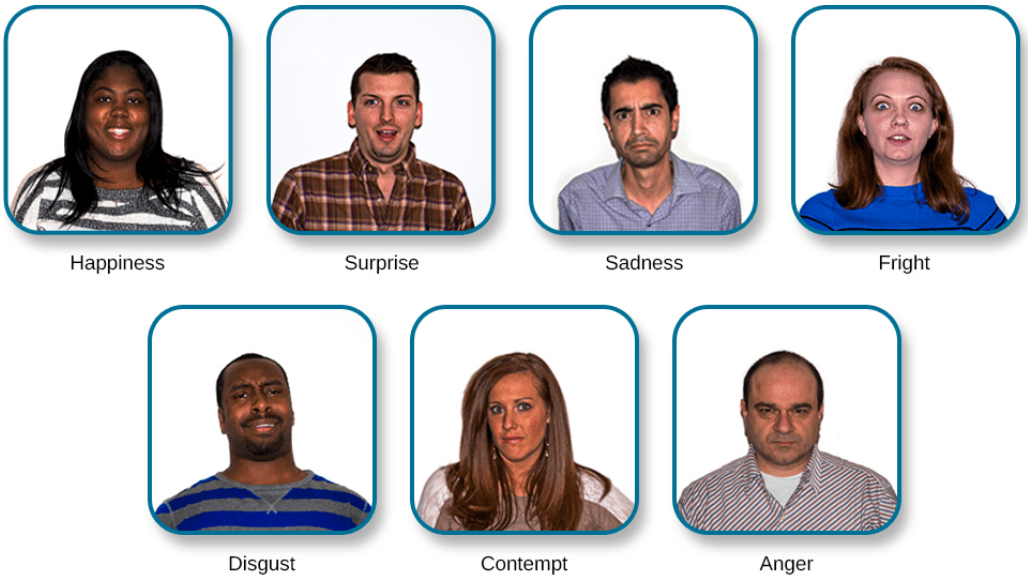

Figure 13.6 Facial expression of basic emotions The initial research by Paul Eckman determined if participants from several cultures could identify the emotion a person is experiencing from a series of photographs similar to those shown here. Image credit: Image courtesy of David Matsumoto and Humintell, LLC www.humintell.com

Eckman's research participants revealed a great deal of accuracy and uniformity in discerning the emotions of *anger, disgust, fear, happiness, sadness or surprise* from the facial expressions portrayed in photographs. His group solidified these findings by repeating the experiment with participants living in different cultures such as Argentina, Brazil, Chile, and Japan. The spoken language of these cultures differs drastically, yet participants showed a remarkable degree of overlap in identifying the six basic emotions across cultures.

The experimental procedures to generate these findings were also applied to three separate groups of non-English speaking natives in New Guinea who were completely unfamiliar with Western Culture. Ekman's team considered it vital to include these essential experimental groups to verify that the ability to perceive emotions from facial expressions shown across cultural boundaries was not the result of exposure to Western cultural influences such as television, magazines, newspaper or theatrical movies. Ekman found that three separate native groups could also identify the six basic emotions from the expressions of models in photographs, although with less accuracy than the combined Western and non-Western participants.

Taken together, Paul Ekman's group was instrumental in revealing that all humans are endowed with an innate capacity to identify a basic set of internal core emotions through the combination of stimuli that comprise different facial expressions. From these and similar empirical studies, Ekman and Cordaro (2011) provided operational definitions to categorize the following six basic emotions.

Anger: the response to interference with our pursuit of a goal we care about. Anger is also triggered by someone attempting to harm us or someone we care about either physically or psychologically. In addition to removing the obstacle or stopping the harm, anger often involves the wish to hurt the target.

Fear: the response to the threat of harm, physical or psychological. Fear activates impulses to freeze or flee. Often fear triggers anger.

Surprise: the response to a sudden unexpected event. It is the briefest emotion.

Sadness: the response to the loss of an object or person to which you are very attached. The prototypical experience is the death of a loved child, parent, or spouse. In sadness, there is resignation, but it can turn into anguish in which there is agitation and protest over the loss and then return to sadness again.

Disgust: repulsion by the sight, smell, or taste of something; disgust may also be provoked by people whose actions are revolting or by ideas that are offensive.

Happiness: feelings that are enjoyed or sought by the person. There are a number of quite different enjoyable emotions, each triggered by a different event, involving a different signal and likely behavior. The evidence is not as strong for all of these as it is

for the emotions listed above.

The concept that there are a core set of basic emotions has been corroborated by research using extensions of the procedures developed by Ekman's group. It is essential to note here that other psychological theories of emotion include more than 6 basic emotions, as we will see in the section on Robert Plutchik. Despite this disagreement about the number of core emotions, other research studies have identified specific changes in the body that accompany the 6 basic emotion categories identified by Ekman and colleagues.

The diagrams depicted in Figure 13.7; represent what is known as body maps and they reveal how the induction of each basic emotion is reflected by elevations (i.e. red to yellow shading) or reductions (i.e. black to blue shading) in a diverse number of bodily regions (Nummenmaa, Glerean, Hari, & Hietanen, 2014).

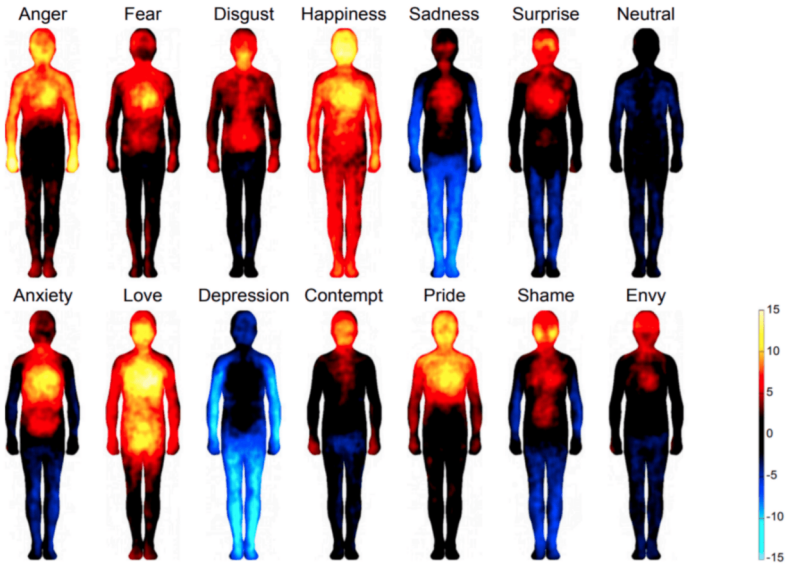

Figure 13.7 Body maps associated with each basic emotion The Body Maps reveal how experiencing each basic emotion elicit elevations (i.e. red to yellow shading) or reductions (i.e. black to blue shading) in bodily activity. Image credit: Mummenmaa et al., 2014. "Bodily maps of emotions." Proceedings of the National Academy of Sciences 111 (2) 646-651; DOI: 10.1073/pnas.1321664111.

For example, states of Anger correspond to increased blood flow to the hands and arms presumably to prepare organisms to defend themselves or fight in the face of threatening environmental stimuli (Levenson, Ekman, & Friesen, 1990). In contrast, states of Fear direct blood flow away from the hands and arms and distribute increased circulation to the legs and feet to prepare organisms to escape and flee from external signals of danger (Ekman, 2003). External stimuli that lead to Disgust (also see row 3 of Figure 13.2) trigger intense muscle activation in the face. Depending on the intensity or modality of the stimuli, this emotion may also induce a gag reflex and restrict further airflow to the nose to reduce the repugnant nature of external olfactory stimuli (Koerner & Antony, 2010). The positive emotion of Happiness increases circulation throughout the body as a consequence of elevated output of oxytocin and serotonin (Uvnaes-Moberg, 1998), whereas states of Sadness are reported to reduce circulation to external limbs used to interact with the environment and direct blood flow to internal visceral organs. The final emotion of Surprise affects facial expression by raising the eyebrows and increasing respiratory functioning in the lungs to prepare organisms to generate sudden approach or avoidance responses to rapidly presented stimuli (Ekman & Friesen, 1975).

Findings from neuroimaging studies with functional magnetic resonance imaging (fMRI) capture the collection of brain neural systems that are engaged in response to experiencing each of the core basic emotions (Saarimäki et al., 2016) (see Methods: fMRI). To provide this snapshot, the brains of human participants were scanned with fMRI while they viewed 10 second affective movie clips that were selected from a database, with scenes representing 5 emotion categories. A second experiment assessed brain related changes in response to emotional imagery. Imagery was manipulated by presenting words to study subjects that commonly evoke affective feelings associated with anger, disgust, fear, happiness, sadness or surprise. It is important to note that all participants were given 36 emotion words (i.e. 6 per words per emotion category) one-week prior to be scanned in the fMRI. The 7-day interval was imposed to allow participants to devise a personal method of eliciting emotions to each word category by either, a) imagining a previous event associated with the words, b) relating the words to a movie scene, or c) producing a body state that corresponds to emotions associated with the word categories. The data in the top left of Figure 13.8 shows that the experimental procedures were successful in generating a specific emotion. Participants were between 90-95% accurate in subjectively identifying the specific emotion category researcher's intended to induce through presentation of the short movie

clips.

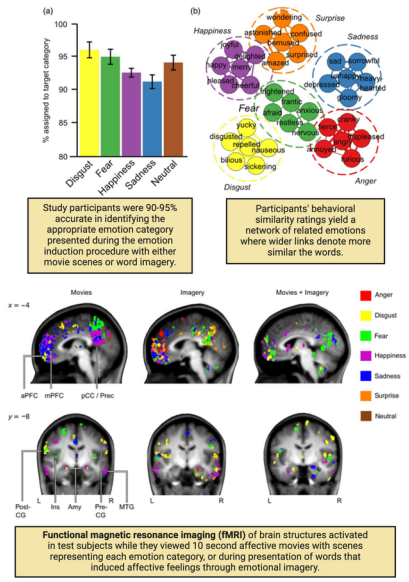

Figure 13.8 Neural systems engaged during the experience of basic emotions Image credit: Images from: Saarimäki H, Gotsopoulos A, Jääskeläinen IP, Lampinen J, Vuilleumier P, Hari R, Sams M, Nummenmaa L. Discrete Neural Signatures of Basic Emotions. Cereb Cortex. 2016 Jun;26(6):2563-2573. Reused with author permission

Data in the top right of Figure 13.8 represents a cluster analysis to show that the pre-selected emotion words specifically induced feelings associated with a specific emotion. The separation of presented words into clearly defined categories provides evidence that select words evoked affective reactions in discrete emotion categories, as opposed to across more than one emotion category.

The findings from fMRI scans are shown in the bottom of Figure 13.8 (brain diagram). The separate emotion categories are represented by the different colors displayed on the right of the figure. The location of brain regions that actively responded to emotions induced by movies or imagery are displayed in brain images on the left of the figure (see abbreviations below). One striking finding that is easily identified in the brain diagrams is that specific emotion categories are not represented in a single brain structure, but rather across brain regions. Take for instance the color purple, that represents Happiness. When this emotion was elicited by movies, imagery or both procedures, there are clear functional changes in the medial and anterior prefrontal cortex (mPFC, aPFC), posterior cingulate cortex (pCC), amygdala and medial temporal gyrus. The remaining fMRI results did not reveal a one-to-one correspondence between changes in any specific brain region with a given emotion category. Rather, some brain structures, such as the insula (Ins), displayed increased activity to stimuli generating the emotions of fear and disgust. There were also notable increases in the amygdala (Amy) by words or movie scenes that induced the emotions of happiness, fear and disgust.

We will discuss the brain systems mediating emotion much more in 13.3 What Is the Contribution of Brain Structures in Emotional States?. For now, we can learn from this experiment that, although we may subjectively discern one given emotion from another, the lack of selective activation of specific brain regions per emotion category reflects that the process of generating emotions from internal states involves several brain systems. This involvement of multiple regions to generate single emotions is quite reasonable given that any given emotion is a collection of processes that result from binding together the context the emotion occurs in, evaluating the constellation of bodily changes created by an event, the value of stimuli that elicits the emotion and the role of memory in retrieving affective states associated with previous encounters with similar events. These findings illustrate how distinct categories of emotion translate into characteristic patterns of neural activity or neural signatures across a network of brain structures, rather than within any specific brain structure. The neural signatures were induced in subjects by a wide spectrum of emotion-eliciting training conditions and the changes produced in the specific distribution of brain networks were consistent across individual participants. These findings raise the question of whether our current imaging tools are sophisticated enough to predict the subjective emotion an individual is experiencing from using solely brain activity.

Robert Plutchik

Ekman's group was instrumental in identifying a basic category of emotions generated by environmental stimuli across all cultures. However, you may judge this discovery as being somewhat limited when considering the range of emotions you

experience personally at any single point in time is both complex and multifaceted. This type of concern was raised by Robert Plutchik who opposed this abbreviated category of emotions. He proposed that the vast range of subjective feelings humans experience may be better explained by considering that basic emotions do not occur in isolation, but may combine to capture the richness and intensity of personal experiences generated by external events. For example, one may immediately experience the emotion of happiness when notified in an email of a job promotion that also comes with a major increase in salary. It is not a far stretch to say that the emotion of happiness garnered by reading this document may also be combined with some fear and apprehension of the greater responsibilities, expectations and demands on time that accompany this new promotion. In a similar vein, consider the range of emotions generated when you are the subject of a surprise birthday party. The unpredicted festive event may be filled with cherished individuals that bring you great joy, happiness and comfort. When all are combined, the joy, happiness and comfort elicited by the surprise party may also be met with extreme anger when considering that the organizers of this event are well aware of your previously stated disdain of surprises. Sports fans are quite familiar with the subjective feeling of disgust over an unfair call by a referee during the final seconds of a match with your rival team. However, when your team is victorious, joy, happiness and excitement join the feelings of disgust that were generated only seconds ago by the referee's error.

The inability for current theories to account for the consequences inherent in each type of scenario described above motivated Robert Plutchik (1960; 1984) to propose that the rich constellation of emotions experienced in humans are a byproduct of eight basic emotions (e.g. *joy, trust, fear, surprise, sadness, disgust, anger and anticipation*) that are depicted in the table and color wheel in the second circle from the center of Figure 13.9.

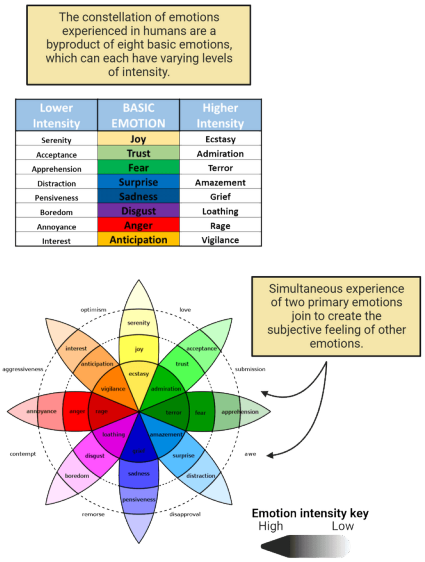

Figure 13.9 Wheel of emotions Image credit: Color wheel from public domain: https://commons.wikimedia.org/wiki/F...chik-wheel.svg

There are low and high degrees of intensity of Plutchik's eight basic emotions that are represented by the lighter and darker hues of colors on the wheel, respectively. Plutchik envisioned basic emotions as building blocks with more complex emotions being blends of the basic ones shown in the second circle. For example, the Covid-19 related mask mandates on airplanes garnered different emotions depending on how serious one may view the long-term health consequences of this virus. An individual may initially experience the lower intensity emotion of *annoyance* by viewing someone in the waiting area without a mask. However, the more intense emotions of *anger* may erupt once you hear the mask-less passenger sneezing upon entering the plane and the higher intensity emotion of *rage* may result when you realize the "mask-less, sneezer" seat is next to yours on a 6-hour flight.

According to Plutchik, the extensive number of subjective emotions produced during any encounter arise from some unique clustering of the emotions included in this spectrum. The separate emotions shown without colors in the outer sphere of the wheel demonstrate how the simultaneous experience of two primary emotions join to create the subjective feeling of other emotions. For example, life experiences that foster both *anticipation* and *joy* will combine to produce *optimism*, or a positive view on future events, whereas events that generate *disgust* and *anger* lead to the experience of *contempt*. The three-dimensional form of the Wheel of Emotions is a separate way to demonstrate that as the color of the emotion moves from the exterior to the center, the intensity of the emotion experienced, intensifies within an individual. Using the airline flight example above, anger that is manifested at its lowest level of intensity is annoyance, yet when combined with anger will lead to the full expression of rage. Plutchik's Wheel of Emotions can also explain how polar opposite emotions may evolve within the same experience. Take for example the emotions you may experience while attending a funeral for a cherished loved one who battled cancer for the past three years. Although it is clear one will experience extreme grief and sadness (depicted as blue in the wheel) at this lost, these

subjective emotions may be accompanied by both a sense of serenity and joy (depicted as light yellow in the wheel) by knowing that the loved one is now free from constant pain, a loss of independence and daily suffering.

Neuroscience in the Lab

How emotions are studied in neuroscience: methods and techniques

Ekman and Cordaro (2011) provided a list of forms of emotional expression that are common across the human species. This list suggests that there are representative overt and internal changes that accompany the experiential or subjective feeling of a given emotion. The four overt responses include changes in verbalizations (i.e. tone, speed, and pitch), facial expressions, body posture and physical responses (i.e. affiliative or positive bonding reactions or aggressive and opposing actions) toward individuals or objects that elicited the emotion. The two internal or unobservable responses include physiological changes in the body and neural changes in activity across critical brain structures. The sheer range of internal and external changes that represent the onset of a given emotion produces a challenge for those studying the underpinnings of emotions. Fortunately, there are several technical tools to address these challenges. In a general sense, there are 2 core components of any emotion experiment. The first includes procedures for eliciting a selected emotion and the second includes the use of technology to capture and quantify how the experimentally elicited emotion impacts any of the overt or internal changes. The following section provides an overview of the tools available to researchers to combine these approaches in understanding brain-behavior relationships.

Emotion Induction, a traditional method of eliciting emotions involves presentation of words, pictures, sounds or movie clips that are already verified to induce a certain emotion. There are several databases containing thousands of pictures that have been evaluated by large, heterogeneous groups of men and women to ensure the pictures elicit emotions in a given category. One commonly used database is known as the International Affective Picture System (IAPS) that was developed by Peter Lang and Margaret Bradley at the University of Florida. Pictures developed for the IAPS have been verified across a large number of research studies and each photo is assigned a rating number so that potential users are informed on how well a picture in the database is rated for emotional arousal and valence in terms of positive or negative impact. There are a number of other emotional picture datasets including the Open Affective Standardized Image Set (OASIS) Emotional Picture Set (EmoPicS) and Geneva affective picture database (GAPED) just to name a few. Movie clips, sounds, words and other emotion-eliciting stimuli are also extracted from commercial databases or other emotion research labs that have validated that these stimuli elicit a targeted emotion with a high degree of accuracy.

Assessing Emotional Reactions. The impact of stimuli used to induce emotions are measured by a number of tools and devices that can reveal changes in either the subjective experience of feelings or fluctuations in the body or brain. The *subjective experience of emotions* is traditionally assessed by providing study participants with a SELF-REPORT survey that contains questions to identify the subject's personal reflection of the emotion experienced, its intensity and duration. A commonly used measure of *physiological changes* that correspond to emotional arousal involves the use of a Polygraph Test. As shown in Figure 13.10, the polygraph contains several sensors that measure the magnitude of an emotional stimulus on several bodily changes.

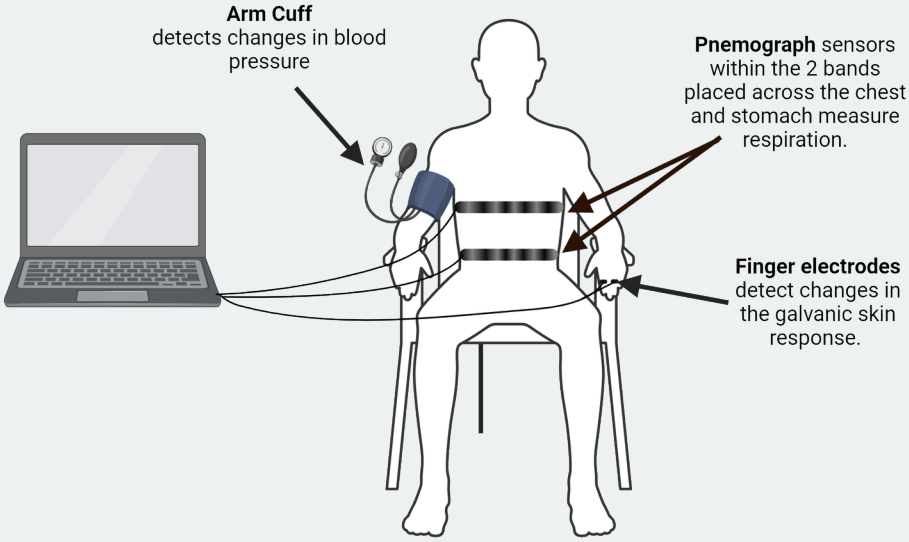

Figure 13.10 Methods of identifying changes in physiological arousal after the induction of emotions Image credit: Photo by Sherkiya Wedgeworth - federalsoup.com/articles/201...pplicants.aspx, CC BY-SA 4.0, commons.wikimedia.org/w/inde...urid=110940529

This device detects the Galvanic Skin Response (GSR), a measure of electrodermal fluctuations in skin (i.e. sweat) that occurs when arousal-induced stimuli increase activity in the sympathetic nervous system. Although GSR is a reliable indicator of physiological changes, this type of measurement is poor at identifying the source of the arousal. For example, increased GSR responses may occur rapidly after presenting research participants with a vivid picture of a snake. However, the GSR cannot reveal whether the picture-related arousal is due to elevations in heart rate, blood pressure, respiration, dilation of the pupils, or the secretion of stress hormones such as epinephrine or cortisol. These changes reflect intense activation of the sympathetic division of the autonomic nervous system and are reflected by electrodes shown in Figure 13.10. When multiple electrodes are used with the polygraph, researchers are able to develop a profile or "physiological fingerprint" that corresponds to the induction for emotions triggered by stimuli that produce sadness, anger, fear, happiness, disgust, etc.

The gold standard used in the search to unravel which brain areas are absolutely essential for generating the basic emotions is functional Magnetic Resonance Imaging (see Methods: fMRI). fMRI is an imaging technique that is capable of capturing the structure and location of individual brain structures that respond to emotional encounters. fMRI scans of participant's brains are recorded before, during and following the induction of emotions. In brief, the brain scans document how these time-locked events activate or suppress neural activity across different brain regions by tracking changes in blood flow across several brain regions that may be critical for processing and generating emotional responses. fMRI is a valuable tool for understanding if individual categories of emotion are mediated by changes in specific brain regions, or alternatively, revealing the constellation of brain structures that are responsible for this process. Functional imaging is also necessary for identifying how the separate stages of emotion perception, emotion evaluation and emotion regulation are effectively carried out by changes across different brain regions.

4.5.14: What Is the Contribution of Brain Structures in Emotional States?

Learning Objectives

By the end of this section, you should be able to

- 13.3.1 Describe how information conveyed from sensory systems and autonomic nervous system inputs to the CNS influence the functioning of limbic areas to generate emotions.
- 13.3.2 Discuss how the coordination of neural input into limbic brain structures are integrated to produce characteristic patterns of physiological and neural changes that evolve into appropriate emotional responses to a given external stimulus.
- 13.3.3 Describe an example of a limitation in generalizing findings from animal studies to humans.
- 13.3.4 Define the roles of specific cortical limbic structures in appraisal of emotionally-salient stimuli, generating the "feelings" from appraisals to develop adaptive strategies, and generating decisions and motor plans for responding to emotional stimuli.

An extensive amount of research is directed toward identifying the source or substrate of individual emotions in the brain. These efforts are quite challenging since distinct brain regions have multiple inter-connections with a diffuse set of other regions that in themselves process different types of internal and external stimuli. Thus, the search for a specific "neural signature or fingerprint" for each category of emotions has been a difficult process. The large variation in neural patterns observed within brain circuits during different states of internal arousal may explain why individual emotions are perceived as feeling different from one another. Still, decades of research in animal models and in humans have given us some insight into the major structures that mediate the experience of emotion and our behavioral/physiological responses to it. In this section, you will then learn how the brain integrates information from both internal systems and external sensory perception to form cognitive appraisal and evaluative functions to generate emotions that are appropriate for any given circumstance.

Papez circuit overview

The complicated but essential process of emotional experience and expression is regulated in part by an assembly of brain structures that comprise the Papez Circuit (Papez, 1937; MacLean, 1952). The important contributors to this neural system include the thalamus, hypothalamus, amygdala, hippocampus, anterior cingulate cortex , orbitofrontal cortex, insula cortex and striatum. This interconnected circuit of cortical and subcortical brain regions takes inputs from the internal and external environment and helps to evaluate those cues to generate emotional responses to them. Figure 13.11 shows the anatomical location of several of these major structures, as well as a schematic for how they connect to one another.

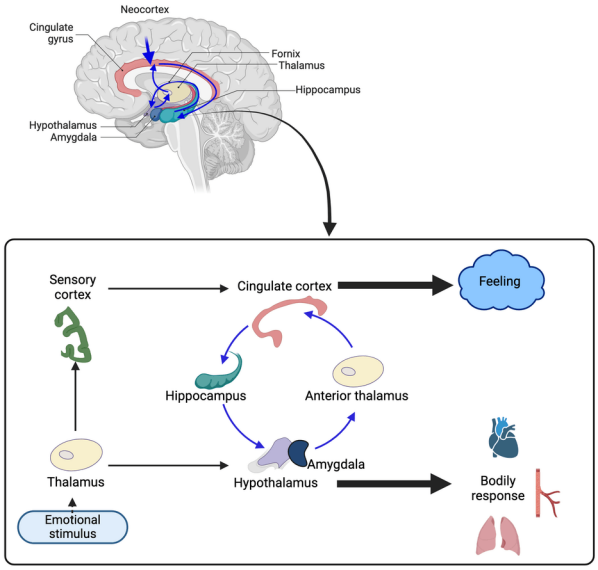

Figure 13.11 Papez circuit and interrelated structures The limbic and subcortical structures of the Papez circuit allow organisms to adapt to changes in the environment. These structures initiate neural and behavioral programs that return internal physiological and psychological states to an ideal balance. Image inspired by work of Dalgleish, T. The emotional brain. (2004). Nature Reviews Neuroscience, 5, 583–589.

The initial evidence that structures in the Papez circuit are involved in constructing emotions was provided by Heinrich Klüver and Paul Bucy (1938). These scientists removed large parts of the temporal lobe in monkeys that included the amygdala, hippocampus and selective white matter tracts or nerve bundles that connect some of the components comprising the Papez circuit. The range of behavioral and emotional deficits produced by removing these critical brain areas is now commonly known as the Kluver-Bucy Syndrome. One key deficit in Kluver-Bucy syndrome that pointed to the importance of these temporal lobe regions in emotion is a complete absence of the agonistic emotions of anger or fear to threatening stimuli (placidity). Appetitive-related emotional responses involving feeding are also severely impaired as subjects that have been satiated by a previous meal will still eat excessive quantities of food or other objects that do not even resemble food. Other perceptual and behavioral impairments included difficulty in identifying objects by sight, the sound of stimuli or touch, even when there is no damage to brain areas that process these three stimulus modalities. There is also severe global amnesia manifested by the inability to convert short-term memory into long-term memory, most likely due to the selective damage to the amygdala or hippocampus (see Chapter 18 Learning and Memory). Compulsive-like interests in exploring the immediate environment (hypermetamorphosis) is also frequently observed in Kluver-Bucy syndrome. These types of impairments were first observed in early studies of monkeys and cats and then were later observed clinically in humans with temporal lobe damage from accidents or following bilateral temporal lobe surgery to alleviate the debilitating symptoms of epilepsy.

Kluver-Bucy syndrome provided some clues to the functions of several components of the Papez circuitry. We now have a more detailed understanding of the unique roles that each brain area in the Papez circuit plays. In the subsequent sections, we will walk through the specific roles of several of these regions.

The thalamus relays interoceptive and exteroceptive sensory information

We will begin our tour of the individual components of the Papez circuit by first understanding the sensory information inputs that generate emotional responses. According to a recent view, emotions are constructed when internal physiological sensations are so intense that they are in the foreground of our awareness. This process of monitoring internal physiological conditions is called interoception. It stands in contrast to exteroception, which is our sensory perception of the external environment (Figure 13.12). Both of these senses contribute to our emotions. The converted signals from collective receptor cells of both forms of sensation (interoceptors and exteroceptors) are conveyed by different nerve pathways to individual regions of the thalamus. The thalamus, in turn, relays this information to both the hypothalamus and amygdala as shown in Figure 13.11. Both of these downstream structures are considered reflexive in nature, in that thalamic activation of particular regions within either structure automatically initiates behavioral, emotional and physiological responses without conscious awareness or thought.

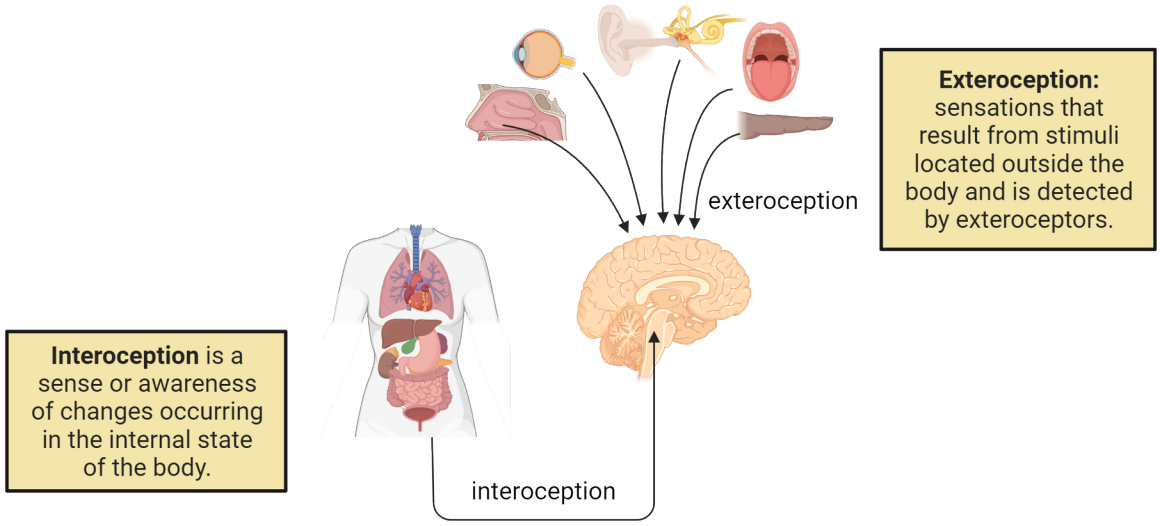

Figure 13.12 Interoception and exteroception

The reflexive emotional responses generated by the hypothalamus

The hypothalamus is critical to coordinating our bodily and psychological responses to the changing demands of our environment. Organisms must constantly adapt to changing environmental conditions in order to survive and reproduce. Fortunately, humans and animals are successful in adapting to dynamic external changes through the aid of body machinery and selective behavioral programs that return internal physiological and psychological states to some comfortable, ideal balance when a change in the environment occurs. We refer to the desired, ideal balance as homeostasis (see Chapter 16 Homeostasis). The hypothalamus receives interoceptive input from throughout the body, via the relays in the thalamus, which it then uses to direct a number of physiological and behavioral responses.

The hypothalamus is composed of many individual nuclei, each of which can elicit specific emotion-related behaviors and their accompanying physiological changes. These behaviors fall broadly in to 3 categories:appetitive responses (*e.g. energy needs, replacement of nutrients and temperature regulation)*, agonistic behaviors (*e.g. self-protecting defending or attack behaviors)* and reproductive mating instincts. The early German researcher Walter Hess (1933) demonstrated in awake cats how applying electrical stimulation to activate neurons in discrete regions of the hypothalamus would produce a host of agonistic, appetitive or autonomic changes. For example, stimulation directed at one group of hypothalamic nuclei could cause the appearance of the emotions of fear and anger (agonistic behaviors). These readily observable emotional signs were accompanied by intense physiological changes in autonomic functioning (e.g. increased heart rate), as well as motor signs and instinctive behaviors where the stimulated cat would attack the first available object in its environment. Moreover, this set of bodily, emotional and behavioral changes persisted as long as the stimulation was applied and ceased only when the stimulation was terminated. In contrast, stimulation applied to other divisions of the hypothalamus slowed down the cat's heart rate and rendered the animal calm, tame, and sleepy (appetitive responses). These and other related findings of the provocation of physiological, emotional and behavioral changes by artificial stimulation of the brain strengthened the belief that physiological changes in the body lead to the development of discrete emotions that in turn determined the nature of behavioral responses an organism will emit on external environmental stimuli. These new discoveries also pointed to a critical contribution of the hypothalamus as a major initiator of behavior and physiological response to emotional stimuli.

The amygdala's reflexive role in emotional learning and fear

The response profiles in the amygdala are similar to those in the hypothalamus. One characteristic distinction between the two is that subdivisions of nuclei within the amygdala may produce reflexive changes not only to important external stimuli that are immediately threatening or rewarding, but also to neutral or once *unattended stimuli* that occur in concert with important events. In other words, the amygdala can form memories about the relationships between two or more stimuli that occur together or even in some sequential fashion during our daily interactions if one of the stimuli has emotional importance. For example, the hypothalamus may initiate feelings of hunger when children are in a classroom simply through olfactory stimuli associated with the smell of food from the cafeteria. The amygdala, however, may generate the same feelings of hunger by simply seeing

students from an adjacent class line up in the hallway to head to the cafeteria. This extension is produced by the capacity of amygdala neurons to form associations between previously neutral stimuli (i.e. students from a neighboring class proceeding to the cafeteria to eat) that serve to predict the eventual satisfaction of a meal you will eventually encounter in the cafeteria. The previous scenario is an example of associative learning that takes place in the amygdala, yet not in the hypothalamus. These learned associations equip humans and animals to use the predictive value of once *unattended stimuli* to anticipate appetitive or aversive events (see Chapter 18 Learning and Memory).

In addition to mediating emotion-related learning, the amygdala also appears to have a particular importance for generating the emotion of fear. Key evidence for the necessity of the amygdala for generating fear in humans has come from study of rare disorders that impair amygdala function, such as Urbach-Wiethe's disease. Urbach-Wiethe's disease is a rare disorder that causes a slow bilateral calcification and destruction of the amygdala starting around age 10 (Markowitsch, 1994) in roughly 50 to 75% of cases examined thus far (Staut & Naidich, 1998).

One of the most extensive case studies of Urbach-Wiethe's disease involves patient SM who was first documented by Tranel & Hyman in 1990. The late onset of the disease (starting in later childhood and progressing slowly from there) may explain why patient SM failed to notice that she did not feel the emotion of fear or threat until she went to the hospital for treatment of epilepsy at age 20. It was during these exams that SM was given brain scans with computed tomography (CT), and later magnetic resonance imaging (MRI), to reveal severe atrophy and destruction of the amygdala in both hemispheres.

Further neuropsychological exams revealed that SM showed unique highly specialized deficits associated with the expression of fear (Adolphs, Tranel & Damasio, 1994). She also failed to recognize facial expressions of fear in photographs similar to those used in the research discussed by Ekman and Pulchik discussed in 13.2 What Category of Feelings Are Considered as the "Basic Emotions"?. She had difficulty discerning what fearful facial expressions mean, yet expressions of happiness, disgust or joy were easily identified. SM is actually an experienced artist, but could not draw or sketch a scared face, since she expressed no knowledge of what such a face would look like. One researcher noted that SM displayed little if any emotional reactions when discussing highly emotional and traumatic life experiences (Tranel et al., 2006). The apparent damage to each of SM's amygdala was also manifested by major impairments in memory for nonverbal visual information, social behavior, and executive control functions, however, other specialized test confirmed that SM's general intelligence and language were no different than normal healthy adults (Tranel and Hyman, 1990). You can read more about the kinds of test done with SM in Diagnostic tests of patient SM.

Diagnostic tests of patient SM

Patient SM had a rare genetic disorder that caused her bilateral amygdala to be destroyed. Careful study of her emotional responses helped reveal a specific deficit in experiencing or expressing fear in a variety of contexts. In a study conducted by Feinstein, Adolphs, Damasio, and Tranel (2011), the emotional reactions of SM were examined under three conditions that produce moderate to extreme fear in normal adults. As shown in the top of Figure 13.13, SM was taken to an exotic pet store and actually handled both a large threatening snake and frightening tarantula spider. Despite her stated hate for snakes and spiders, when asked to rate her fear during these encounters from "0" (no fear) to "10" (intense fear), her fear levels never exceeded the rating of 2. Although, she did express the feeling of extreme curiosity, rather than fear. She also was accompanied by researchers into the building shown in top right of Figure 13.13, the previous Waverly Hills Sanatorium, one of the most notorious "naturally haunted" buildings in existence. It is converted into a tourist attraction during Halloween. This tourist attraction-made-"lab test" for SM was complete with haunting noises, monsters, and actors dressed in horrifying costumes that would often jump out from hidden locations to scare and frighten visitors. SM failed to display the slightest emotion of fright or fear during the tour but rather was observed laughing and scaring the monsters by poking them in the head. In a separate component of the study, Feinstein's group also documented SM's emotional response to a series of short movies that elicit different emotional reactions and included ten video clips from notable horror films. As shown in the middle of Figure 13.13, the maximum amount of fear elicited by these scary film clips in SM involved a rating of "1". Note how different the emotion of fear was expressed in SM relative to healthy controls who rated their subjective feelings of being frightened by the scary clips from "5 to 8".

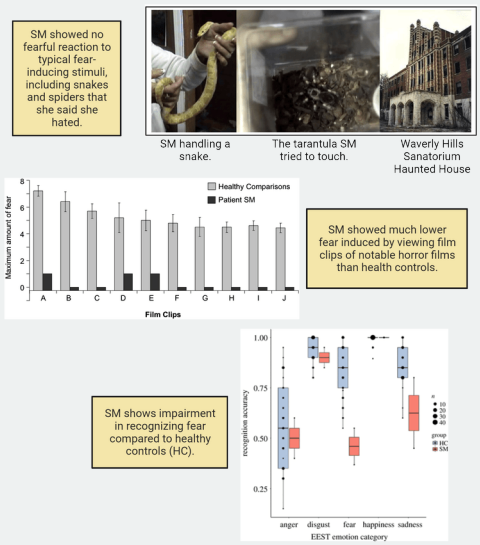

Figure 13.13 The human amygdala and the induction and experience of fear Image credit: Top photo and middle graph: Reprinted from Current Biology, Vol 21, Feinstein, J. S., Adolphs, R., Damasio, A., Tranel, D. The Human Amygdala and the Induction and Experience of Fear, Pages No. 34-38, Copyright 2011, with permission from Elsevier; Bottom box plot: Cardinale, E. M., Rever, J., O'Cpnnell, K., Turkeltaub, P. E., Trancel, D., Buchanan, T. W., Marsh, A.A. (2021). Bilateral amygdala damage linked to impaired ability to predict others' fear but preserved moral judgements about causing others fear. Proceedings of the Royal Society B. Vol 288 (1943). doi.org/10.1098/rspb.2020.2651. Reproduced with permission

More recent findings with patient SM verified a role of the amygdala in recognizing and appraising fear related stimuli in social conditions (Cardinale, et al., 2021). SM and healthy controls were given a series of 100 written statements previously shown to cause the reader to experience different levels of fear. The phrases included statements such as *('I could easily hurt you', 'I don't want to be friends anymore')*. Both SM and controls were tasked with predicting which emotion category (i.e. anger, disgust, fear, happiness or sadness) someone would experience when a given statement was directed to them. The results, displayed in the bottom of Figure 13.13, confirm the essential nature of the amygdala in registering and generating emotional responses to fear and threat-related environment stimuli. SM's ability to accurately recognize verbal stimuli that generates fear and sadness was significantly poorer than controls. In contrast, her capacity to identify statements leading to the emotions of happiness, disgust or anger were no different than the control group. The reliability of these results was demonstrated by documenting SM's performance across two separate test sessions. She displayed consistent poor emotion recognition performance for fear-eliciting statements in both sessions with a score of 55% accuracy relative to controls performance of 98% in the first session and an even worse 36% accuracy vs the control performance of 99% during the final testing session. The documented inability to experience fear as a result of bilateral and almost complete destruction of the amygdala in the case study involving SM provides convincing support for the important role played by the amygdala in both the appraisal and expression of one category of emotions involving both fear and sadness. These findings are supported by the growing amount of evidence showing a critical role of the amygdala in emotion-related disorders such as post-traumatic stress disorder (PTSD), anxiety and depression.

Neuroscience in the Lab

Neuroscientific Approaches in examining Fear/Threat Conditioning: An animal model of fear and anxiety in humans

The section above highlighted the role of the amygdala in producing the emotion of fear in response to threat related stimuli from the environment. In addition to studying diseases like Urbach-Weithe's disease, a great deal of animal research has confirmed the role of the amygdala in fear by showing that experimental lesions of parts of this brain region led to the apparent absence of fear. Today, more sophisticated approaches such as optogenetics are now available to study how brain regions mediate emotions in animal models. Optogenetics takes advantage of the finding that light sensitive proteins known as Channelrhodopsins-2 (ChR2) become active when exposed to light and release a number of excitatory ions that can be used to activate neurons in specific neural circuits. Methods: Optogenetics has more details about this method, but in short, by genetically expressing ChR2 in neurons and then shining a fiberoptic light on those neurons researchers can make neurons fire and then study what kinds of behavioral responses they see.

A study conducted by Kwon and colleagues (Kwon et al., 2014) employed the optogenetic technique to reveal how associative learning (*i.e. forming learned associations between 2 or more events that occur together in space or time*) in a fear conditioning task produces specific, plastic changes within the amygdala that results in the emotional expression of fear (see Chapter 18 Learning and Memory). In traditional forms of fear conditioning (top of Figure 13.14), a neutral tone is presented at a decibel that does not scare or induce any fear reactions in an animal. After 30 seconds of tone presentation, a mildly aversive footshock is administered to the animal's paws through the metal grid panels in the floor. Generally, only 5 to 6 "tone-footshock" pairings are necessary before the animal learns the predictive value of the "once-neutral" tone and begins to exhibit extreme emotional fear responses to the neutral tone, even before the footshock appears. The characteristic response indicative of the emotion of fear is the agonistic "freezing response". This form of associative learning discussed earlier is produced by the amygdala forming associations between the external auditory "tone" stimulus with the threatening and painful "footshock" stimulus applied to the animal's paws.

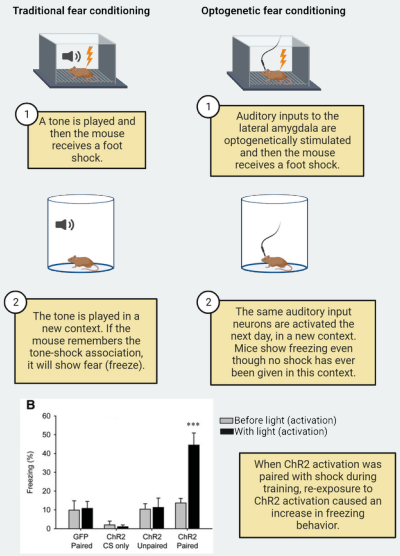

Figure 13.14 Optogenetic activation of fear memory Data from: Kwon et al., "Optogenetic activation of presynaptic inputs in lateral amygdala forms associative fear memory." Learn Mem. 2014 Nov; 21(11): 627–633. CC BY-NC 4.0

Kwon's group used optogenetics to determine if the amygdala is the actual site where associations between the tone is formed with the footshock during the generation of fear to neutral stimuli. The main manipulation involved using viral vectors to incorporate ChR2 within the parts of the auditory cortex that provide one source of auditory input to the lateral amygdala. The clever part of this study involved substituting the neutral tone with optogenetic activation of the auditory projections. To produce associative learning in this study, experimental animals received six pairings of optogenetic stimulation of auditory axons innervating the amygdala with a footshock, *rather than tone*-shock pairings (middle of Figure 13.14). The main question of interest here is whether associative memories develop following this artificial form of simulating auditory stimuli and pairing this experience with a threatening event.

This question was assessed twenty-four hours later by placing the animals in a new context (Context B), void of any previous associations and essentially fearless since no footshock was presented during this memory test. While in this neutral context, auditory inputs innervating the lateral amygdala were activated once again with optogenetic blue lights to represent the stimulus that was previously paired with the fearful footshock. The authors found that reactivating the connections between auditory inputs and the lateral amygdala (i.e. ChR2 paired group) was sufficient to produce the emotional response of fear even though no footshock was given in this new context. Notice in the graph in the bottom of Figure 13.14, the low level of fear learning observed in mice that received only optogenetic stimulation without footshock (ChR2 CS only) or those given optogenetic activation of auditory inputs that were not paired directly with footshock delivery (i.e. ChR2 Unpaired). The absence of associative learning in these group reveal that stimulation of inputs to the amygdala is not sufficient to produce emotional learning. Associative processes leading to learning in the lateral amygdala occurs only when auditory stimulation is paired with some emotion provoking event such as footshock delivery. The findings demonstrate that activation of auditory signals in the lateral amygdala serve as a potent conditioned stimulus that forms long term memories with the footshock to produce emotional responses of fear.

Insula Cortex

Thus far, we have discussed more reflexive regions of the Papez circuit, the amygdala and hypothalamus. Now, we will move on to brain regions that form cognitive appraisal and evaluative functions to generate emotions that are appropriate for any given circumstance. One major area that is involved in this process is the insula cortex. Insula cortex activity leads to an awareness of affective feelings and eventual emotions. Early studies conducted by the famous neurosurgeon Walter Penfield established that patients receiving electrical stimulation in the insula cortex reported unusual visceral sensations consistent with the experience of disgust associated with uneasy sensations in the stomach or throat, smelling or tasting something bad, and the experience of nausea (Penfield & Faulk 1955). In subsequent studies, it was found that insula stimulation produces a range of other emotions including feelings of empathy, intuition, unfairness, risk and uncertainty, trust and cooperation. The unique behavioral deficits that emerge after damage to the anterior insula cortex provide even greater clues to its function in emotions. Following insula lesions, patients do not express the emotion of disgust to unpleasant scenes involving body products, mutilations, etc. that are evoked in humans with an intact insula (Adolphs et al. 2003). They are also impaired in identifying signs of other emotions from either the facial expressions or inflections in voice produced by others.

The clinical and empirical observations discussed above make sense, given that the insula receives representations of the current state of internal bodily sensations (interoception) along with recreated replicas of the external environment (exteroception). The insula also has bi-directional communication with a variety of other cortical brain regions involved in emotion, memory, language and reasoning, such as the amygdala, ventral striatum, ventral medial prefrontal cortex, dorsolateral prefrontal cortex and anterior cingulate cortex. These connections are shown in Figure 13.15. Together, communication between these regions permit the insula to form appraisals of each emotional event by incorporating interoceptive and exteroceptive changes already processed in this area, with subjective feelings, personal reflections on the feelings and the cognitive resources to express them.

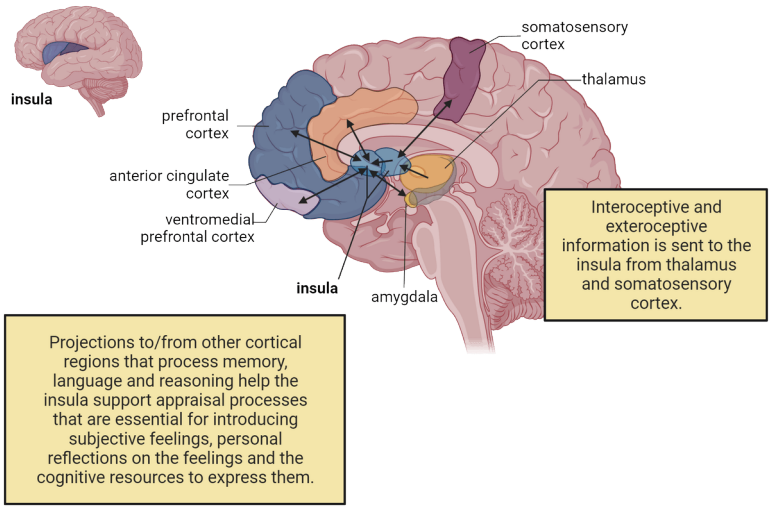

Figure 13.15 Insula cortex connections and function

Prefrontal Cortex

The prefrontal cortex can be functionally divided into two major areas: the orbitofrontal cortex and the dorsolateral prefrontal cortex. Figure 13.16 shows the relative locations of these regions on a 3D human brain surface rendering. Each of these regions has distinct functions in emotions.

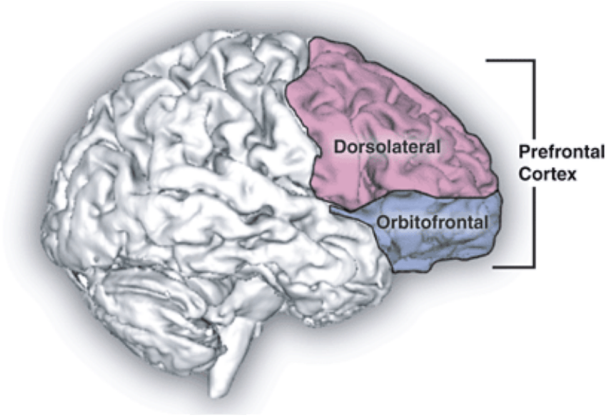

Figure 13.16 Prefrontal cortex regions Image By Natalie M. Zahr, Ph.D., and Edith V. Sullivan, Ph.D. - Natalie M. Zahr, Ph.D., and Edith V. Sullivan, Ph.D. "Translational Studies of Alcoholism Bridging the Gap" Alcohol Research & Health, Volume 31, Number 3, p.215-(2008)[1], Public Domain, https://commons.wikimedia.org/w/inde...?curid=8663554

Orbitofrontal cortex

As shown in Figure 13.17, the ventromedial prefrontal cortex is a part of the prefrontal cortex, located just above the eye sockets (or orbits). This location is why it is also called the orbitofrontal cortex.

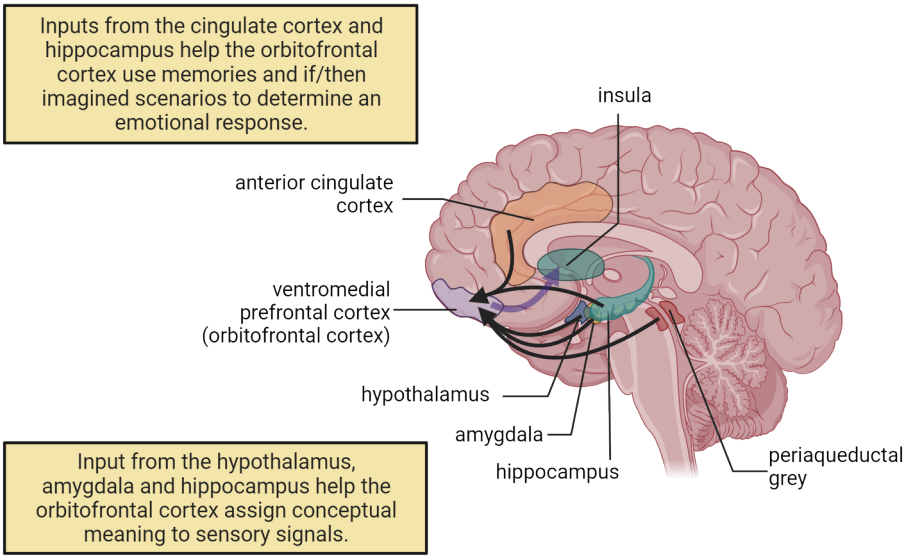

Figure 13.17 Ventromedial prefrontal cortex

The orbitofrontal cortex has multiple reported roles in emotion but we will focus here on 2 major ones: 1) assessing the goal-relevance of exteroceptive signals from the environment and 2) using internally generated thoughts pertaining to both episodic memories (*i.e. memory for personal events*) and imagined future events to determine the types of responses an organism should display to maintain allostasis in the face of new circumstances. The product of these internally generated processes in the orbitofrontal cortex is submitted to the insula to assist in the appraisal of new events. The importance of this evaluative process makes it easier to understand why humans that lack the vital contribution of the orbitofrontal cortex due to damage or surgery display extreme states of anger, lack self-control, and are more prone to rapid aggression without thinking about the consequences of these negative responses. Below, we discuss some of the connections in the brain that facilitate these two functions, which are also exemplified in Figure 13.17.

- *Assessing goal-relevance of exteroceptive signals*: Orbitofrontal cortex neurons are supplied with neural signals representing

every stimulus modality (exteroceptors) in the outer world. This arrangement may explain why neural activity in the orbitofrontal cortex is elevated when humans are exposed to somatosensory stimulation, visually presented scenes of erotic images, or facial expression involving either rewarding stimuli such as smiles or aversive stimuli in the form of angry expressions (for a review see, Dixon, Thiruchselvam, Todd, & Christoff, 2017). Interconnections with the amygdala, hypothalamus, and periaqueductal gray then help with assessing the goal-relevance of these exteroceptive signals. These areas provide information regarding rewards, punishment, current physiological needs and the agonistic or appetitive behaviors to exert on the environment to achieve these goals. The orbitofrontal cortex uses this information to assign positive or negative emotional labels to exteroceptive stimuli by considering how responses exerted on the environment in the past led to either favorable or undesirable consequences for the organism. The assessment role of the orbitofrontal cortex is in many ways an extension of the role of the amygdala in assigning affective value to sensory stimuli. The orbitofrontal cortex extends the role of the amygdala by learning the ever-changing relationships between sensory features of exteroceptive stimuli.

- *Using internal thoughts, memories and imagined events to determine a response*: The orbitofrontal cortex receives a great deal of information from brain structures involved in planning and simulating "if/then" scenarios of the possible outcomes of a given response. It is also the recipient of inputs from brain regions that store long term episodic memories of the outcomes of responses made in the past to exteroceptive stimuli including the hippocampus and cingulate cortex. These kinds of connections are the reason that activity of some orbitofrontal cortex neurons are more readily observed when humans are engaged in internally oriented thinking, but inhibited when it is necessary to focus attention on externally presented stimuli. The orbitofrontal cortex draws on these connections to contribute to an organism's personal appraisal of higher-order internal events, self-reflection of thoughts and memories triggered by a given event.

Dorsolateral Prefrontal Cortex.

The dorsolateral prefrontal cortex is a separate structure attributed a role in the process of emotional appraisal. Cognitive mechanisms in the dorsolateral prefrontal cortex are quite complex and perform a range of high-level computations on the behavioral actions an organism makes. Dorsolateral prefrontal cortex neurons are given the executive task of understanding the rules governing any given social environment, the goals of the organism in terms of allostasis and performing continuous updates or corrections of one's ongoing emotional state (see Chapter 19 Attention and Executive Function). This highly complex responsibility is a necessary component of emotion regulation, the process where value is assigned to emotional feelings created by initial appraisal processes and the behavioral actions that were generated as a result. The dorsolateral prefrontal cortex sits in the "executive's seat" by attending to the emotional evaluation process occurring in the cortical and subcortical structures discussed above. It uses this information to guide responses in specific contexts away from non-adaptive, short term payoffs of immediate rewards, towards more favorable behavioral actions that materialize into beneficial future outcomes.

Anterior Cingulate Cortex

The theories proposed by James-Lange and Cannon-Bard both stressed the importance of physiological reactions within the body as contributors to the development of emotions. We now know that this component of both theories is mediated by neural activation of the anterior cingulate cortex. The functions of the anterior cingulate cortex can be divided into 3 domains, summarized in Figure 13.18.

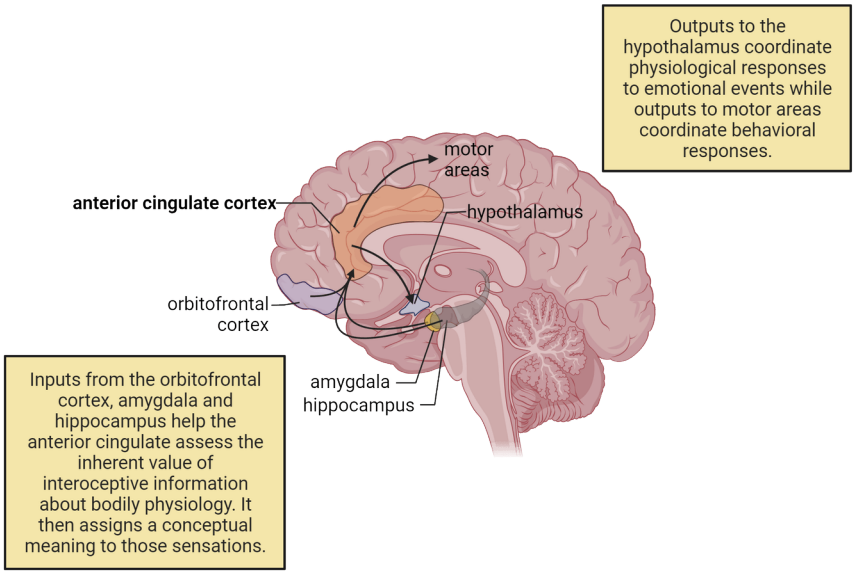

Figure 13.18 Anterior cingulate cortex and emotion

First, the anterior cingulate monitors internal physiology (e.g. heart rate, respiration) and makes evaluations to determine what level or intensity of physiological bodily adjustments are necessary to cope with the challenges posed by new experiences. To make these assessments, it uses important inputs from the orbitofrontal cortex, amygdala and hippocampus that project understanding of the inherent value, meaning, and also anticipated outcomes of a given situation. Downstream connections to the hypothalamus and other brainstem regions then allow it to influence internal physiological reactions.

Second, the cingulate cortex gives conceptual meaning to the physiological information it receives. It generates feelings of satisfaction when it deems the physiological information to reflect adaptation to external events, or states of displeasure when it assesses the behavioral and internal changes as not beneficial to the organism. Please note that the previous sections identified other brainstem and cortical structures that also process interoceptive signals. The contribution of the anterior cingulate cortex to emotions is somewhat different, however, since the appraisal processes undertaken in this area results in organisms developing*conceptual meanings* to the bodily sensations they experience. For example, many individuals avoid public speaking and the anticipation of even being in the stimulus context of an audience produces heightened levels of arousal and a number of unwanted interoceptive changes including raised heart rate, heavy breathing, tight feeling in the stomach or butterflies. These interoceptive changes also occur in experienced speakers, yet the*conceptual meaning* they apply to these changes may not be fear, anxiety or fright, but simply a suite of necessary signals to mark or denote the significance of the behavioral responses they are about to exert on the environment (i.e. public audience). The same application of *conceptual meaning* to internal changes is what distinguishes experienced, accomplished athletes from those who crumble under the stress and anxiety produced by these same interoceptive changes. The cognitive processing that takes place in the anterior cingulate cortex is what engenders one to not only to be aware of fluctuations in their interoceptive sensations, but to use conceptual knowledge to understand and regulate their emotional feelings that emerge in different contextual settings.

Third, the anterior cingulate cortex also assigns some positive or negative value to potential actions. It does this by assessing the degree of effort required to produce any potential action and maintaining a record of the observed consequences of the behavioral response (i.e. favorable or unfavorable) during an emotional encounter (Rangel, Camerer, & Montague, 2008). Direct anatomical connections with areas of the motor system allow the cingulate to create action or response plans (see Chapter 10 Motor Control).

Neuroscience Across Species

Generalization of findings of fear, threat and anxiety across species

Much of our study of emotions has been informed by animal studies, especially in rodents. While animal studies have greatly advanced our understanding of neural circuitry underlying emotion, not all results from animals have generalized well to humans. The neural circuitry supporting fear provides a good example of the challenges of generalizing from animal models to humans. Fear is a particularly well-studied emotion in rodent models because rodents have characteristic fear-related

behaviors that are easy to observe, such as freezing. Early work in animal studies generated the idea that a dedicated fear circuit exists in the brains of both rodents and humans to serve an evolutionary function of survival. The key to the fear circuit idea is that it is a single system and each piece is necessary to produce fear. Numerous animal studies have supported the existence of a fear circuit in rodent models with the amygdala performing a particularly critical role in generating fear.

More contemporary viewpoints challenge the fear circuitry position and propose that emotional responses are generated by a network of brain systems which differ in humans and rodents. Evidence against the fear circuit view in humans was obtained by studies demonstrating that humans with amygdala damage continued to display emotions of fear and threat despite an absence of the primary structure involved in the “fear circuit”. This study permitted three amygdala-lesioned participants to inhale 35% carbon dioxide CO_2, which is known to produce panic attacks and fear in normal participants. Despite having extensive amygdala damage as a result of Urbach-Wieth disease, all three participants displayed excessive fear responses, panic attacks, and elevated physiological markers of fear such as increased respiration and heart rate (Feinstein, et al., 2013). These findings are unique in that previous studies reported a complete absence of fear or threat in Urbach-Wieth participants during presentation of fearful external stimuli including live snakes, spiders, tour of a haunted house or emotionally evocative horror films (Feinstein, Adolphs, Damasio & Tranel, 2011). These findings support the idea of a network of brain emotional systems in humans. This network is capable of responding to external threats (mediated via the amygdala). In addition, other brain emotion systems may elicit fear and threat through connections with acid-detecting chemoreceptors that are sensitive to internal changes produced by elevated concentrations of CO_2 within the body.

The network position considers that, in humans, subjective feelings are mental states of *feeling* that are generated by higher order brain structures such as the prefrontal cortex, insula and cingulate cortices. These cortical structures are involved in planning, decision making, emotional regulation and emotional appraisal processing. According to this view, brain systems that generate*feelings* are completely separate from subcortical structures such as the amygdala and hypothalamus that play primary roles in detecting fear or threat. The major function of the subcortical systems are to prepare the organism by directing physiological changes in the body and defensive behavioral responses when organisms detect immediate sources of harm or danger such as those depicted in Figure 13.2, (or *a rapidly approaching vehicle, animal or human; a surprise quiz*), or when these uncomfortable states are uncertain or implied by some form of environmental stimuli (*e.g. plummeting economy that directly affects your line of employment; changes in the criteria for acceptance into graduate, medical, law or business school*).

4.5.15: Mood and Emotional Disorders Associated with Depression

Learning Objectives

By the end of this section, you should be able to

- 13.4.1 Provide an overview of what is currently known regarding the etiology of mood disorders.
- 13.4.2 Delineate the distinct and overlapping neural circuits underlying depression.
- 13.4.3 Understand the origin of current therapeutic approaches for treating the symptoms underlying depression.

We have learned the critical roles of the amygdala, hypothalamus, insula, anterior cingulate and prefrontal cortex in the regulation of emotions. Disorders of emotion are so difficult to treat because malfunctions within any of these structures, or more commonly between their interconnections, can lead to severe disturbances in behavior. Many of the symptoms of mood disorders involving anxiety or depression include severe changes in the appetitive and agonistic behaviors that are governed by the hypothalamus. Hypothalamic functioning is regulated through strong projections from the amygdala. Hypoactivity in these inputs lead to the characteristic symptoms associated with depression that are described in detail in the Diagnostic and Statistical Manual of Mental Disorders (DSM). The DSM is the handbook psychologists and psychiatrists use to develop diagnoses of patients with mental disorders. Symptoms of depression are manifested by reduced appetite, sex drive, motivation, sleep disturbances and sympathetic autonomic activity. Disruptions in these agonistic behaviors is accompanied by more higher-level disturbances in cognitive functioning leading to increased worrying, obsessive anxiety, sadness, hopelessness, irritability and withdrawal from social forms of engagement. Cortical areas in the Papez circuit add a layer of higher cognitive subjective evaluation of how we think and feel about our environment. Disturbances in this circuitry may constrain the amygdala and hypothalamus to improperly regulate agonistic and appetitive behaviors that are targets of emotional disorders. One variable that distinguishes mental disorders of depression or anxiety from the natural changes in fear or sadness routinely experienced by all is the actual duration the emotional disturbances persist within an individual. For example, a diagnosis of depression in the DSM includes each of the above disturbances in body and thinking that extends consistently beyond a period of two-weeks. This section will explore our emerging understanding of the neural circuitry of depression.

Neurochemical imbalances as a cause of depression

The internal psychological and physiological changes associated with this disease may develop from either extreme reaction to unfortunate environmental events or may be endogenous or internal in nature. Some environmental events producing depression include loneliness, traumatic experiences, grief, romantic rejection, long-term stress, or loss of status or hierarchy from unemployment. The endogenous contributors to depression involve identifiable chemical imbalances in the neural circuits that regulate the neurotransmitters, norepinephrine, serotonin or glutamate.

One of the first clues prompting scientists to examine the role of neurotransmitters in depression originated from observations of patients in Sea View Hospital on Staten Island, New York in the 1950's (reviewed in López-Muñoz, Alamo, Juckel, & Assion, 2007). These patients were forced into the sanitorium after being diagnosed with the very contagious and fatal disease of tuberculosis. You can imagine how patients would develop extreme depression based on the severity of this disease, isolation from family and friends due to forced confinement and loss of employment and careers while being sanctioned to a sanitorium. The patients were treated with the drug iproniazid because of its potent effects on the respiratory system and capacity to increase activity in the central nervous system. These actions are produced by preventing enzymatic breakdown of the neurotransmitter norepinephrine by inhibiting the enzyme monoamine oxidase (MAO). The MAO enzyme plays a role in destroying the residual norepinephrine that is taken back up into the cell after it is released in the synaptic cleft following an action potential. Inhibiting MAO results in elevated levels of norepinephrine that serves as a potent transmitter in activating the amygdala, hypothalamus, hippocampus and several other arousal related structures in the Papez circuit. Surprisingly, patients treated with the MAO inhibitor iproniazid were described as dancing in the halls, in a constant "party mood", and frequently euphoric despite having holes in their lungs from tuberculosis and no hope of a cure from this fatal disease. This effective mood improving drug was soon discontinued because of its toxic effects on the liver and a search for new classes of antidepressants began.

A greater understanding of iproniazid's effectiveness prompted investigations to study a new class of MAO inhibiting drugs known

as tricyclic antidepressants. In the 1950's and 60's, clinical signs of depression were experimentally reproduced in the lab by injecting the drug reserpine in monkeys and rabbits (Sandler, 1990). Reserpine treatment destroys norepinephrine molecules within the synaptic vesicles of axons. Administration of the tricyclic antidepressant imipramine was very effective in reversing the depression produced by reserpine treatment and restoring the animals to a sense of well-being. Later investigations revealed that MAO inhibition also elevated brain concentrations of the neurotransmitter serotonin, and this finding is the basis for the discovery of a class of drugs known as selective serotonin reuptake inhibitors (SSRI).

SSRIs work by blocking the reuptake of serotonin at serotonergic synapses (Figure 13.19) (see Chapter 14 Psychopharmacology). This blockade allows serotonin to build up in the synapse and therefore increase activation of postsynaptic receptors.

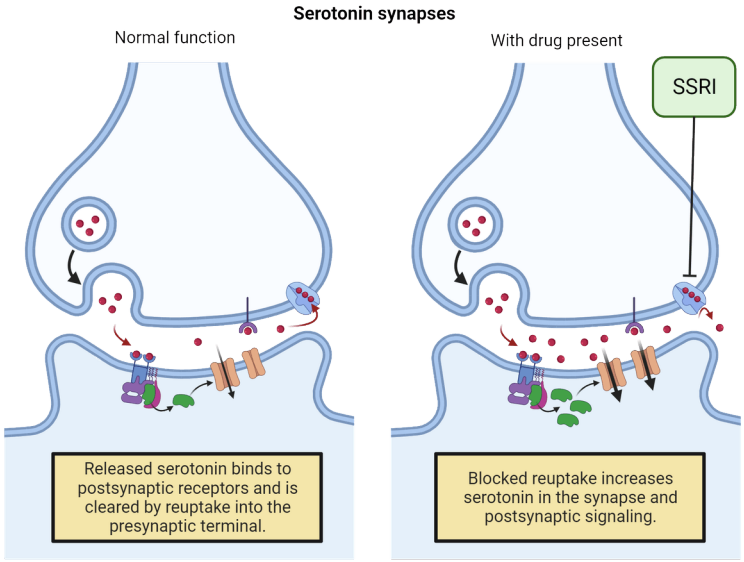

Figure 13.19 SSRI mechanism

The most commonly known SSRI is Prozac, although other compounds in this class such as Paxil and Zoloft are just as effective in alleviating symptoms of depression. All of these SSRIs elevate serotonin in the brain without any direct actions on norepinephrine.

Restoring deficiencies in brain concentrations of norepinephrine and serotonin does alleviate depressive symptoms, but these changes alone are not the only culprits contributing to this disruptive mood disorder. As a reminder from Chapter 3 Basic Neurochemistry, serotonergic and norepinephrine axons originate primarily in discrete brainstem nuclei (the raphe nucleus and locus coeruleus) (Figure 13.20). They send their axons broadly throughout the brain, releasing neurotransmitter in many brain regions of the Papez circuit and in the prefrontal structures that can regulate the Papez circuit.

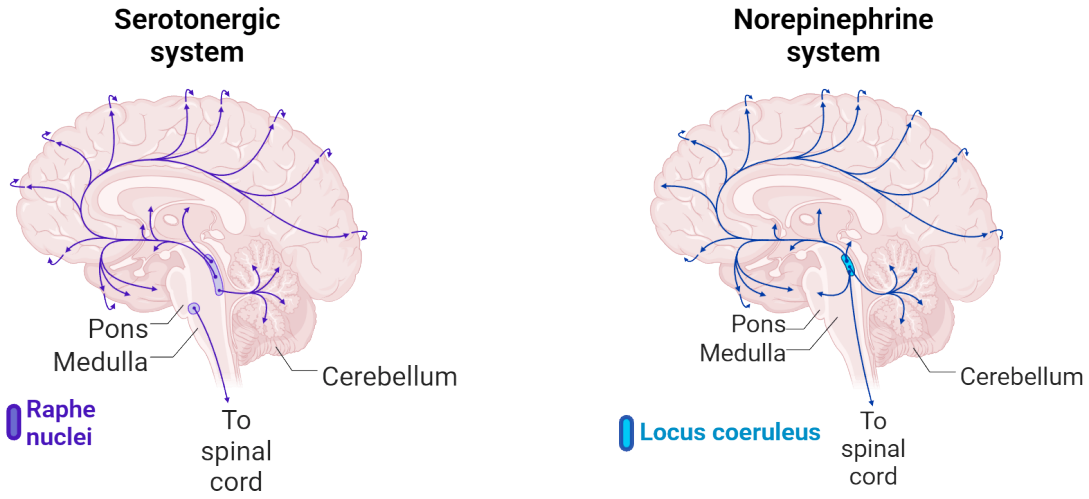

Figure 13.20 Serotonergic and norepinephrine systems

Neurotransmitters play a special role in facilitating or inhibiting neural communication between brain structures, therefore a closer examination of *where* these restorative changes take place will increase our understanding of the etiology of depression. To better understand the brain regions contributing to depression, we next turn to evidence for the role of the prefrontal cortex in onset and relief of depression.

Prefrontal cortical dysfunction as a cause of depression

Michael Koenigs at the University of Wisconsin reported on two unusual case studies that provided answers to the potential sources of depression within emotion-related brain structures comprising the Papez circuit. The two separate case studies involved a woman and man who attempted suicide by self-inflicted wounds to the brain by a gunshot (Koenigs, Huey, Calamia, Raymont, Tranel, & Grafman, 2008) and a cross-bow, respectively (Ellenbogen, Hurford, Liebeskind, Neimark, & Weiss, 2005). Both attempts at suicide were unsuccessful and the patients recovered. In both patients, the wounds produced profound damage to the ventromedial prefrontal cortex (which includes the orbitofrontal cortex) in both hemispheres (see red circles in Figure 13.21 for the location of the gunshot wound) but spared the dorsolateral prefrontal cortex.

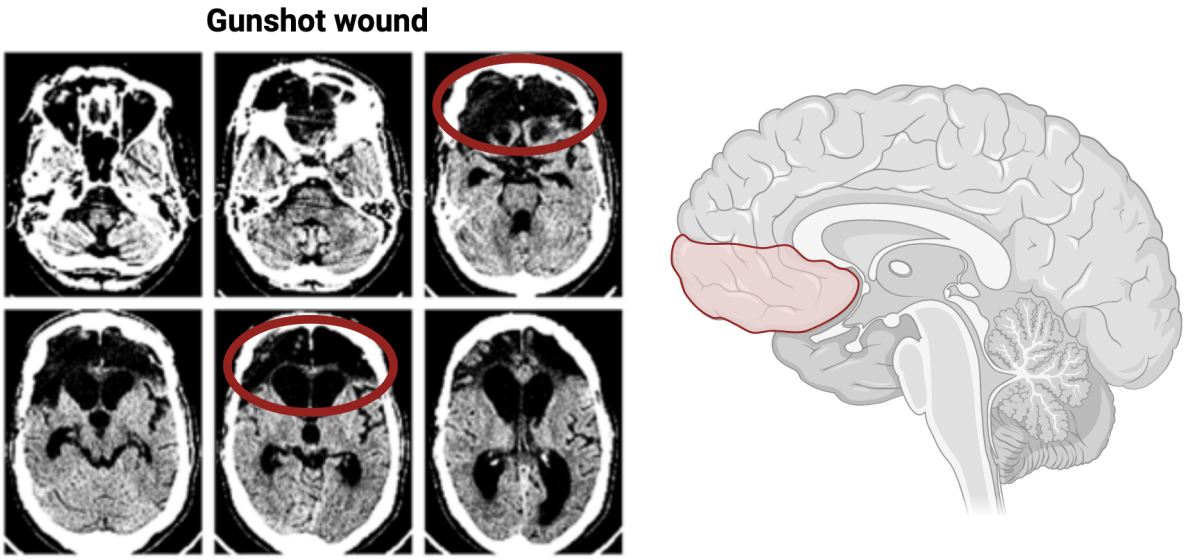

Figure 13.21 Damage in vmPFC after suicide attempts An attempt at suicide with a gunshot wound that damaged the ventromedial PFC in both hemispheres but spared the dorsolateral PFC. The patient reported absolutely no feelings of sadness or suicidal thoughts after recovering. Image credits: Gunshot image from Koenigs M, Huey ED, Calamia M, Raymont V, Tranel D, Grafman J. Distinct regions of prefrontal cortex mediate resistance and vulnerability to depression. J Neurosci. 2008 Nov 19;28(47):12341-8. Copyright 2008 Society for Neuroscience. https://www.jneurosci.org/content/28/47/12341, image located in supplemental material.

Surprisingly, the woman reported absolutely no feelings of sadness or suicidal thoughts after recovering. Her personal observations were corroborated by the patient's boyfriend and clinicians. They all noted a complete absence of depressive symptoms and that her mood disorder was essentially cured after her injury. The man who produced similar damage to this area was reported to be "*inappropriately cheerful and completely indifferent*" to his new state of brain injury. Together, the findings pointed to the ventromedial prefrontal cortex as possible generator of melancholic, morbid and depressive symptoms and highlighted a key brain region where clinicians may exploit to alleviate symptoms of this disease.

Take a moment and consider the magnitude of implications surrounding this discovery. First, the intensity and degree of depression was so severe that both individuals consciously chose death as an alternative to continuing to live in such a debilitating emotional state. This decision also reveals the symptoms they experienced were not mild or moderate forms of depression but the more deep and unrelenting forms that are often unresponsive to therapy or antidepressant treatment. Fortunately, the outcomes of these case studies afforded scientists and clinicians an opportunity to narrow down and isolate a single region of the brain as the dysfunctional key to unlock a mystery of this disease.

While these two case studies are compelling, they cannot prove that loss of the ventromedial prefrontal cortex specifically caused the improved mood of the patients. To provide more conclusive proof, a more formal empirical study was conducted by Michael Koenigs' group in 2008 to determine if abnormal activity in the ventromedial prefrontal cortex contributes to the aberrant emotional symptoms common to depression. Koenig initiated a large-scale study that included participants from the Vietnam Head Injury Study registry and the Patient Registry of the Cognitive Neuroscience Division at the University of Iowa. They limited their selection to individuals with verifiable brain injuries to either the ventromedial prefrontal cortex or dorsolateral prefrontal cortex from penetrating head wounds incurred during the Vietnam War or Iowans with injury to these areas after stroke, accidents or surgery. The Beck Depression Inventory (BDI) was the tool used to assess the severity of depression present in the two groups of brain injured participants. The BDI uses a scale of where scores of 8 or below indicate "no or low depression" whereas "high depression" is marked by scores above 20. Koenig's group not only replicated the observations noted in the case studies, that ventromedial prefrontal cortex damage alleviates depression, but they also discovered that damage to the dorsolateral prefrontal cortex actually exacerbates symptoms associated with this disease.

The overall findings of this study are shown in (Figure 13.22).

Top: Left: Diagram of 2 brains showing the location of the ventromedial prefrontal cortex and dorsolateral prefrontal cortex. Right: Bar graph of Proportion of Individuals across 4 injury conditions (no injury, non-PFC, vmPFC, dorsal PFC). Bars shown for low, intermediate and high beck Depression Inventory ratings. Bottom: Point graph for Mean severity of depression score across

Figure 13.22 Severity of depression in patients with vmPFC vs dlPFC lesions Graphs from Koenigs M, Huey ED, Calamia M, Raymont V, Tranel D, Grafman J. Distinct regions of prefrontal cortex mediate resistance and vulnerability to depression. J Neurosci. 2008 Nov 19;28(47):12341-8. Copyright 2008 Society for Neuroscience. https://www.jneurosci.org/content/28/47/12341

It is important to note that almost 100% of participants with ventromedial prefrontal cortex damage were diagnosed with little or no depression on the BDI. In contrast, over 75% of participants with dorsolateral prefrontal cortex damage displayed symptoms that correspond to high levels of depression on the BDI scale. The graph in Figure 13.22 provides a more comprehensive description of the suite of "Cognitive/Affective" vs "Somatic" or bodily depressive symptoms assessed with the BDI. Note the absence of ratings in most categories by participants with bilateral damage to the ventromedial prefrontal cortex and the opposite results of much higher ratings of pathological symptoms in those with bilateral damage to the dorsolateral prefrontal cortex. A separate important finding to take away from this study is that the behavioral outcomes produced by ventromedial prefrontal cortex damage renders these individuals less susceptible to depression than normal healthy controls (i.e. no lesion group).

So how can the anecdotal case studies and findings from this study be integrated with your understanding of how cortical structures contribute to the development of emotions? In review, we know the range of physiological changes accompanying negative emotions are coordinated through top-down control from the ventromedial prefrontal cortex to the periaqueductal gray, hypothalamus, and amygdala. Thus, damage to this area most likely diminishes the type of physiological responses these patients experience in response to emotional stimuli that generates negative mood in normal individuals. The ventromedial prefrontal cortex is also associated with self-awareness and self-reflection and lesions to this area produce a loss of self-insight that is characterized by reduced negative affect and diminished ability to experience negative emotions such as shame, guilt, embarrassment, and regret, self-dislike, and even sadness (Fitzgerald, 2003). As a consequence, damage to the ventromedial prefrontal cortex may decrease symptoms of depression by blunting self-awareness and self-reflection (Beer, John, Scabini, & Knight, 2006) which is consistent with the self-reported levels of these emotional reactions by ventromedial prefrontal cortex damaged subjects shown in Figure 13.22.

The heightened level of depression evident following dorsolateral prefrontal cortex lesions may be related to the multiple cognitive functions that occur simultaneously in this area. For example, activity in the dorsolateral prefrontal cortex is observed when an individual maintains events in working memory, or is engaged in abstract reasoning or in the process of forming intentions that will be converted into goal directed actions (Phan, Fitzgerald, Nathan, Moore, Uhde, &Tancer, 2005). The consequence or readout of this reappraisal of goal strategies is mediated through dorsolateral prefrontal cortex projections to the pre-, supplemental and motor cortex that ends in some physiological and behavioral response to emotional stimuli. Therefore, if the reappraisal process that may inhibit negative emotions is normally adaptive in protecting against depression, it is clear how disruptions in this process with dorsolateral prefrontal cortex damage may lead to increased symptoms of depression (Ongur & Price, 2000).

Translational applications of understanding the role of cortical and subcortical structures in mood disorders

Dr. Helen Mayberg is an initial pioneer in the use of deep-brain stimulation (DBS) as an alternative approach to alleviate mood disorders in patients with persistent depression after prolonged, yet ineffective drug or psychotherapy treatment (Mayberg, 2009) (see Methods: Deep Brain Stimulation). She is co-inventor of using chronic intermittent DBS therapy to target Area 25 (the subcallosal cingulate or SCC) and this approach is now licensed to the pharmaceutical company, Abbott Laboratories. The SCC and nerve tracts surrounding Area 25 are "emotional hubs" in the brain because they communicate the processing of negative, unpleasant, and sad emotional content to other brain regions through the many white matter or nerve pathways depicted in the tractography image in the top right of (Figure 13.23) (Vogt, 2005). These important connections carry the products of emotional processing in temporal lobe structures, hippocampus, amygdala and medial prefrontal cortex to other regions of the emotional circuit (Harnett, Ference, Knight, & Knight, 2020).

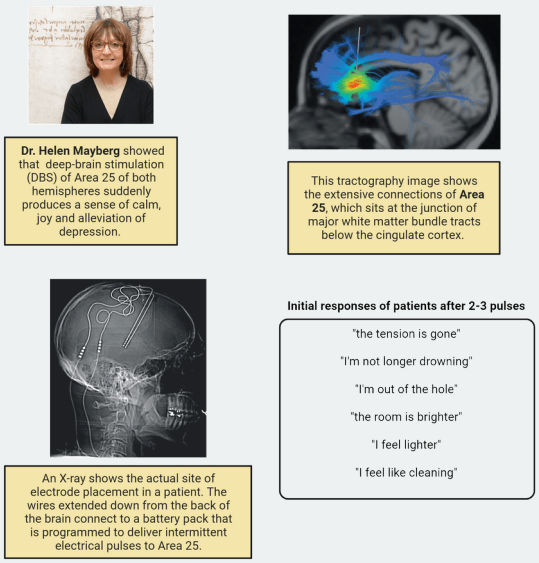

Figure 13.23 Work of Helen Mayberg Image of Helen Mayberg from Heiden P, Pieczewski J and Andrade P (2022) Women in Neuromodulation: Innovative Contributions to Stereotactic and Functional Neurosurgery. Image of DBS probes in a braincourtesy of Helen Mayberg, MD. Icahn Scool of Medicine Mount Sinai. Reproduced with permission.

Dr. Mayberg was motivated to examine Area 25 after several reports noted hypermetabolism and *overactivity* in this brain region of depressed patients. Other studies demonstrated that activity in Area 25 was normalized (i.e. reduced) in patients experiencing beneficial outcomes in depressive symptoms after successful drug treatment (reviewed in Mayberg, 2009). It may seem counterintuitive to introduce additional stimulation through DBS to an area already known to be abnormally hyperactive in depressed patients. However, Dr. Mayberg reasoned that stimulating white fiber pathways running under the SCC would serve to reboot or reset the overactivity in the SCC. DBS generally increases neuronal activity in a given area, but the opposite occurs when stimulation affects a large pool of neurons containing the inhibitory neurotransmitter GABA. Activation of this pool of inhibitory neurons surrounding the SCC serves to reduce ongoing activity in this region and correct or re-balance the overactive signals projected from the SCC to other emotion-processing areas through the nerve tracts shown in Figure 13.23.

Detailed descriptions and interviews of Dr. Mayberg's discovery are profiled in a "CNN Presents" segment hosted by Dr. Sanjay Gupta and a "News Focus" paper in the journal Science, by Emily Underwood (Underwood, 2013). These segments described the initial successful DBS surgeries Dr. Mayberg performed at Emory University with the patient Mrs. Edi Guyton (openstax.org/r/Neuro13Gupta). The interview with Mrs. Guyton reveals that prior to the DBS, she couldn't smile, be happy or even express to others how she felt which led to cutting both of her wrists at attempts of suicide while a college student. This pattern continued for over 40 years with two additional attempts at suicide despite psychotherapy and drug treatment. Mrs. Guyton agreed to surgery to implant electrodes that provide the stimulation to nerve fibers around the SCC.

The lower left X-ray in Figure 13.23 shows what placement of electrodes looks like. Patients for this type of surgery are awake, although lightly sedated so the surgeons may analyze their mental and emotional state prior to, during and after the initial stimulation of area 25 ensues. When Mrs. Guyton used a scale from 1 (feeling pretty good) to 10 (very depressed) to rate her feelings before the stimulation, she offered a score of 8 (8 = dread). Once the DBS electrodes were turned on to deliver electrical pulses to Area 25, she stated "I just almost smiled; something I have not done in a long time". The stimulation also made her think about playing with her granddaughter Susan, even though she stated these are feelings that had never occurred before. In essence, she thought they were gone. Linda Patterson is another one of Dr. Mayberg's patients who noted after the surgery "I felt the best I've felt in my entire life and capable of experiencing the emotions of joy, exhilaration, the calming feeling of contentment as though I'm living in a different world."

What is striking about these positive testimonies is they evolve immediately after the first or second pulses of electricity are emitted through the nerve tracts surrounding the SCC, not after 2 to 3 weeks of stimulation. Two to 3 weeks is the normal time-course for antidepressant drugs to render any positive effects in reducing depression symptoms. A list of some of the phrases Dr. Mayberg's patients expressed in surgery following the initial stimulations of the SCC are shown in the bottom right of Figure 13.23. Follow-up evaluations of Mrs. Guyton 5 years after the surgery for DBS electrodes, revealed that "she feels good, all the time; If there is joy in my life, I have the capacity to feel it. She is thankful for her new life." These testimonies attest to the promise of this new approach of resetting patterns of aberrant neural activity in the junction between Area 25 and the highway of

emotion-related pathways that run under this area.

View this Interactive Content online

Five theories of emotion were presented that emphasized the idea of subjective feelings of emotions emerging from interactions between the environment or exteroceptive stimuli and internal physiological changes, that in turn influence how appraisal/cognitive processes in the brain generate different emotions. The collective theories agree on the essential nature of the three components for emotions to develop. However, they each propose a different sequence or order in which sensory and brain appraisal processes lead to an awareness of personal subjective feelings. The James-Lange theory stresses that the feeling component of emotion derives from the perceived pattern of bodily sensations following encounters with external events. Cannon-Bard on the other hand emphasizes that internal body changes associated with physiological arousal and the development of emotional attributes occur simultaneously, yet independently. Ideas proposed in the two-factor theory by Schachter-Singer model stress the importance of cognitive appraisals of context in the brain as a key factor in determining the category of emotions that will be attributed to any event as opposed to the intensity of physiological responses produced by the experience. This view was advanced by Magda Arnold, Richard Lazarus and other appraisal theorists who suggested a range or dimensions that are evaluated during the appraisal process to ultimately determine which emotions are generated from any given emotional encounter. The final Constructionists theories differ from each of the previous four through their emphasis on the brain in assessing stimuli from the immediate context while simultaneously comparing this input with past episodes saved in memory. These two sources of information are then used to *construct* a hypothesis or prediction of what an organism is experiencing to yield the category or labels we assign to emotions.

13.2 What Category of Feelings Are Considered as the “Basic Emotions”?

Paul Ekman’s research is most noted for revealing that all humans are endowed with an innate capacity to identify basic categories of different subjective emotions. He conducted an extensive number of experiments with participants from different countries to verify that these innate skills are not influenced by cultural norms. His research demonstrated that humans from a wide range of cultural backgrounds were fairly accurate in detecting the six core basic emotions from expressions viewed in test photographs. Robert Plutchik advanced Ekman’s views by noting the presence of eight basic emotions. Plutchik’s research was noteworthy for describing how complex emotions develop. His Wheel of Emotions diagram explains how one or more of the eight basic emotions are integrated with higher or lower intensity feelings to create the complex emotions one may encounter.

13.3 What Is the Contribution of Brain Structures in Emotional States?

The three components essential for emotional awareness involves an evaluation of exteroceptive stimuli, their impact on interoceptive physiological changes and complicated appraisal processes that inform the body of which goal directed “agonistic or appetitive” responses to generate to stimuli within the immediate environment. The Papez circuit is critical to all of these components. Subcortical structures of the Papez circuit, like the hypothalamus and amygdala, operate in the background, out of conscious awareness, to control many of the mind/body interactions that permit organisms to detect the significance of a given circumstances and to select the appropriate adaptive responses to preserve a state of homeostasis and allostasis. The combination of appraisal, conceptual, decision-making and motor planning exercises performed within the cortical regions of the Papez circuit allows organisms to successfully meet the appetitive or agonistic challenges in the environment. Some caution

must be exerted however, in translating findings from animal studies to direct applications in humans. One challenge for all of neuroscience research is to understand which neural circuits underlying emotions in animals are also found in humans.

13.4 Mood and Emotional Disorders Associated with Depression

Emotional disturbances associated with depression continue to baffle scientists, clinicians and mental health providers. These causes of depression-related disorders are challenging to dissect because they can result from dysregulation of any of the structures within the Papez circuit or interconnections between them. The two main causes of depression involve extreme negative reactions to environmental events or from an internal imbalance in neurotransmitter functioning. Although the latter cause is effectively treated in most cases by restoring deficiencies in brain neurochemicals, more resistant forms of depression may involve alterations in the activity of emotion circuits in the brain. Contemporary research and clinical findings reveal an important contribution of the ventromedial prefrontal cortex as possible generator of melancholic, morbid and depressive symptoms while the dorsolateral prefrontal cortex may protect against depression by inhibiting negative emotions through conceptual and reappraisal processing. Findings emerging from these types of investigations are affording the scientific community opportunities to narrow down the possible substrates underlying depression and to target specific neural circuits to unlock the mystery of this disease.

4.5.17: Key Terms

13.1 Foundational and Contemporary Theories of Emotion

environmental context, bodily or physiological states, brain systems, autonomic specificity, bottom-up theory, top-down theory, two-factor theory, appraisal-based theories, appraisal dimensions, primary appraisals, secondary appraisals, constructionist theories

13.2 What Category of Feelings Are Considered as the “Basic Emotions”?

Core emotions, body maps, functional magnetic resonance imaging (fMRI)

13.3 What Is the Contribution of Brain Structures in Emotional States?

Papez Circuit, thalamus, hypothalamus, amygdala, hippocampus, anterior cingulate cortex, orbitofrontal cortex (ventromedial prefrontal cortex), insula cortex, Kluver-Bucy Syndrome, interoception, exteroception, homeostasis, allostasis, appetitive responses, agonistic behaviors, reproductive mating instincts, optogenetics, channelrhopdopsin-2, associative learning, dorsolateral prefrontal cortex, emotion regulation

13.4 Mood and Emotional Disorders Associated with Depression

Diagnostic and Statistical Manual of Mental Disorders, monoamine oxidase (MAO), norepinephrine, iproniazid, tricyclic antidepressants, imipramine, selective serotonin reuptake inhibitors (SSRIs), Beck Depression Inventory (BDI), deep-brain stimulation (DBS), Area 25 (the subcallosal cingulate or SCC)

This page titled 4.5.17: Key Terms is shared under a CC BY-NC 4.0 license and was authored, remixed, and/or curated by Ivette Merced via source content that was edited to the style and standards of the LibreTexts platform.

4.5.19: Multiple Choice

13.1 Foundational and Contemporary Theories of Emotion

1.
Three interrelated variables are presented repeatedly throughout the chapter that represent important factors underlying emotions. Which of the following is NOT included in this list?

a. Brain systems
b. Physiological states
c. Context
d. Hormonal changes

2 .
The James-Lange theory of emotion attempted to explain how the experience of emotion influences behavior. According to their understanding, emotions develop:

a. after the brain interprets the significance of stimuli in the external environment to survival (e.g. a bear).
b. after an organism begins to perceive the magnitude of its body's level of autonomic arousal to some experience.
c. after forming complex appraisals of both context and bodily changes.
d. Only a and b

3.
Emotions that generate changes in the corrugator supercilii and zygomaticus facial muscles are generally observed during states of:

a. happiness.
b. anger.
c. suppressed moods.
d. surprise.

4 .
The James-Lange theory is known as a:

a. bottom-up theory.
b. top-down theory.
c. constructionist theory.
d. appraisal theory.

5.
The Cannon-Bard position was strengthened by their observation that cats display species typical emotional reactions to threatening stimuli, even when:

a. the flow of information from the viscera to the brain is interrupted by severing visceral and spinal nerves.
b. body to brain communication is blocked by removing the vagus nerve.
c. the hypothalamus is damaged.
d. they are placed in direct opposition to an angry dog.

6 .
According to Cannon-Bard, the _____ is activated by encounters in the external environment and then relays information regarding this context in two simultaneous directions to produce emotions.

a. hypothalamus
b. cortex
c. thalamus
d. amygdala

7.
The Cannon-Bard theory also proposed that “neural signals sent to initiate physiological reactions in the body to adapt to the specific nature of the experience” are generated in the:

a. hypothalamus and amygdala.
b. cortex and thalamus.
c. thalamus and hypothalamus.
d. amygdala and cortex.

8 .
Schachter and Singer’s (1962) famous study informed subjects they would receive an injection of saline or epinephrine and then informed them of the reactions to expect from the injection (i.e. you will experience a change in heart rate), while providing no information regarding the effects of the stress hormone to a second uninformed group.
The “Saline Injection” group was reported to have _____ response when placed with the ANGRY actor and showed _____ response when placed with the EUPHORIC actor.

a. a mild / a mild
b. a strong angry / a strong euphoric
c. a strong angry / a mild euphoric
d. no emotional / no emotional

9 .
The “Epinephrine [UNINFORMED]” group displayed _____ response after 20 minutes exposure with the ANGRY actor but showed _____ response when placed with the EUPHORIC actor for the same duration of time.

a. a mild / a mild
b. a strong angry / a strong euphoric
c. a strong angry / a mild euphoric
d. no emotional / no emotional

10.
According to the Schacter-Singer theory, the emotional responses reported by subjects in the “Epinephrine-INFORMED” group, that were exposed to either the Angry or Euphoric actor occurred because:

a. epinephrine injections produce strong physiological arousal.
b. they used the INFORMED knowledge regarding the physiological changes they would feel to label the emotional changes they experienced.
c. they used the current CONTEXT, (i.e. *Angry* or *Euphoric*), to develop a label for the UNEXPLAINED, physiological changes they experienced.
d. Both a and b

11.
Which of the following theorists developed this account to explain how emotional reactions emerge: “what produces emotional reactions is not the stimuli we encounter externally, but how we subjectively interpret or appraise these stimuli relative to personal variables, such as the meaning stimuli present in terms of our goals in life?”

a. Cannon-Bard
b. Schacter-Singer
c. Appraisal Theorists
d. James-Lange

12 .
The Cannon-Bard theory asserts that the process of “appraising the possible danger, safety or other emotional features of an experience” is performed by the:

a. hypothalamus
b. cortex
c. thalamus
d. amygdala

13.
Which view of emotions, stresses that the brain itself, rather than individual features of environmental stimuli, is what adds meaning to, or predictions of, what is occurring in our immediate circumstances?

a. Cannon-Bard
b. Schacter-Singer
c. Appraisal Theorists
d. Constructionist Theorists

14 .
Which of the following theorists developed this account to explain how emotional reactions emerge: “the vast reservoir of stored information regarding previously experienced stimuli, your reaction to these events, and the outcome of your responses is used by the brain to provide some of the conceptual meaning or perceptions to any new experiences an organism will face?”

a. Cannon-Bard
b. Constructionist Theorists
c. Appraisal Theorists
d. James-Lange

13.2 What Category of Feelings Are Considered as the “Basic Emotions”?

15.
The experimental procedures Paul Eckman used to generate his initial findings on *emotion identification* were also applied to three separate groups of non-English speaking natives in New Guinea. It was necessary for Eckman to conduct this study to:

a. verify the ability to perceive emotions in previous studies was not the result of exposure to Western cultural influences such as television, magazines, or movies.
b. determine if separate non-Western cultures experienced all of the 6 basic emotions.
c. prove that nomadic cultures exposed to environmental dangers on a daily basis are less skilled at identifying emotional responses of fear and surprise.
d. Only b and c

16 .
Ekman and Cordaro (2011) provided a list of forms of overt emotional expression that are common across the human species. Which of the following is not included in this list:

a. changes in verbalizations (i.e. tone, speed, and pitch).
b. alternations in facial expressions.
c. fluctuations in body posture and physical responses.
d. flushing or increased redness in the skin.

17.
The subjective experience of emotions is traditionally assessed by:

a. providing study participants with a SELF-REPORT survey.
b. measuring the intensity and duration of a subject’s personal emotion with EEG.
c. equipping study participants with Galvanic Skin Conductance (GSR) electrodes to detect emotional reactions to highly arousing videos or pictures.
d. Only b and c

13.3 What Is the Contribution of Brain Structures in Emotional States?

18 .
Skin conductance response (SCR) is a reliable indicator of physiological changes since this type of measurement:

a. is accurate in identifying the source of the arousal from changes in heart rate, blood pressure or respiration.
b. can detect general elevations in sympathetic nervous system activity.
c. is useful in denoting when parasympathetic activity dominates over sympathetic nervous system activity.
d. None of the above

19.
Heinrich Klüver and Paul Bucy (1938) removed large parts of the brain in monkeys to produce the well-known Kluver-Bucy syndrome. Which brain region was NOT removed in this type of surgery?

a. Temporal lobe
b. Amygdala
c. Hippocampus
d. Hypothalamus

20 .
Animals or humans who develop the Kluver-Bucy syndrome also display:

a. difficulty in identifying objects by sight, the sound of stimuli or touch.
b. binge or overeating.
c. high levels of anxiety.
d. complete loss of appetite.

13.4 Mood and Emotional Disorders Associated with Depression

21.
The thalamus plays a major role in emotions by receiving and processing:

a. interoceptive signals from the body.
b. exteroceptive signals from the environment.
c. changes in emotional state.
d. Only a and b

22 .
The thalamus automatically initiates behavioral, emotional, and physiological responses through influences on which of the following:

a. hypothalamus.
b. nucleus accumbens.
c. amygdala.
d. Only a and c

23.
One of the first clues prompting scientists in the 1950s to examine the role of neurotransmitters in depression originated from:

a. observations of primates given the drug reserpine.
b. observations of humans with tuberculosis that were sanctioned to a sanitorium.
c. new evidence showing the beneficial effects of dopamine on mood.
d. None of the above

24 .
Michael Koenigs' group in 2008 initiated a large-scale study to determine if abnormal activity in the different regions of the prefrontal cortex contributes to the emotional symptoms common to depression. The results of this study indicate:

a. participants with ventromedial prefrontal cortex damage were diagnosed with little or no depression on the BDI.
b. participants with dorsolateral prefrontal cortex damage displayed high levels of depression on the BDI scale.
c. ventromedial prefrontal cortex damaged participants displayed high levels of depression d. dorsolateral prefrontal cortex damaged participants show little or no depression
d. Only a and b

4.5.20: Fill in the Blank

13.1 Foundational and Contemporary Theories of Emotion

1.
It is now known that activation of the corrugator supercilii and zygomaticus facial muscles produces the facial expression of _____.
2 .
In the _____ theory proposed by Cannon-Bard, the initiation of an emotional state is generated in the cortex.

13.2 What Category of Feelings Are Considered as the “Basic Emotions”?

3.
The emotion of _____ would occur following an unexpected event and is very brief.

13.3 What Is the Contribution of Brain Structures in Emotional States?

4 .
Self-protecting behaviors are considered _____.
5.
The limbic and subcortical structures of the _____ allow you to adapt to environmental changes.
6 .
Neurons in the _____ allow for associative learning.

4.5.21: The Neurological Bases of Emotions

Learning Objectives

- Identify what general and specific brain parts are involved in emotions.
- Analyze the anatomical and chemical bases of basic emotions.
- Analyze the biopsychological methods of studying emotions.
- Evaluate the functions of emotions.

Overview

There is a strong connection between brain/body and emotions/affective states. Human and animal research findings have shown brain networks and associated neurotransmitters involved in basic emotion/affective systems.

Affective Neuroscience: What is it?

Affective neuroscience examines how the brain creates emotional responses. Emotions are psychological phenomena that involve changes to the body (e.g., facial expression), changes in autonomic nervous system activity, feeling states (subjective responses), and urges to act in specific ways (motivations; Izard, 2010). Affective **neuroscience** aims to understand how matter (brain structures and chemicals) creates one of the most fascinating aspects of the mind, the emotions. Affective neuroscience uses unbiased, observable measures that provide credible evidence to other sciences and laypersons on the importance of emotions. It also leads to biologically based treatments for affective disorders (e.g., depression).

Figure 4.5.21.1: Although we all experience emotions all the time, they are very difficult to describe and study. Fortunately, technological advances are making this easier. (Image: Waag Society, https://goo.gl/F0KdnB, CC BY-NC-SA 2.0, goo.gl/iF4hmM)

The human brain and its responses, including emotions, are complex and flexible. In comparison, nonhuman animals possess simpler nervous systems and more basic emotional responses. Invasive neuroscience techniques, such as electrode implantation, lesioning, and hormone administration, can be more easily used in animals than in humans. Human neuroscience must rely primarily on noninvasive techniques such as electroencephalography (EEG) and functional magnetic resonance imaging (fMRI), and on studies of individuals with brain lesions caused by accident or disease. Thus, animal research provides useful models for understanding affective processes in humans. Affective circuits found in other species, particularly social mammals such as rats, dogs, and monkeys, function similarly to human affective networks, although nonhuman animals' brains are more basic.

In humans, emotions and their associated neural systems have additional layers of complexity and flexibility. Compared to animals, humans experience a vast variety of nuanced and sometimes conflicting emotions. Humans also respond to these emotions in complex ways, such that conscious goals, values, and other cognitions influence behavior in addition to emotional responses.

Across species, emotional responses are organized around the organism's survival and reproductive needs. Emotions influence perception, cognition, and behavior to help organisms survive and thrive (Farb, Chapman, & Anderson, 2013). Networks of structures in the brain respond to different needs, with some overlap between different emotions. Specific emotions are not located in a single structure of the brain. Instead, emotional responses involve networks of activation, with many parts of the brain activated during any emotional process. In fact, the brain circuits involved in emotional reactions include nearly the entire brain (Berridge & Kringelbach, 2013). Brain circuits located deep within the brain below the cerebral cortex are primarily responsible for generating basic emotions (Berridge & Kringelbach, 2013; Panksepp & Biven, 2012). In the past, research attention was focused on specific brain structures that will be reviewed here, but future research may find that additional areas of the brain are also important in these processes.

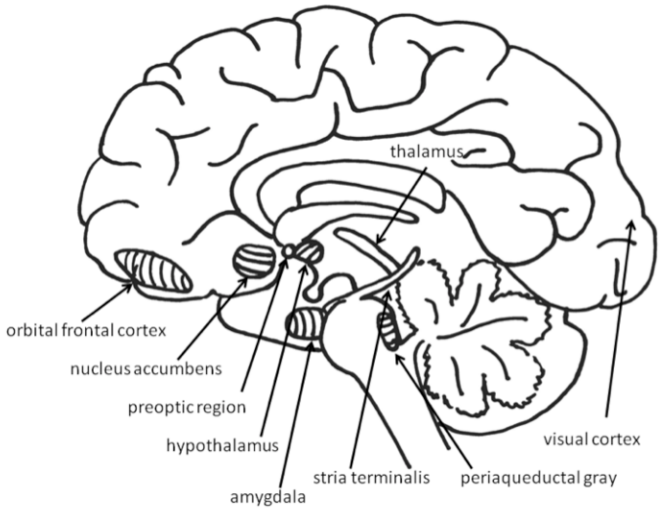

Figure 4.5.21.2: Structures in the brain - orbital frontal cortex, nucleus accumbens, preoptic region, hypothalamus, amygdala, stria terminalis, PAG, visual cortex and thalamus play a role in emotion.

Basic Emotions

Desire: The neural systems of reward seeking

One of the most important affective neuronal systems relates to feelings of desire, or the appetite for rewards. Researchers refer to these appetitive processes using terms such as "wanting" (Berridge & Kringelbach, 2008), "seeking" (Panksepp & Biven, 2012), or "behavioural activation sensitivity" (Gray, 1987). When the appetitive system is aroused, the organism shows enthusiasm, interest, and curiosity. These neural circuits motivate the animal to move through its environment in search of rewards such as appetizing foods, attractive sex partners, and other pleasurable stimuli. When the appetitive system is underaroused, the organism appears depressed and helpless.

Much evidence for the structures involved in this system comes from animal research using direct brain stimulation. When an electrode is implanted in the lateral **hypothalamus** or in cortical or mesencephalic regions to which the hypothalamus is connected, animals will press a lever to deliver electrical stimulation, suggesting that they find the stimulation pleasurable. The regions in the desire system also include the amygdala, nucleus accumbens, and **frontal cortex** (Panksepp & Biven, 2012). The neurotransmitter dopamine, produced in the mesolimbic and mesocortical dopamine circuits, activates these regions. It creates a sense of excitement, meaningfulness, and anticipation. These structures are also sensitive to drugs such as cocaine and amphetamines because they are dopamine agonists (Panksepp & Biven, 2012).

Figure 4.5.21.3: Just looking at an image of appealing food should increase the activity in your left frontal cortex. Yum! (CC0 Public Domain, goo.gl/m25gce)

Research in both humans and nonhuman animals shows that the left frontal cortex (compared to the right frontal cortex) is more active during appetitive emotions such as desire and interest. Researchers first noted that persons who had suffered damage to the left frontal cortex developed depression, whereas those with damage to the right frontal cortex developed mania (Goldstein, 1939). The relationship between left frontal activation and approach-related emotions (that is those emotions that involve a movement toward the stimulus such as with happiness and also with anger) has been confirmed in healthy individuals using EEG and fMRI (Berkman & Lieberman, 2010). For example, increased left frontal activation occurs in 2- to 3-day-old infants when sucrose is placed on their tongues (Fox & Davidson, 1986), and in hungry adults as they view pictures of desirable desserts (Gable & Harmon-Jones, 2008). In addition, greater left frontal activity in appetitive situations has been found to relate to dopamine (Wacker, Mueller, Pizzagalli, Hennig, & Stemmler, 2013).

"Liking": The Neural Circuits of Pleasure and Enjoyment

Surprisingly, the amount of desire an individual feels toward a reward need not correspond to how much he or she likes that reward. This is because the neural structures involved in the enjoyment of rewards are different from the structures involved in the desire for the rewards. "Liking" (e.g., enjoyment of a sweet liquid) can be measured in babies and nonhuman animals by measuring licking speed, tongue protrusions, and happy facial expressions, whereas "wanting" (desire) is shown by the willingness to work hard to obtain a reward (Berridge & Kringelbach, 2008). Liking has been distinguished from wanting in research on topics such as drug abuse. For example, drug addicts often desire drugs even when they know that the ones available will not provide pleasure (Stewart, de Wit, & Eikelboom, 1984).

Research on liking has focused on a small area within the **nucleus accumbens** and on the posterior half of the ventral pallidum. These brain regions are sensitive to opioids and endocannabinoids (endogenously produced substances that have effects similar to marijuana). Stimulation of other regions of the reward system increases wanting, but does not increase liking, and in some cases even decreases liking. The research on the distinction between desire and enjoyment contributes to the understanding of human addiction, particularly why individuals often continue to frantically pursue rewards such as cocaine, opiates, gambling, or sex, even when they no longer experience pleasure from obtaining these rewards due to habituation.

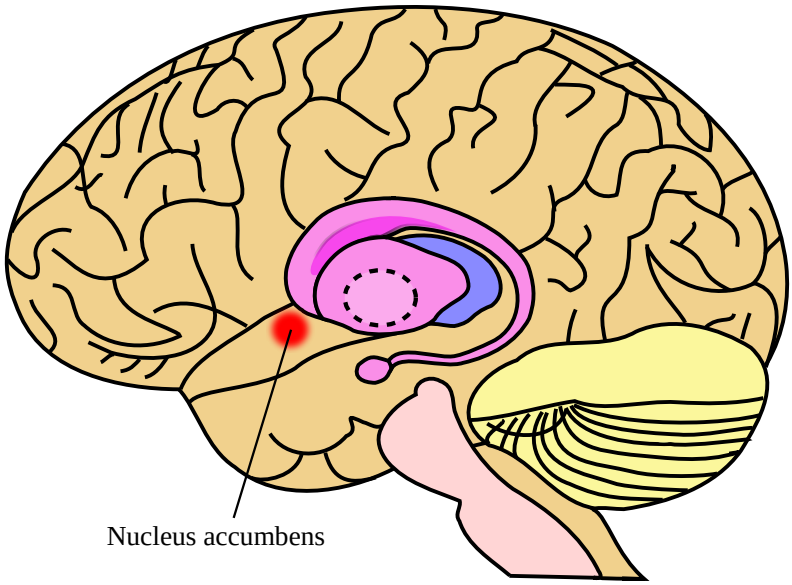

Figure 4.5.21.4: The experience of pleasure also involves the orbitofrontal cortex. Neurons in this region and the nucleus accumbens particularly shown here in red fire when monkeys taste, or merely see pictures of, desirable foods. In humans, this region is activated by pleasant stimuli including money, pleasant smells, and attractive faces (Gottfried, O'Doherty & Dolan, 2002; O'Doherty, Deichmann, Critchley, & Dolan, 2002; O'Doherty, Kringelbach, Rolls, Hornak, & Andrews, 2001; O'Doherty, Winston, Critchley, Perrett, Burt, & Dolan, 2003). (File:BrainCaudatePutamen.svg: User:Leevanjackson Derivative work: User:SUM1, CC BY-SA 4.0, via Wikimedia Commons)

The experience of pleasure also involves the orbitofrontal cortex. Neurons in this region fire when monkeys taste, or merely see pictures of, desirable foods. In humans, this region is activated by pleasant stimuli including money, pleasant smells, and attractive faces (Gottfried, O'Doherty & Dolan, 2002; O'Doherty, Deichmann, Critchley, & Dolan, 2002; O'Doherty, Kringelbach, Rolls, Hornak, & Andrews, 2001; O'Doherty, Winston, Critchley, Perrett, Burt, & Dolan, 2003).

Fear: The Neural System of Freezing and Fleeing

Figure 4.5.21.5: Because fear is so important for our survival (i.e., fear informs us when something threatens us), our brains are able to "recognize" frightening stimuli before we ourselves are even consciously aware of them. (Copyright; CC0 Public Domain, goo.gl/m25gce)

Fear is an unpleasant emotion that motivates avoidance of potentially harmful situations. Slight stimulation of the fear-related areas in the brain causes animals to freeze, whereas intense stimulation causes them to flee. The fear circuit extends from the central amygdala to the **periaqueductal gray** in the midbrain. These structures are sensitive to glutamate, corticotrophin releasing factor, adreno-cortico-trophic hormone, cholecystokinin, and several different neuropeptides. Benzodiazepines and other tranquilizers inhibit activation in these areas (Panksepp & Biven, 2012). As is discussed in a later section, stress plays a

role in releasing these chemicals activating the fight/flight/freeze response. As discussed elsewhere (Chapter 6 and again in Chapter 16), benzodiazepines are used to lower anxiety or anticipation of a fearful situation by inhibiting the activity of these areas because they are GABA agonists.

The role of the **amygdala** in fear responses has been extensively studied. Perhaps because fear is so important to survival, two pathways send signals to the amygdala from the sensory organs. When an individual sees a snake, for example, the sensory information travels from the eye to the **thalamus** and then to the visual cortex. The **visual cortex** sends the information on to the amygdala, provoking a fear response. However, the thalamus also quickly sends the information straight to the amygdala, so that the organism can react before consciously perceiving the snake (LeDoux, Farb, & Ruggiero, 1990). The pathway from the thalamus to the amygdala is fast but less accurate than the slower pathway from the visual cortex. Damage to the amygdala or areas of the ventral hippocampus interferes with fear conditioning in both humans and nonhuman animals (LeDoux, 1996).

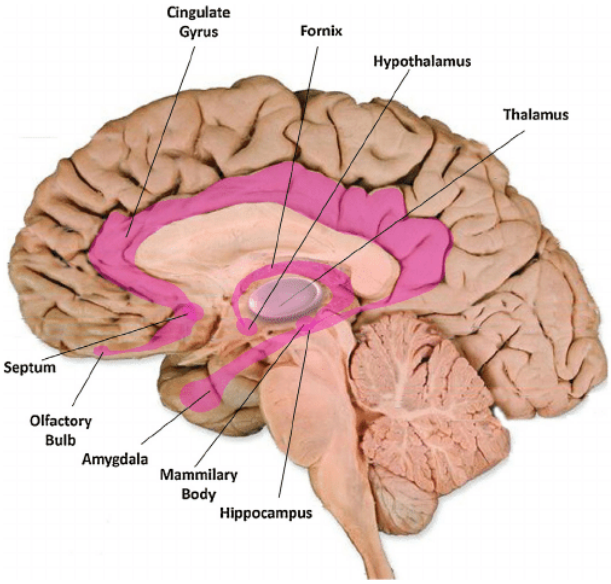

Figure 4.5.21.6: The limbic system (highlighted here in pink), which includes the hypothalamus, thalamus, amygdala, and the hippocampus, is involved in mediating emotional response and memory. (Limbic system by SoniaM2020 licensed CC BY-SA 4.0)

Love: The Neural Systems of Care and Attachment

Figure 4.5.21.7: Just as scientists today distinguish between types of love like “romantic” and “parental,” so did the ancient Greeks who used the terms “eros” and “storge.” [Image: Go-tea 郭天, https://goo.gl/KLFxJP, CC BY 2.0, goo.gl/zHmGV2]

For social animals such as humans, attachment to other members of the same species produces the positive emotions

of attachment: love, warm feelings, and affection. The emotions that motivate nurturing behavior (e.g., maternal care) are distinguishable from those that motivate staying close to an attachment figure in order to receive care and protection (e.g., infant attachment). Important regions for maternal nurturing include the dorsal **preoptic area** (Numan & Insel, 2003) (see Figure) and the bed nucleus of the **stria terminalis**(Panksepp, 1998).

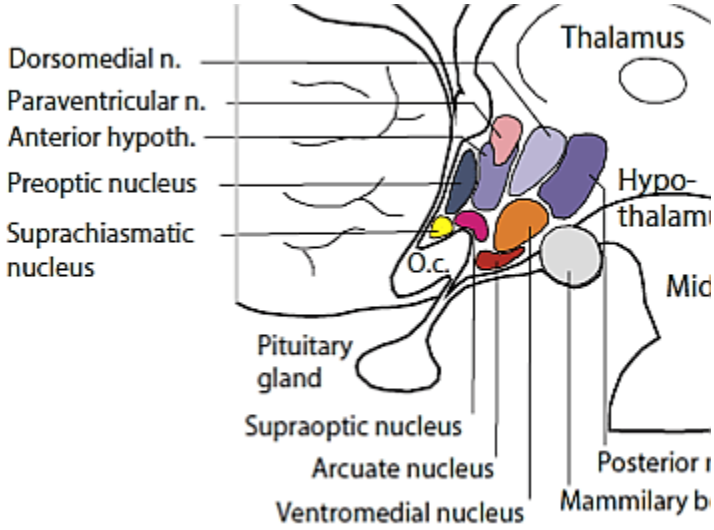

Figure 4.5.21.8: Figure showing key hypothalamic nuclei including the preoptic nucleus in dark blue anterior to the anterior hypothalamus, behind the frontal cortex and above the SCN and supraoptic nucleus. Sanador2.0, CC BY-SA 3.0, via Wikimedia Commons

These regions overlap with the areas involved in sexual desire, and are sensitive to some of the same neurotransmitters, including oxytocin, arginine-vasopressin, and endogenous opioids (endorphins and enkephalins).

Grief: The Neural Networks of Loneliness and Panic

The neural networks involved in infant attachment are also sensitive to separation. These regions produce the painful emotions of grief, panic, and loneliness. When infant humans or other infant mammals are separated from their mothers, they produce distress vocalizations, or crying. The attachment circuits are those that cause organisms to produce distress vocalizations when electrically stimulated.

The attachment system begins in the midbrain periaqueductal gray, very close to the area that produces physical pain responses, suggesting that it may have originated from the pain circuits (Panksepp, 1998). Separation distress can also be evoked by stimulating the dorsomedial thalamus, ventral septum, dorsal preoptic region, and areas in the bed nucleus of stria terminalis (near sexual and maternal circuits). (Panksepp, Normansell, Herman, Bishop, & Crepeau, 1988)

These regions are sensitive to endogenous opiates, oxytocin, and prolactin. All of these neurotransmitters *prevent* separation distress. Opiate drugs such as morphine and heroin, as well as nicotine, artificially produce feelings of pleasure and gratification, similar to those normally produced during positive social interactions. This may explain why these drugs are addictive. Panic attacks appear to be an intense form of separation distress triggered by the attachment system, and panic can be effectively relieved by opiates. Testosterone also reduces separation distress, perhaps by reducing attachment needs. Consistent with this, panic attacks are more common in women than in men.

Knowledge Emotions

Paul Silvia (University of North Carolina, Greensboro) suggested that when people think of emotions they usually think of the obvious ones, such as happiness, fear, anger, and sadness. He instead looks at the knowledge emotions, a family of emotional states that foster learning, exploring, and reflecting. Surprise, interest, confusion, and awe come from events that are unexpected, complicated, and mentally challenging, and they motivate learning in its broadest sense, be it learning over the course of seconds (finding the source of a loud crash, as in surprise) or over a lifetime (engaging with hobbies, pastimes, and intellectual pursuits, as in interest). Of course there are several causes, consequences, and individual differences. As a group, the knowledge emotions motivate people to engage with new and puzzling things rather than avoid them. Over time, engaging with new things, ideas, and

people broadens someone's experiences and cultivates expertise. The knowledge emotions thus don't gear up the body like fear, anger, and happiness do, but they do gear up the mind—a critical task for humans, who must learn essentially everything that they know.

So while emotions are something we think of in terms of feelings and the fight or flight response, or even as longer lasting sadness or love, Silvia's ideas point out the less noticed strong connection between emotion and cognition. It is clear that emotions can and do provide a strong basis for how and what we think about.

Plasticity: Experiences Can Alter the Brain

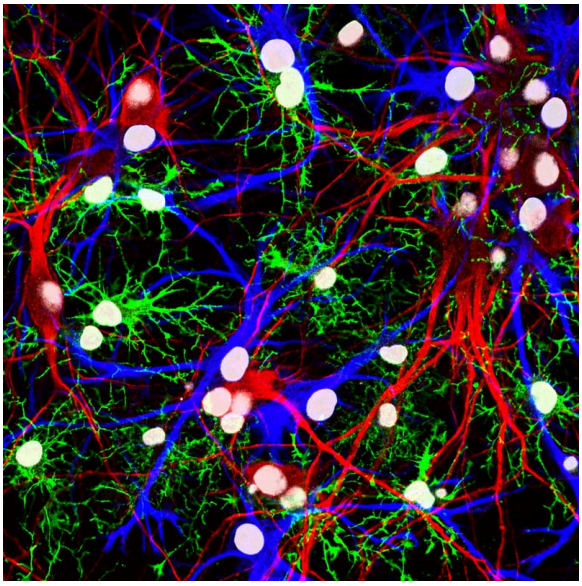

Figure 4.5.21.9: Neural plasticity can be summed up in the phrase: "Neurons that fire together, wire together." Or in other words, when certain emotions are paired with certain contexts, we learn to associate the two together. Here we see the networks of neurons that are connected to each other. [Image: NICHD NIH, https://goo.gl/T3PUlg, CC BY 2.0, goo.gl/BRvSA7]

The responses of specific neural regions may be modified by experience. For example, the front shell of the nucleus accumbens is generally involved in appetitive behaviors, such as eating, and the back shell is generally involved in fearful defensive behaviors (Reynolds & Berridge, 2001, 2002). Research using human neuroimaging has also revealed this front–back distinction in the functions of the nucleus accumbens (Seymour, Daw, Dayan, Singer, & Dolan, 2007). However, when rats are exposed to stressful environments, their fear-generating regions expand toward the front, filling almost 90% of the nucleus accumbens shell. On the other hand, when rats are exposed to preferred home environments, their fear-generating regions shrink and the appetitive regions expand toward the back, filling approximately 90% of the shell (Reynolds & Berridge, 2008). Consider how this might be generalized to human experiences that are stressful versus those that are generally comforting and comfortable.

Brain Structures Have Multiple Functions

Although much affective neuroscience research has emphasized whole structures, such as the amygdala and nucleus accumbens, it is important to note that many of these structures are more accurately referred to as complexes. They include distinct groups of nuclei that perform different tasks. At present, human neuroimaging techniques such as fMRI are unable to examine the activity of individual nuclei in the way that invasive animal neuroscience can. For instance, the amygdala of the nonhuman primate can be divided into 13 nuclei and cortical areas (Freese & Amaral, 2009). These regions of the amygdala perform different functions. The central nucleus sends outputs involving brainstem areas that result in innate emotional expressions and associated physiological responses. The basal nucleus is connected with striatal areas that are involved with actions such as running toward safety. Furthermore, it is not possible to make one-to-one maps of emotions onto brain regions. For example, extensive research has examined the involvement of the amygdala in fear, but research has also shown that the amygdala is active during uncertainty (Whalen, 1998) as well as positive emotions (Anderson et al., 2003; Schulkin, 1990).

Conclusion

Research in affective neuroscience has contributed to knowledge regarding emotional, motivational, and behavioral processes. The study of the basic emotional systems of nonhuman animals provides information about the organization and development of more complex human emotions. Although much still remains to be discovered, current findings in affective neuroscience have already influenced our understanding of drug use and abuse, psychological disorders such as panic disorder, and complex human emotions such as desire and enjoyment, grief and love.

4.5.22: Valence of Emotions

Learning Objectives

- Describe the functions of emotions and categories of positive and negative ones.
- Differentiate intensity and fluctuation of different emotions.
- Analyze the significance of context and external environment in emotional experiences.
- Evaluate how it is possible to feel more than one emotion at a time, and how that is represented in the brain.

Overview

Emotions don't just feel good or bad, they also contribute crucially to people's well-being and health. In general, experiencing positive emotions is good for us, whereas experiencing negative emotions is bad for us. However, research on emotions and well-being suggests this simple conclusion is incomplete and sometimes even wrong. Taking a closer look at this research, this section provides a more complex relationship between emotion and well-being. At least three aspects of the emotional experience appear to affect how a given emotion is linked with well-being: the intensity of the emotion experienced, the fluctuation of the emotion experienced, and the context in which the emotion is experienced. While it is generally good to experience more positive emotion and less negative emotion, this is not always the guide to the good life.

Given how we feel adds much of the flavor to life's highest—and lowest—moments, can you think of an important moment in your life that didn't involve strong feelings? In fact, it might be hard to recall *any* times when you had no feeling at all. Given how full life is with feelings and given how profoundly feelings affect us, it is not surprising that much theorizing and research has been devoted to uncovering how we can optimize our feelings, or "emotion experiences," as they are referred to in psychological research.

Feelings Contribute to Well-Being

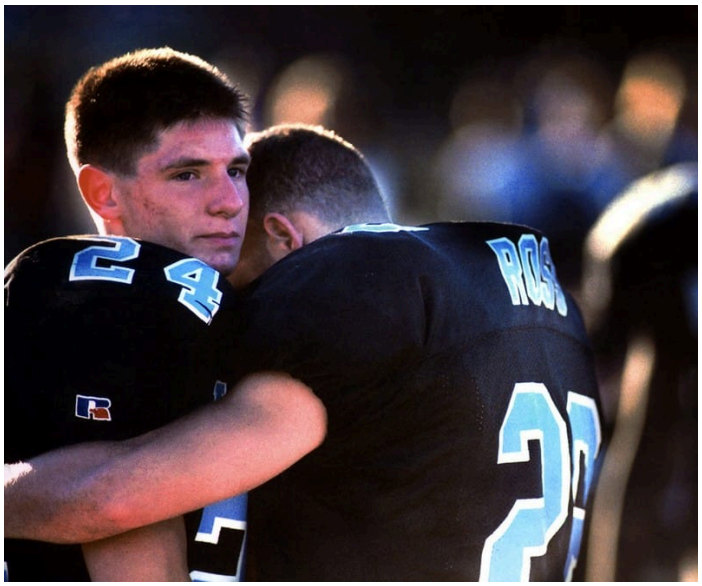

Figure 4.5.22.1: Although we tend to think we should always strive for "positive" or "feel-good" emotions, in some situations a negative emotion might be best. For example feeling disappointment when experiencing a failure might help motivate you for future success. [Image: CC0 Public Domain, goo.gl/m25gce]

So, which **emotions** are the "best" ones to feel? Take a moment to think about how you might answer this question. At first glance, the answer might seem obvious. Of course, we should experience as much positive emotion and as little negative emotion as possible! Why? Because it is pleasant to experience positive emotions and it is unpleasant to experience negative emotions (Russell & Barrett, 1999). The conclusion that positive feelings are good and negative feelings are bad might seem so obvious as

not to even warrant the question, much less bother with psychological research. In fact, the very labels of “positive” and “negative” imply the answer to this question. However, for the purposes of this section, it may be helpful to think of “positive” and “negative” as descriptive terms used to discuss two different types of experiences, rather than a true value judgment. Thus, whether positive or negative emotions are good or bad for us needs to be tested in particular situations (See 4.5.22.1).

As it turns out, this empirical question has been on the minds of theorists and researchers for many years. Many psychologists began asking whether the effects of feelings could go beyond the obvious momentary pleasure or displeasure. In other words, can emotions do more for us than simply make us feel good or bad? This is not necessarily a new question; variants of it have appeared in the texts of thinkers such as Charles Darwin (1872) and Aristotle (1999). However, modern psychological research has provided empirical evidence that feelings are not just inconsequential byproducts. Rather, each emotional experience, however fleeting, has effects on cognition, behavior, and the people around us. For example, feeling happy is not only pleasant, but is also useful to feel when in social situations because it helps us be friendly and collaborative, thus promoting our positive relationships. Over time, the argument goes, these effects add up to have tangible effects on people’s **well-being** (good mental and physical health).

A variety of research has been inspired by the notion that our emotions are involved in, and maybe even causally contribute to, our well-being. This research has shown that people who experience more frequent positive emotions and less frequent negative emotions have higher well-being (e.g., Fredrickson, 1998; Lyubomirksy, King, & Diener, 2005), including increased life satisfaction (Diener, Sandvik, & Pavot, 1991), increased physical health (Tugade, Fredrickson, & Barrett, 2004; Veenhoven, 2008), greater resilience to stress (Folkman & Moskowitz, 2000; Tugade & Fredrickson, 2004), better social connection with others (Fredrickson, 1998), and even longer lives (Veenhoven, 2008). Notably, the effect of positive emotion on longevity is about as powerful as the effect of smoking on reducing lifespan! Perhaps most importantly, some research directly supports that emotional experiences *cause* these various outcomes rather than being just a consequence of them (Fredrickson, Cohn, Coffey, Pek, & Finkel, 2008; Lyubomirsky et al., 2005).

Figure 4.5.22.2: Not only do the emotions we feel vary by the context, but also the emotions we should feel depend on the circumstances, too. [Image: puppywind, https://goo.gl/BQKhKK, CC BY-NC-ND 2.0, goo.gl/h9gK3o]

At this point, you might be tempted to conclude that you should always strive to experience as much positive emotion and as little negative emotion as possible. However, there is evidence to suggest that this conclusion may be premature. This is because this conclusion neglects three central aspects of the emotion experience. First, it neglects the intensity of the emotion: Positive and negative emotions might not have the same effect on well-being at all intensities. Second, it neglects how emotions fluctuate over time: Stable emotion experiences might have quite different effects from experiences that change a lot. Third, it neglects the context in which the emotion is experienced: The context in which we experience an emotion might profoundly affect whether the emotion is good or bad for us (See Figure 4.5.22.2). So, to address the question “Which emotions should we feel?” we must answer, “It depends!” We next consider each of the three aspects of feelings, and how they influence the link between feelings and well-being.

The Intensity of the Emotion Matters

Experiencing more *frequent* positive emotions is generally beneficial. But does this mean that we should strive to feel as *intense* positive emotion as possible? Recent research suggests that this unqualified conclusion might be wrong.

In fact, experiencing very high levels of positive emotion may be harmful (Gruber, 2011; Oishi, Diener, & Lucas, 2007). For instance, experiencing *very* high levels of positive emotion makes individuals more likely to engage in risky behaviors, such as binge eating and drug use (Cyders & Smith, 2008; Martin et al., 2002). Furthermore, intense positive emotion is associated with the experience of mania (Gruber et al., 2009; Johnson, 2005). It appears that the experience of positive emotions follows an inverted U-shaped curve in relation to well-being: more positive emotion is linked with increased well-being, but only up to a point, after which even more positive emotion is linked with decreased well-being (Grant & Schwartz, 2011). These empirical findings underscore the sentiment put forth long ago by the philosopher Aristotle: Moderation is key to leading a good life (1999).

Too much positive emotion may pose a problem for well-being. Might too little negative emotion similarly be cause for concern? Although there is limited empirical research on this subject, initial research supports this idea. For example, people who aim *not* to feel negative emotion are at risk for worse well-being and adaptive functioning, including lower life satisfaction, lower social support, worse college grades, and feelings of worse physical health (Tamir & Ford, 2012a). Similarly, feeling too little embarrassment in response to a social faux pas may damage someone's social connections if they aren't motivated by their embarrassment to make amends (Keltner & Buswell, 1997). Low levels of negative emotion also seem to be involved in some forms of psychopathology. For instance, blunted sadness in response to a sad situation is a characteristic of major depressive disorder (Rottenberg, Gross, & Gotlib, 2005) and feeling too little fear is a hallmark of psychopathy (Marsh et al., 2008; Patrick, 1994).

In sum, this first section suggests that the conclusion "Of course we should experience as much positive emotions and as little negative emotions as possible" is sometimes wrong. As it turns out, there can be too much of a good thing and too little of a bad thing.

The Fluctuation of the Emotion Matters

Figure 4.5.22.3: Throughout our lives, our emotions vary such that we experience great highs and great lows. However, if you average those emotions over time, we tend to end up somewhere in the middle. [Image: Moazzam Brohi, https://goo.gl/acZniv, CC BY 2.0, goo.gl/BRvSA7]

Emotions naturally vary—or fluctuate—over time (Davidson, 1998) (See Figure 4.5.22.3). We probably all know someone whose emotions seem to fly everywhere—one minute they're ecstatic, the next they're upset. We might also know a person who is pretty even-keeled, moderately happy, with only modest fluctuations across time. When looking only at *average* emotion experience, say across a month, both of these people might appear identical: moderately happy. However, underlying these identical averages are two very different patterns of fluctuation across time. Might these **emotion fluctuations** across time—beyond average intensity—have implications for well-being?

Overall, the available research suggests that how much emotions fluctuate does indeed matter. In general, greater fluctuations are associated with worse well-being. For example, higher fluctuation of positive emotions—measured either within a single day or across two weeks—was linked with lower well-being and greater depression (Gruber, Kogan, Quoidbach, & Mauss, 2013). Fluctuation in negative emotions, in turn, has been linked with increased depressive symptoms (Peeters, Berkhof, Delespaul, Rottenberg, & Nicolson, 2003), borderline personality disorder (Trull et al., 2008), and neuroticism (Eid & Diener, 1999). These associations tend to hold even when controlling for average levels of positive or negative emotion, which means that beyond the overall intensity of positive or negative emotion, the fluctuation of one's emotions across time is associated with well-being. While it is not entirely clear why fluctuations are linked to worse well-being, one explanation is that strong fluctuations are indicative of emotional instability (Kuppens, Oravecz, & Tuerlinckx, 2010).

Of course, this should not be taken to mean that we should rigidly feel the exact same way every minute of every day, regardless of context. After all, psychological flexibility—or the ability to adapt to changing situational demands and experience emotions accordingly—has generally demonstrated beneficial links with well-being (Bonanno, Papa, Lalande, Westphal, & Coifman, 2004; Kashdan, & Rottenberg, 2010). The question remains, however: what exact amount of emotional fluctuation constitutes unhealthy instability and what amount of emotional fluctuation constitutes healthy flexibility.

Again, then, we must qualify the conclusion that it is always better to experience more positive emotions and less negative emotions. The degree to which emotions fluctuate across time plays an important role. Overall, relative stability (but not rigidity) in emotion experience appears to be optimal for well-being.

The Context of the Emotion Experience Matters

This section has already discussed two features of emotion experiences that affect how they relate to well-being: the intensity of the emotion and the fluctuation of the emotion over time. However, neither of these features takes into account the context in which the emotion is experienced. At least three different contexts may critically affect the links between emotion and well-being: (1) the external environment in which the emotion is being experienced, (2) the other emotional responses (e.g., physiology, facial behavior) that are currently activated, and (3) the other emotions that are currently being experienced.

The External Environment

Figure 4.5.22.4: Feeling an emotion that matches the person's context (e.g., experiencing happiness at a birthday party) is typically the most functional or beneficial emotion to feel. [Image: OakleyOriginals, https://goo.gl/IxfIsq, CC BY 2.0, goo.gl/BRvSA7]

Emotions don't occur within a vacuum. Instead, they are usually elicited by and experienced within specific situations that come in many shapes and sizes —from birthday parties to funerals, job interviews to mundane movie nights. The situation in which an emotion is experienced has strong implications for whether a given emotion is the "best" emotion to feel. Take happiness, for example. Feeling happiness at a birthday party may be a great idea (See Figure 4.5.22.4). However, having the exact same experience of happiness at a funeral would likely not bode well for your well-being.

When considering how the environment influences the link between emotion and well-being, it is important to understand that each emotion has its own function. For example, although fear is a negative emotion, fear helps us notice and avoid threats to our safety (öhman & Mineka, 2001), and may thus be the "best" emotion to feel in dangerous situations. Happiness can help people cooperate with others, and may thus be the best emotion to feel when we need to collaborate (e.g., Van Kleef, van Dijk, Steinel, & van Beest, 2008). Anger can energize people to compete or fight with others, and may thus be advantageous to experience it in confrontations (e.g., Tamir & Ford, 2012b; Van Kleef et al., 2008). It might be disadvantageous to experience happiness (a positive emotion) when we need to fight with someone; in this situation, it might be better to experience anger (a negative emotion). This suggests that emotions' implications for well-being are not determined only by whether they are positive or negative but also by whether they are well-matched to their context.

In support of this general idea, people who experience emotions that fit the context at hand are more likely to recover from depression and trauma (Bonanno et al., 2004; Rottenberg, Kasch, Gross, & Gotlib, 2002). Research has also found that participants who want to feel emotions that match the context at hand (e.g., anger when confronting someone)—even if that emotion was negative—are more likely to experience greater well-being (Tamir & Ford, 2012a). Conversely, people who pursue emotions without regard to context—even if those emotions are positive, like happiness—are more likely to experience lower subjective well-being, more depression, greater loneliness, and even worse grades (Ford & Tamir, 2012; Mauss et al., 2012; Mauss, Tamir, Anderson, & Savino; 2011; Tamir & Ford, 2012a).

In sum, this research demonstrates that regardless of whether an emotion is positive or negative, the context in which it is experienced critically influences whether the emotion helps or hinders well-being.

Other Emotional Responses

Figure 4.5.22.5: If we experience the emotion of amusement (from seeing something funny), we often have the physiological response to laugh. This is an example of emotion coherence, where we express a particular behavior associated with a particular emotion. [Image: Ed Schipul, https://goo.gl/7NUYmR, CC BY-SA 2.0, goo.gl/rxiUsF]

The subjective experience of an emotion—what an emotion *feels* like—is only one aspect of an emotion. Other aspects include behaviors, facial expressions, and physiological activation (Levenson, 1992). For example, if you feel excited about having made a new friend, you might want to be near that person, you might smile, and your heart might be beating faster as you do so. Often, these different responses travel together, meaning that when we feel an emotion we *typically* have corresponding behaviors and physiological responses (e.g.,Ekman, 1972; Levenson, 1992) (See Figure 4.5.22.5) . The degree to which responses travel together has sometimes been referred to as **emotion coherence** (Mauss, Levenson, McCarter, Wilhelm, & Gross, 2005). However, these different responses do not co-occur in all instances and for all people (Bradley & Lang, 2000; Mauss et al., 2005; for review, see Fridlund, Ekman, & Oster, 1987). For example, some people may choose not to express an emotion they are feeling internally (English & John, 2013), which would result in lower coherence.

Does coherence—above and beyond emotion experience per se—matter for people's well-being? To examine this question, one study measured participants' emotion coherence by showing them a funny film clip of stand-up comedy while recording their experience of positive emotion as well as their behavioral displays of positive emotion (Mauss, Shallcross, et al., 2011). As

predicted, participants differed quite a bit in their coherence. Some showed almost perfect coherence between their behavior and experience, whereas others' behavior and experience corresponded not much at all. Interestingly, the more that participants' behavior and experience cohered in the laboratory session, the lower levels of depressive symptoms and the higher levels of well-being they experienced 6 months later. This effect was found when statistically controlling for overall intensity of positive emotions experienced. In other words, experiencing high levels of positive emotion aided well-being *only if it was accompanied by corresponding positive facial expressions*.

But *why* would coherence of different emotional responses predict well-being? One of the key functions of an emotion is social communication (Keltner & Haidt, 1999), and arguably, successful social communication depends on whether an individual's emotions are being *accurately* communicated to others. When someone's emotional behavior doesn't match their experience, it may disrupt communication because it could make the individual appear confusing or inauthentic to others. In support of this theory, the above study found that lower coherence was associated with worse well-being because people with lower coherence felt less socially connected to others (Mauss, Shallcross, et al., 2011). These findings are also consistent with a large body of research examining the extent to which people mask the outward display of an emotional experience, or *suppression*. This research has demonstrated that people who habitually use suppression not only experience worse well being (Gross & John, 2003), but they also seem to be particularly worse off with regard to their social relationships (Srivastava, Tamir, McGonigal, John, & Gross, 2009).

These findings underscore the importance of examining whether an individual's experience is traveling together with his or her emotional responses, above and beyond overall levels of subjective experience. Thus, to understand how emotion experiences predict well-being, it is important not only to consider the experience of an emotion, but also the other emotional responses currently activated.

Other Emotions

Up until now, we have treated emotional experiences as though people can only experience one emotion at a time. However, it should be kept in mind that positive and negative emotions are not simply the opposite of one another. Instead, they tend to be independent of one another, which means that a person can feel positive and negative emotions at the same time (Larsen, McGraw, Mellers, & Cacioppo, 2004). For example, how does it feel to win a prize when you expected a greater prize? Given "what might have been," situations like this can elicit both happiness and sadness. Or, take "schadenfreude" (a German term for deriving pleasure from someone else's misfortune), or "aviman" (an Indian term for prideful, loving anger), or nostaligia (an English term for affectionate sadness about something from the past): these terms capture the notion that people can feel both positively and negatively within the same emotional experience. And as it turns out, the other emotions that someone feels (e.g., sadness) during the experience of an emotion (e.g., happiness) influence whether that emotion experience has a positive or negative effect on well-being.

Figure 4.5.22.6: What experiences can you recall where you felt mixed emotions? Happiness and disappointment? Hope and fear? Admiration and envy? [Image: Ron Cogswell, https://goo.gl/JKuzmU, CC BY 2.0, goo.gl/BRvSA7]

Importantly, the extent to which someone experiences different emotions at the same time—or *mixed emotions*—may be beneficial for their well-being (See Figure 4.5.22.6). Early support for this theory was provided by a study of bereaved spouses. In the study, participants were asked to talk about their recently deceased spouse, which undoubtedly elicited strong negative emotions. However, some participants expressed positive emotions in addition to the negative ones, and it was those participants who recovered more quickly from their loss (Bonanno & Keltner, 1997). A recent study provides additional support for the benefits of mixed emotions, finding that adults who experienced more mixed emotions over a span of 10 years were physically healthier than adults whose experience of mixed emotions did not increase over time (Hershfield, Scheibe, Sims & Carstensen, 2013). Indeed, individuals who can experience positive emotions even in the face of negative emotions are more likely to cope successfully with stressful situations (Larsen, Hemenover, Norris, & Cacioppo, 2003).

Why would mixed emotions be beneficial for well-being? Stressful situations often elicit negative emotions, and recall that negative emotions have some benefits, as we outlined above. However, so do positive emotions, and thus having the ability to "take the good with the bad" might be another key component of well-being. Again, experiencing more positive emotion and less negative emotion may not always be optimal. Sometimes, a combination of both may be best.

Conclusion

Are emotions just fleeting experiences with no consequence beyond our momentary comfort or discomfort? A variety of research answers a firm "no"—emotions are integral predictors of our well-being. This module examined how, exactly, emotion experience might be linked to well-being. The obvious answer to this question is: *of course,* experiencing as much positive emotions and as little negative emotions as possible is good for us. But although this is true in general, recent research suggests that this obvious answer is incomplete and sometimes even wrong. As philosopher Robert Solomon said, "Living well is not just maximizing the good feelings and minimizing the bad. (...) A happy life is not necessarily filled with happy moments" (2007, p. 86).

Discussion Questions

1. Much research confirms the relative benefits of positive emotions and relative costs of negative emotions. Could positive emotions be detrimental, or could negative emotions be beneficial? Why or why not?
2. We described some contexts that influence the effects of emotional experiences on well-being. What other contexts might influence the links between emotions and well-being? Age? Gender? Culture? How so?
3. How could you design an experiment that tests...(A) When and why it is beneficial to feel a negative emotion such as sadness? (B) How is the coherence of emotion behavior and emotion experience linked to well-being? (C) How likely a person is to feel mixed (as compared to simple) emotions?

Vocabulary

Emotion
An experiential, physiological, and behavioral response to a personally meaningful stimulus.

Emotion coherence
The degree to which emotional responses (subjective experience, behavior, physiology, etc.) converge with one another.

Emotion fluctuation
The degree to which emotions vary or change in intensity over time.

Well-being
The experience of mental and physical health and the absence of disorder.

4.5.23: Fight or Flight

Learning Objectives

- Compare different theories about the generation of emotions.
- Describe the anatomical and chemical bases of anger and fear.
- Analyze how epigenetic research has enhanced our understanding of the nature-nurture debate surrounding anger and fear.

Overview

An important function of emotions in humans, and other animals that live in groups of any kind, is to communicate with other members of one's own species. The emotions that are particularly important to communicate to other members are those related to fear, and those related to anger. When we think of the physiological arousal associated with emotions, we often talk about the "fight or flight" response. These correspond nicely with the two major negative emotions - anger and fear. Multiple animal paradigm studies and human neuroscientific research, including studies with psychopathological conditions, have served to examine the nature of these emotions. Some of these theories and findings will be discussed.

Theories of Emotional Distinctions

Can emotions be better described as *qualitatively* distinct, for example, as discrete “basic emotions” or “natural kinds” (Ekman et al., 1983; Izard, 1992; Panksepp, 2005) or as *quantitatively* distinct, for example, as points along a circumplex defined by dimensions like arousal and valence (Russell and Barrett, 1999; Barrett and Wager, 2006)? Recent years have seen a protracted debate in the literature about how to most accurately capture the nature of emotion (Barrett et al., 2007; Izard, 2007; Panksepp, 2007; Tracy and Randles, 2011), with proposed models of emotion including not only basic emotion and dimensional models, but also those that focus upon goal-relevant appraisals of emotional stimuli (Moors et al., 2013), emotions as coping responses (Roseman, 2013), and emotions as survival circuits (LeDoux, 2012). An extended conversation about the strengths and weaknesses of these various views will not be reviewed in full here, rather, the focus will be on the basic consideration of whether different emotions (e.g., fear, anger) are best viewed as qualitatively or quantitatively distinct.

Qualitative Ideas

Figure 4.5.23.1: Individual emotions as they develop - first we only have basic emotions (fear, anger, disgust, contempt, joy, sadness and interest). Then self conscious (guilt, pride, embarrassment, shame, triumph) ones devleop. And then finally more cognitively complex (envy, gratitude, disappointment, regret, hope, schadenfreude, empathy, compassion) ones appear.(Copyright; Individual emotions by U3161650, CC BY-SA 4.0, via Wikimedia Commons)

Models that posit emotions to be qualitatively distinct, such as “basic emotion” models, holds that a limited number of emotions like fear, anger, and positive excitement emerge from dissociable neurophysiological processes (Ekman et al., 1983; Izard, 1992;

Panksepp, 2005; Lench et al., 2011). In Figure 4.5.23.1 we see one representation of this idea that initially we have basic emotions including fear, anger, disgust, contempt, joy, sadness and interest, which then grow to include self conscious emotions (guilt, pride, embarrassment, shame, triumph) and finally cognitively complex emotions (envy, gratitude, disappointment, regret, hope, schadenfreude, empathy, compassion). These neurophysiological processes are generally linked to activity in the evolutionarily ancient subcortical structures of the midbrain, striatum, and limbic system most commonly linked to emotion (Panksepp, 2005; Vytal and Hamann, 2010). So, for example, the generation of positive excitement is linked to activation in a striatal circuit centered on dopaminergic neurons in the nucleus accumbens (Ikemoto and Panksepp, 1999), whereas the generation of fear is associated with activity in a circuit involving the periaqueductal gray, anterior and medial hypothalamus, and amygdala (LeDoux, 2000). In this view, finer gradations of experience result when basic emotions are modulated or elaborated by higher-level cognitive processes controlled by the cerebral cortex, but the emergence of qualitatively distinct emotions is not dependent on these cortically-controlled processes (Panksepp, 2005).

Quantitative Ideas

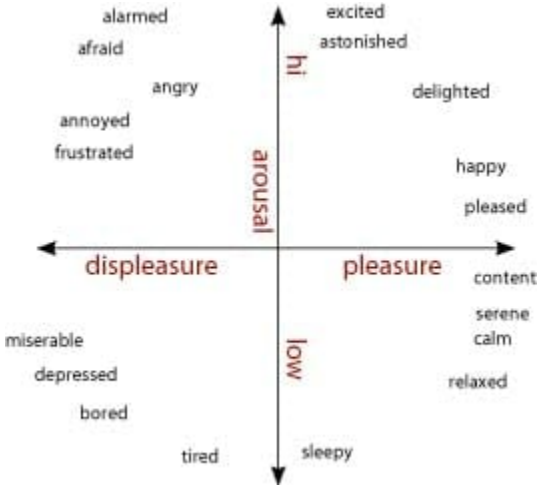

Figure 4.5.23.2: Model showing two orthogonal dimensions of valence (on the horizonal axis) and arousal (on the vertical axis) with examples of emotions and where they might fall on the graph. For example, delight falls in the top right quadrant because it indicates high arousal and high pleasure while boredom falls in the diagonally opposite quadrant, and relaxed in the bottom right (Copyright; Psychologist Russell's model of arousal and valence by http://imagine-it.org/gamessurvey/, licensed CC BY 3.0, via Wikimedia Commons)

Models that posit emotions to be quantitatively distinct hold that emotions like fear, anger, and happiness are best described as points on one or more core dimensions. Core dimensions typically proposed to distinguish among emotions are physiological arousal or activation (low—high) and valence (bad—good) (Bradley et al., 2001). [Some have proposed a withdrawal—approach dimension as a substitute or supplement to the valence axis (Wager et al., 2003; Christie and Friedman, 2004; van Honk and Schutter, 2006)]. As shown in figure 4.5.23.2, arranged orthogonally, these dimensions form a circumplex upon which emotions can be plotted and quantitatively compared (Barrett and Russell, 1999; Russell and Barrett, 1999; Colibazzi et al., 2010). Positive excitement is plotted as high in arousal and positive in valence, and sadness is low in arousal and negative in valence. Fear is typically plotted as high arousal and strongly negative, as is anger (Russell and Barrett, 1999). Further distinctions among emotions are thought to reflect differences in cognitive construals of the events surrounding the basic changes in arousal and valence. Thus, whether an individual experiences anger or fear (which are similar in terms of arousal or valence) may be shaped by interpretations of neurophysiological changes in valence and arousal in light of the eliciting stimulus and the individual's idiosyncratic stores of semantic knowledge, memories, and behavioral responses that shape the subjectively experienced state (Russell, 2003). Under this view, distinctions among experienced emotional states are highly dependent on these cognitively complex processes, which are subserved by a distributed network of regions of the cerebral cortex (Lindquist et al., 2012).

These models generate distinct predictions to the question of whether a disorder or lesion could result in a single emotion being disabled without affecting the experience of other emotions. The discrete emotions view would argue that a disorder or lesion that resulted in dysfunction in the specific structures subserving a particular emotion could affect the experience of one emotion while leaving others intact. In contrast, the dimensional view would require either that other emotions that are dimensionally similar to the affected emotion also be affected, or that deficits in a particular emotion would reflect dysfunction in cortically-driven higher-level cognitive processes.

Psychopathy Supports the Qualitative Model

The case of psychopathy lends clear support to notion that fear is qualitatively distinct from other emotions. In psychopathy, the bulk of the clinical and empirical evidence points toward the conclusion that fear responding is uniquely disabled, with other high-arousal (positive excitement, anger) and negatively valenced (anger, disgust) emotions remaining intact. The dimensional view cannot easily explain why in psychopaths the high arousal, negatively valenced state of anger is easily (perhaps too easily) generated, whereas the high arousal, negatively valenced state of fear is not. The problem cannot lie in a failure to fully engage neurocognitive systems underlying either the arousal or valence dimension, because psychopaths experience other high-arousal emotions (positive excitement) as well as other negatively valenced emotions (disgust). It also cannot result from some difficulty arising at the interaction of these axes, because anger and fear are highly similar in terms of both dimensions. Models that substitute a withdrawal—approach axis for a negative—positive axis are no more successful; the two most strongly withdrawal-linked emotions are disgust and fear, and there is no evidence for disgust-based impairments in psychopathy. Individuals with psychopathy also fail to recognize and therefore have no empathic response to others' fear.

On the whole, the empirical data support the idea that the amygdala, along with its efferent projections, is an essential structure for the generation of conditioned fear responses, which account for the majority of experienced fear (Davis, 1992, 1997). Extensive early evidence demonstrated that the amygdala plays a crucial role in the creation of conditioned fear in rodents. For example, lesions to the amygdala prevent rats from developing a conditioned fear response, like freezing in response to a stimulus that predicts shock (Blanchard and Blanchard, 1972). Later studies clarified the roles of the various subnuclei of the amygdala, demonstrating that the lateral nucleus is primarily involved in the acquisition of the fear response whereas the central nucleus is involved in both the acquisition and the expression of conditioned fear responses (Davis, 1992; Wilensky et al., 2006). The amygdala's many efferent projections coordinate autonomic and behavioral responses to fear eliciting stimuli. Projections from the central nucleus of the amygdala to the lateral hypothalamus are involved in activating autonomic sympathetic nervous system responses, and projections to the ventrolateral periaqueductal gray direct the expression of behavior responses, such as defensive freezing (Davis, 1992; LeDoux, 2012). The amygdala's central role in coordinated fear responding can be demonstrated by electrical stimulation studies showing that complex patterns of behavioral and autonomic changes associated with fear responses result from stimulation of the relevant regions of the amygdala (Davis, 1992). Heavy reliance on animal models is justified in the study of fear responding and the amygdala given how strongly conserved the amygdala nuclei involved in responding to conditioned threats are across species ranging from reptiles to birds to rodents to primates (LeDoux, 2012).

Research Suggesting Connections Between Anger and Fear

Neumann et al. (2010) hypothesize that aggressive behaviors, that are of two basic types - reactive and proactive, are mediated by anxiety-based neurological bases. Based on animal models, they suggest the following: "Male aggression is necessary for the acquisition and maintenance of nutrition, territory, and mating partners. Species-specific rules have to be strictly obeyed to guarantee effective and harmless communication. Thus, adaptive offensive aggression is comprised primarily of harmless threat behaviors allowing the opponent to escape or to switch to submissive behaviors in order to avoid direct physical confrontation. In rodents, such signs of offensive aggression include piloerection (intimidation of the opponent by larger appearance) and lateral threat (arched back and exposure of the flank). In case of an offensive attack, less vulnerable body parts of the opponent, such as those covered with muscles and a thick layer of skin, are targeted to avoid serious injuries (Blanchard and Blanchard, 1977 ; Blanchard et al., 2003). While offensive aggression is usually expressed during a fight for territory or exclusive mating, defensive aggression is mainly displayed in life-threatening situations and is linked to increased fear (Blanchard and Blanchard, 1981). As opposed to offensive aggression, defensive aggression is less or not signaled in advance, and attack targets include more vulnerable body parts (such as the head, belly, and genitals) (Blanchard and Blanchard, 1977 ; Blanchard et al., 2003)." The resident-intruder animal paradigms have been used to measure these ideas (see Figure 4.5.23.3).

Figure 4.5.23.3: Resident mouse with aggressive behavior and intruder mouse. Image by DataBase Center for Life Science (DBCLS) licensed CC-BY 4.0 via Wikimedia commons.

They also claim: "Anxiety may be interpreted as an emotional anticipation of an aversive situation and is reflected by species-specific behavioural fear responses to stressful and threatening stimuli characteristic for individual trait anxiety. Fear is not seen as basal state (as is anxiety), but as a complex behavioural response, such as startle or freezing. Further, in addition to factors which determine innate (trait) anxiety, several environmental or pharmacological factors may interact with the genetic background and determine the individual level of state anxiety and the final behavioural phenotype. Emotionality, often used as synonym for anxiety as well as fearfulness, may be seen in a broader sense, comprising both trait and state anxiety and stimulus-related fear. Emotionality is one of the major components underlying the ability of an organism to assess stressful stimuli and scenarios, and to adequately cope with them." (Neumann et al., 2010)

Neumann et al. (2010) show that several clinical and laboratory studies with humans and rodents have shown that there are complicated mechanisms by which anxiety and aggression are co-regulated. There are several neurochemicals found to be involved in complex ways as follows:

Glucocorticoids - The regulation of the HPA (Hypothalamic-Pituitary-Adrenal) axis seems very much connected to the experience of anxiety and aggression. However, the direction is not straightforward in that both high and low glucocorticoids are related to high aggression.

Vasopressin - Vasopressin is produced in the hypothalamus, and testosterone is produced in the gonads, and both modulate aggression as well as anxiety in males. Vasopressin is also involved in reducing anxiety as well as pair-bonding.

Testosterone - Along with aggression, testosterone rises in puberty, castration reduces both (through reduction in Vasopressin also). There are some environmental factors that have a moderating effect, but in general, testosterone is clearly related to modulating aggression in males.

Serotonin - lower 5-HT seems linked to greater aggression and violence in female rhesus. Genetic factors and early life stressors tend to mediate these effects.

GABA - when anxiety levels are increased, aggression increased depending on genetic predispositions to it, and activity also increased in "brain regions including the central amygdala, BST (Bed nucleus of the stria terminalis), lateral septum, and PVN (paraventricular nucleus) that are associated with stress-, fear- and aggression-related behaviour."

"The striking evidence for an overlap in neuroendocrine and neurochemical systems regulating aggression as well as anxiety suggests a strong correlation between these two behaviours. Thus, aggression and anxiety are not always co-regulated, but, under some circumstances, these behaviours may come under the control of the same genes and neuroactive substances including sexual steroids, neuropeptides and neuroamines within specific brain circuitries. Such a view is in agreement with clinical findings. On the one hand, excessive and violent behaviours are seen in humans exposed to adverse early life experiences and in patients with depression- and anxiety-related disorders, or PTSD. On the other hand, rather conflicting data exist on the effects

of anxiolytic drugs on anti-social and aggressive behaviours. In future studies that focus on the neurobiological mechanisms of (co-)regulation of aggression and anxiety, epigenetic modifications need to be considered in addition to the neuronal and neuroendocrine parameters discussed above." (Neumann et al, 2010).

Nature v. Nurture

Both genetic factors and experiences play a role in aggressive behaviors. The genetic regulation of serotonin release appears to play a role in aggression in many mammals including humans. For example, Peeters et al.'s (2020) study concluded that the short version of the serotonin transporter gene (S-allele of the 5-HTTLPR) seems to be linked to greater reactive aggression, and those individuals with higher avoidance tendencies toward angry facial expressions. Their findings indicate that evaluative impulses in response to social cues play an important role in mediating the genetic predisposition of the 5-HTTLPR polymorphism to increased expression of reactive aggression. Because of the chief role of MAOs in the metabolism of key neurotransmitters involved in aggressive behavior, most notably serotonin, it is not surprising that a substantial body of research has linked aggressive phenotypes with the MAO system. Many results inspired both the scientific community and media outlets to refer to *MAO-A* as the *warrior* or *criminal* gene. Although initial pharmacological studies supported a role for MAOIs in the reduction of aggressive phenotypes, data from these studies were hard to interpret because of the side effects of MAOIs, and because of their impact on a myriad of unrelated behaviors. Substantive evidence supporting the role of the *MAO* genes in aggression comes from studies in knockout (KO) mice. Selective knockout models for the *MAO-A* gene, for instance, exhibited increased aggressiveness compared to their wild-type counterparts. Genetic studies in humans provide evidence that *MAO-A* is linked to aggression but only when other environmental factors are also present during development (e.g., abuse, stressors). Other lines of research have demonstrated that the gene product of *MAO-A* (rather than the gene per se) influences violent traits. For instance, cortical and subcortical MAO-A activity in vivo -measured with positron emission tomography (PET)- was negatively associated with trait aggression (attribution: Mentis, Dardiotis, Katsouni & Chrousos, 2021).

Over the last two decades, the study of the relationship between *nature* and *nurture* in shaping human behavior has encountered a renewed interest. Behavioral genetics showed that distinct polymorphisms of genes that code for proteins that control neurotransmitter metabolic and synaptic function are associated with individual vulnerability to aversive experiences, such as stressful and traumatic life events, and may result in an increased risk of developing psychopathologies associated with violence. On the other hand, recent studies indicate that experiencing aversive events modulates gene expression by introducing stable changes to DNA without modifying its sequence, a mechanism known as “epigenetics”. For example, experiencing adversities during periods of maximal sensitivity to the environment, such as prenatal life, infancy and early adolescence, may introduce lasting epigenetic marks in genes that affect maturational processes in brain, thus favoring the emergence of dysfunctional behaviors, including exaggerate aggression in adulthood.

Adverse environmental influences during critical periods of development have been correlated with epigenetic markers that affect glucocorticoid receptor function. As seen in many studies, low cortisol release is correlated with low self control and higher aggression. Production of oxytocin is related to higher social functioning and attachment formation. Oxytocin secretion is stimulated by early maternal care, whereas adverse experiences in prenatal and early infancy development are related to lower oxytocin receptor methylation (a process involved in epigenetics). Serotonin is related to regulation of aggression. Genes responsible for controlling the reuptake of serotonin from the synaptic cleft are affected by early stressors (including trauma as well as conditions generated by poverty like poor medical care, housing quality and exposure to violent neighborhoods) that alter brain anatomy and function such as cortical thickness and amygdala reactivity. (See Figure 4.5.23.4 for the multiple ways in which stress and traumas lead to epigenetic modifications in the oxytocin, serotonin and HPA axis systems that affect aggressive behavior: reactive and proactive aggression, hostility, delinquency externalizing problems, violence, conduct disorders, physical and verbal aggression and callous unemotional traits.)

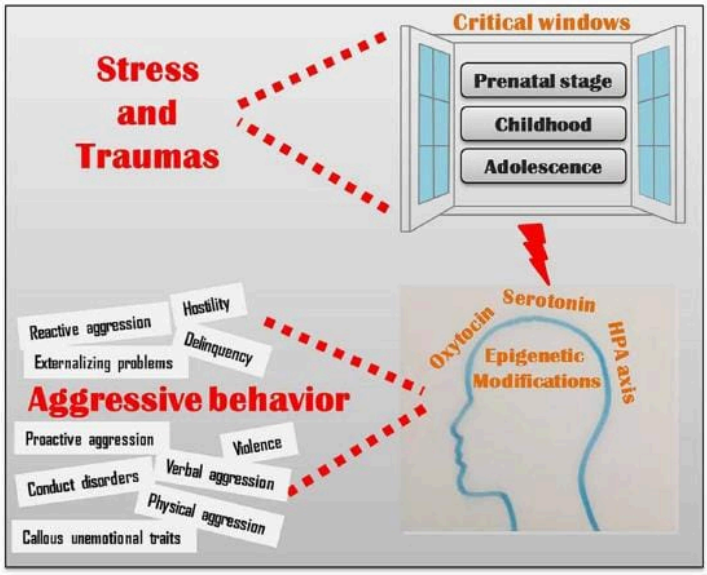

Figure 4.5.23.4: The epigenetic control of biological pathways, including the neuroendocrine, serotonergic and oxytocinergic pathways, significantly mediates the behavioral responses to the environment (Copyright; Genes and Aggressive Behavior: Epigenetic Mechanisms Underlying Individual Susceptibility to Aversive Environments by Sara Palumbo, Veronica Mariotti, Caterina Ioffreda & Silvia Pellegrini in Frontiers in Behavioral Neuroscience (2018) licensed CC BY 4.0)

Palumbo, Mariotti, Ioffreda and Pellegrini (2018) conclude that epigenetics is shedding a new light on the fine interaction between *nature* and *nurture*, by providing a novel tool to understand the molecular events that underlie the relationship among genes, brain, environment and behavior. Altogether, the results of the studies that we briefly discussed in the present article, clearly indicate that, when it comes to (human) behavior, *nature* and *nurture* are not to be regarded as two distinct and separate factors, contrary to the alternating predominance of either one that has been proposed in different historic phases (Levitt, 2013; Moore, 2016). Indeed, distinct genetic backgrounds differentially modulate the individual susceptibility to the environment and at the same time various environmental conditions differentially affect gene expression, in an intimate and fascinating manner that scientists have now begun to disentangle. The findings from this research pave the way to a novel approach to the understanding of human behavior, with important implications also for social sciences, including philosophy, ethics and law.

Conclusions

Anger and fear are considered basic emotions. While they are primarily negative, they serve very important survival functions. They appear to have clear genetic and biological bases that have been discussed in the research above.

4.5.24: Social Neuroscience

Learning Objectives

- Analyze the neural and physiological bases of social behavior including brain areas that are associated with social tasks.
- Evaluate how social behaviors and phenomena affect biological systems.

Overview

The current section provides an overview of the new field of social neuroscience, which combines the use of neuroscience methods and theories to understand how other people influence our thoughts, feelings, and behavior. The module reviews research measuring neural and hormonal responses to understand how we make judgments about other people and react to stress. Through these examples, it illustrates how social neuroscience addresses three different questions: (1) how our understanding of social behavior can be expanded when we consider neural and physiological responses, (2) what the actual biological systems are that implement social behavior (e.g., what specific brain areas are associated with specific social tasks), and (3) how biological systems are impacted by social processes.

Psychology has a long tradition of using our brains and body to better understand how we think and act. For example, in 1939 Heinrich Kluver and Paul Bucy removed (i.e. lesioned) the temporal lobes in some rhesus monkeys and observed the effect on behavior. Included in these **lesions** was a subcortical area of the brain called the **amygdala**. After surgery, the monkeys experienced profound behavioral changes, including loss of fear. These results provided initial evidence that the amygdala plays a role in emotional responses, a finding that has since been confirmed by subsequent studies (Phelps & LeDoux, 2005; Whalen & Phelps, 2009).

What Is Social Neuroscience?

Social neuroscience similarly uses the brain and body to understand how we think and act, with a focus on how we think about and act toward other people. More specifically, we can think of social neuroscience as an interdisciplinary field that uses a range of neuroscience measures to understand how other people influence our thoughts, feelings, and behavior. As such, social neuroscience studies the same topics as social psychology, but does so from a multilevel perspective that includes the study of the brain and body. Figure 4.5.24.1 shows the scope of social neuroscience with respect to the older fields of social psychology and neuroscience. Although the field is relatively new – the term first appeared in 1992 (Cacioppo & Berntson, 1992) – it has grown rapidly, thanks to technological advances making measures of the brain and body cheaper and more powerful than ever before, and to the recognition that neural and physiological information are critical to understanding how we interact with other people.

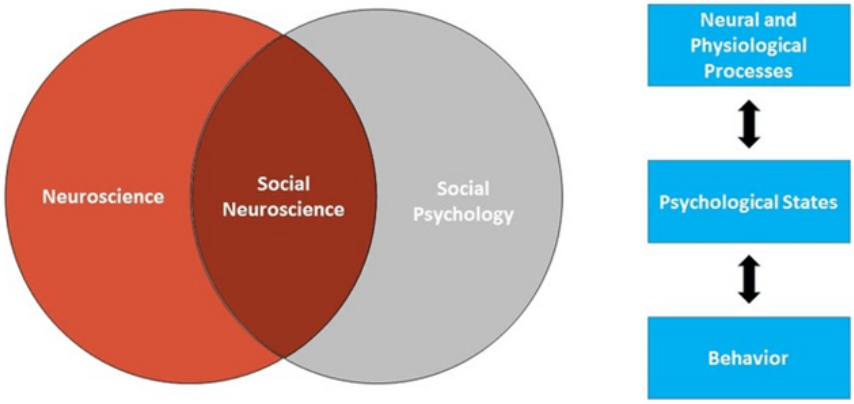

Figure 4.5.24.1: Social neuroscience is the intersection of social psychology and neuroscience. Under this multilevel approach, neural/physiological processes and behavior are two things we can measure or observe. Psychological states cannot be directly observed, but understanding them is the goal. Social neuroscientists use the observable neural/physiological processes and behavioral responses to make inferences about unobservable psychological states. The bidirectional arrows show that all levels of analysis are assumed to influence each other (e.g., psychological states can influence neural responses, and neural responses can influence psychological states). (Copyright; Tiffany Ito & Jennifer Kubota, via Noba Project, licensed CC BY-NC-SA 4.0)

Social neuroscience can be thought of as both a methodological approach (using measures of the brain and body to study social processes) and a theoretical orientation (seeing the benefits of integrating neuroscience into the study of social psychology). The overall approach in social neuroscience is to understand the psychological processes that underlie our social behavior. Because those psychological processes are intrapsychic phenomena that cannot be directly observed, social neuroscientists rely on a combination of measurable or observable neural and physiological responses as well as actual overt behavior to make inferences about psychological states (see Figure 4.5.24.1). Using this approach, social neuroscientists have been able to pursue three different types of questions: (1) What more can we learn about social behavior when we consider neural and physiological responses? (2) What are the actual biological systems that implement social behavior (e.g., what specific brain areas are associated with specific social tasks)? and (3) How are biological systems impacted by social processes?

How Automatically Do We Judge Other People?

Social categorization is the act of mentally classifying someone as belonging in a group. Why do we do this? It is an effective mental shortcut. Rather than effortfully thinking about every detail of every person we encounter, social categorization allows us to rely on information we already know about the person's group. For example, by classifying your restaurant server as a man, you can quickly activate all the information you have stored about men and use it to guide your behavior. But this shortcut comes with potentially high costs. The stored group beliefs might not be very accurate, and even when they do accurately describe some group members, they are unlikely to be true for every member you encounter. In addition, many beliefs we associate with groups – called **stereotypes** – are negative. This means that relying on social categorization can often lead people to make negative assumptions about others.

The potential costs of social categorization make it important to understand how social categorization occurs. Is it rare or does it occur often? Is it something we can easily stop, or is it hard to override? One difficulty answering these questions is that people are not always consciously aware of what they are doing. In this case, we might not always realize when we are categorizing someone. Another concern is that even when people are aware of their behavior, they can be reluctant to accurately report it to an experimenter. In the case of social categorization, subjects might worry they will look bad if they accurately report classifying someone into a group associated with negative stereotypes. For instance, many racial groups are associated with some negative stereotypes, and subjects may worry that admitting to classifying someone into one of those groups means they believe and use those negative stereotypes.

Figure 4.5.24.2: This man is wearing an elastic electrode cap into which individual electrodes (inside the white circles) are sewn into standardized locations. [Image: Hans, CC0 Public Domain, goo.gl/m25gce]

Social neuroscience has been useful for studying how social categorization occurs without having to rely on self-report measures, instead measuring brain activity differences that occur when people encounter members of different social groups. Much of this work has been recorded using the **electroencephalogram**, or **EEG**. EEG is a measure of electrical activity generated by the brain's neurons. Comparing this electrical activity at a given point in time against what a person is thinking and doing at that same time allows us to make inferences about brain activity associated with specific psychological states. One particularly nice feature of EEG is that it provides very precise timing information about when brain activity occurs. EEG is measured non-invasively with small electrodes that rest on the surface of the scalp. This is often done with a stretchy elastic cap, like the one shown in Figure 4.5.24.2, into which the small electrodes are sewn. Researchers simply pull the cap onto the subject's head to get the electrodes into place; wearing it is similar to wearing a swim cap. The subject can then be asked to think about different topics or engage in different tasks as brain activity is measured.

To study social categorization, subjects have been shown pictures of people who belong to different social groups. Brain activity recorded from many individual trials (e.g., looking at lots of different Black individuals) is then averaged together to get an overall idea of how the brain responds when viewing individuals who belong to a particular social group. These studies suggest that social categorization is an **automatic process** – something that happens with little conscious awareness or control – especially for dimensions like gender, race, and age (Ito & Urland, 2003; Mouchetant-Rostaing & Giard, 2003). The studies specifically show that brain activity differs when subjects view members of different social groups (e.g., men versus women, Blacks versus Whites), suggesting that the group differences are being encoded and processed by the perceiver. One interesting finding is that these brain changes occur both when subjects are purposely asked to categorize the people into social groups (e.g., to judge whether the person is Black or White), and also when they are asked to do something that draws attention away from group classifications (e.g., making a personality judgment about the person) (Ito & Urland, 2005). This tells us that we do not have to intend to make group classifications in order for them to happen. It is also very interesting to consider how quickly the changes in brain responses occur. Brain activity is altered by viewing members of different groups within 200 milliseconds of seeing a person's face. That is just two-tenths of a second. Such a fast response lends further support to the idea that social categorization occurs automatically and may not depend on conscious intention.

Overall, this research suggests that we engage in social categorization very frequently. In fact, it appears to happen automatically (i.e., without us consciously intending for it to happen) in most situations for dimensions like gender, age, and race. Since classifying someone into a group is the first step to activating a group stereotype, this research provides important information about how easily stereotypes can be activated. And because it is hard for people to accurately report on things that happen so quickly, this issue has been difficult to study using more traditional self-report measures. Using EEGs has, therefore, been helpful in providing interesting new insights into social behavior.

Do We Use Our Own Behavior to Help Us Understand Others?

Classifying someone into a social group then activating the associated stereotype is one way to make inferences about others.

However, it is not the only method. Another strategy is to imagine what our own thoughts, feelings, and behaviors would be in a similar situation. Then we can use our simulated reaction as a best guess about how someone else will respond (Goldman, 2005). After all, we are experts in our own feelings, thoughts, and tendencies. It might be hard to know what other people are feeling and thinking, but we can always ask ourselves how we would feel and act if we were in their shoes.

There has been some debate about whether simulation should/could be used to get into the mind of others or is an effective way to get into the minds of others (Carruthers & Smith, 1996; Gallese & Goldman, 1998). Social neuroscience research has addressed this question by looking at the brain areas used when people think about themselves and others. If the same brain areas are active for the two types of judgments, it lends support to the idea that the self may be used to make inferences about others via simulation.

We know that an area in the prefrontal cortex called the **medial prefrontal cortex** (mPFC) – located in the middle of the frontal lobe – is active when people think about themselves (Kelley, Macrae, Wyland, Caglar, Inati, & Heatherton, 2002). This conclusion comes from studies using **functional magnetic resonance imaging**, or fMRI. While EEG measures the brain's electrical activity, fMRI measures changes in the oxygenation of blood flowing in the brain. Remember as discussed in chapter 2, when neurons become more active, blood flow to the area increases to bring more oxygen and glucose to the active cells. fMRI allows us to image these changes in oxygenation by placing people in an fMRI machine or scanner (Figure 4.5.24.3), which consists of large magnets that create strong magnetic fields. The magnets affect the alignment of the oxygen molecules within the blood (i.e., how they are tilted). As the oxygen molecules move in and out of alignment with the magnetic fields, their nuclei produce energy that can be detected with special sensors placed close to the head. Recording fMRI involves having the subject lay on a small bed that is then rolled into the scanner. While fMRI does require subjects to lie still within the small scanner and the large magnets involved are noisy, the scanning itself is safe and painless. Like EEG, the subject can then be asked to think about different topics or engage in different tasks as brain activity is measured. If we know what a person is thinking or doing when fMRI detects a blood flow increase to a particular brain area, we can infer that part of the brain is involved with the thought or action. fMRI is particularly useful for identifying which particular brain areas are active at a given point in time.

Figure 4.5.24.3: Functional magnetic resonance imaging (fMRI) scanner used to image the brain while people perform tasks. The scanner allows researchers to view the changes in blood oxygenation in specific locations in the brain during a task. Images are collected using powerful magnets and radio waves that shift the position of atoms in oxygenated blood that rushes to areas involved in performing the task. MRIs are non-invasive and there are no known risks from exposure to the magnetic fields or radio waves. Subjects lay on the while bed with their head inside the head coil, then the bed is moved into the scanner. [Image: Janne Moren, https://goo.gl/MKb2jn, CC BY-NC-SA 2.0, goo.gl/Toc0ZF]

The conclusion that the mPFC is associated with the self comes from studies measuring fMRI while subjects think about themselves (e.g., saying whether traits are descriptive of themselves). Using this knowledge, other researchers have looked at whether the same brain area is active when people make inferences about others. Mitchell, Neil Macrae, and Banaji (2005) showed subjects pictures of strangers and had them judge either how pleased the person was to have his or her picture taken or how symmetrical the face appeared. Judging whether someone is pleased about being photographed requires making an inference about someone's internal feelings – we call this **mentalizing**. By contrast, facial symmetry judgments are based solely on physical appearances and do not involve mentalizing. A comparison of brain activity during the two types of judgments shows more activity in the mPFC when making the mental versus physical judgments, suggesting this brain area is involved when

inferring the internal beliefs of others.

There are two other notable aspects of this study. First, mentalizing about others also increased activity in a variety of regions important for many aspects of social processing, including a region important in representing biological motion (**superior temporal sulcus** or STS), an area critical for emotional processing (amygdala), and a region also involved in thinking about the beliefs of others (**temporal parietal junction**, TPJ) (Gobbini & Haxby, 2007; Schultz, Imamizu, Kawato, & Frith, 2004) (See Figure 4.5.24.4). This finding shows that a distributed and interacting set of brain areas is likely to be involved in social processing. Second, activity in the most ventral part of the mPFC (the part closer to the belly rather than toward the top of the head), which has been most consistently associated with thinking about the self, was particularly active when subjects mentalized about people they rated as similar to themselves. Simulation is thought to be most likely for similar others (as in other people who one assumes to be similar to oneself), so this finding lends support to the conclusion that we use simulation to mentalize about others. After all, if you encounter someone who has the same musical taste as you, you will probably assume you have other things in common with him. By contrast, if you learn that someone loves music that you hate, you might expect him to differ from you in other ways (Srivastava, Guglielmo, & Beer, 2010). Using a simulation of our own feelings and thoughts will be most accurate if we have reason to think the person's internal experiences are like our own. Thus, we may be most likely to use simulation to make inferences about others if we think they are similar to us.

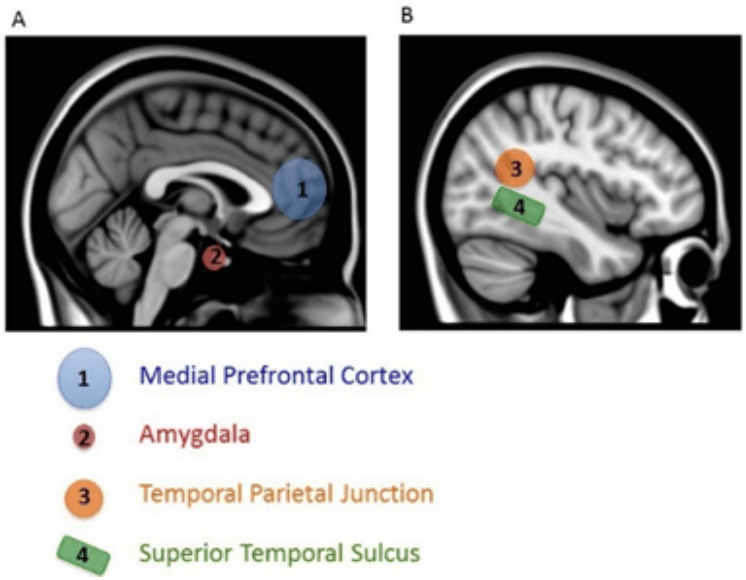

Figure 4.5.24.4: The areas of the brain most commonly associated with processing of self and others. Panel A is a medial sagittal view, Panel B is a lateral sagittal view. The medial prefrontal cortex (mPFC) (Structure 1) is commonly activated when thinking about one's self and when thinking about similar others. Additionally, the amygdala (Structure 2) is important for learning about and detecting important things in our environments and plays an important role in fear learning and expression. The temporal parietal junction (TPJ) (Structure 3), located at the intersection of the parietal and temporal lobes, is activated when people think about the beliefs of others. Activity in the superior temporal sulcus (STS) (Structure 4) is commonly observed when people view biological motion. The common activation of this network of regions when people think about the feelings, thoughts, and intentions of others indicates that the processing of others involves a number of complex psychological processes.

This research is a good example of how social neuroscience is revealing the **functional neuroanatomy** of social behavior. That is, it tells us which brain areas are involved with social behavior. The mPFC (as well as other areas such as the STS, amygdala, and TPJ) is involved in making judgments about the self and others. This research also provides new information about how inferences are made about others. Whereas some have doubted the widespread use of simulation as a means for making inferences about others, the activation of the mPFC when mentalizing about others, and the sensitivity of this activation to similarity between self and other, provides evidence that simulation occurs.

What Is the Cost of Social Stress?

Stress is an unfortunately frequent experience for many of us. **Stress** – which can be broadly defined as a threat or challenge to our well-being – can result from everyday events like a course exam or more extreme events such as experiencing a natural disaster. When faced with a stressor, **sympathetic nervous system** activity increases in order to prepare our body to respond to the challenge. This produces what Selye (1950) called a **fight or flight response**. The release of **hormones**, which act as

messengers from one part of an organism (e.g., a cell or gland) to another part of the organism, is part of the stress response. This is further discussed in the next section.

A small amount of stress can actually help us stay alert and active. In comparison, sustained stressors, or chronic stress, detrimentally affect our health and impair performance (Al'Absi, Hugdahl, & Lovallo, 2002; Black, 2002; Lazarus, 1974). This happens in part through the chronic secretion of stress-related hormones (e.g., Davidson, Pizzagalli, Nitschke, & Putnam, 2002; Dickerson, Gable, Irwin, Aziz, & Kemeny, 2009). In particular, stress activates the **hypothalamic-pituitary-adrenal (HPA) axis** to release **cortisol** (see Figure 4.5.24.5). Chronic stress, by way of increases in cortisol, impairs attention, memory, and self-control (Arnsten, 2009). Cortisol levels can be measured non-invasively in bodily fluids, including blood and saliva. Researchers often collect a cortisol sample before and after a potentially stressful task. In one common collection method, subjects place polymer swabs under their tongue for 1 to 2 minutes to soak up saliva. The saliva samples are then stored and analyzed later to determine the level of cortisol present at each time point.

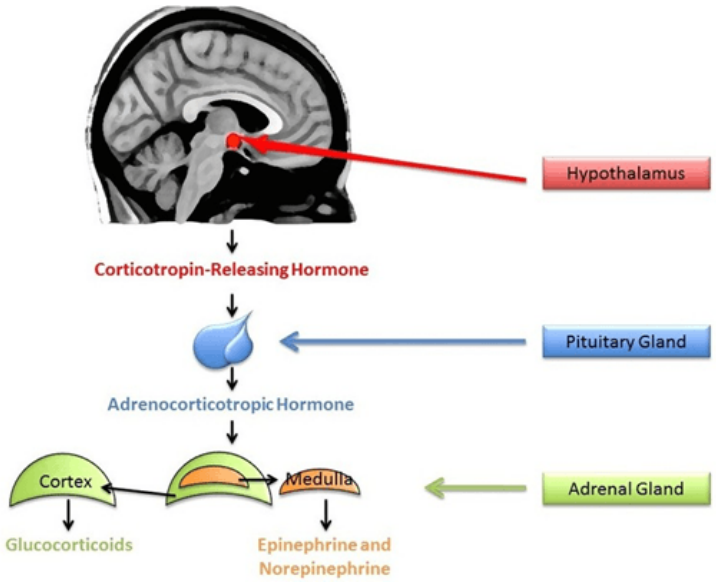

Figure 4.5.24.5: The Hypothalamic-pituitary-adrenal (HPA) axis. Black arrows represent the stress response pathway starting in the brain at the hypothalamus (an area within the brain). Stress triggers neurons in the hypothalamus to release corticotrophin-releasing hormone (CRH). The CRH is transported to the pituitary gland, another area in the brain, that activates the secretion of andrenocorticotropic hormone (ACTH). In turn, ACTH stimulates the adrenal glands that sit on top of the kidneys. The adrenal glands are composed of the outer adrenal cortex and inner adrenal medulla. The adrenal cortex secretes glucorcorticoids (including cortisol) and the medulla secretes epinephrine and norepinephrine. Stress, both psychological and physical, activates the HPA axis and results in the systemic release of cortisol, epinephrine, and norepinephrine.

Whereas early stress researchers studied the effects of physical stressors like loud noises, social neuroscientists have been instrumental in studying how our interactions with other people can cause stress. This question has been addressed through **neuroendocrinology**, or the study of how the brain and hormones act in concert to coordinate the physiology of the body. One contribution of this work has been in understanding the conditions under which other people can cause stress. In one study, Dickerson, Mycek, and Zaldivar (2008) asked undergraduates to deliver a speech either alone or to two other people. When the students gave the speech in front of others, there was a marked increase in cortisol compared with when they were asked to give a speech alone. This suggests that like chronic physical stress, everyday social stressors, like having your performance judged by others, induces a stress response. Interestingly, simply giving a speech in the same room with someone who is doing something else did not induce a stress response. This suggests that the mere presence of others is not stressful, but rather it is the potential for them to judge us that induces stress.

Worrying about what other people think of us is not the only source of social stress in our lives. Other research has shown that interacting with people who belong to different social groups than us – what social psychologists call **outgroup** members – can increase physiological stress responses. For example, cardiovascular responses associated with stress like contractility of the heart ventricles and the amount of blood pumped by the heart (what is called cardiac output) are increased when interacting with outgroup as compared with **ingroup** members (i.e., people who belong to the same social group we do) (Mendes, Blascovich, Likel, & Hunter, 2002). This stress may derive from the expectation that interactions with dissimilar others will be uncomfortable (Stephan & Stephan, 1985) or concern about being judged as unfriendly and prejudiced if the interaction goes poorly (Plant & Devine, 2003).

The research just reviewed shows that events in our social lives can be stressful, but are social interactions always bad for us? No. In fact, while others can be the source of much stress, they are also a major buffer against stress. Research on **social support** shows that relying on a network of individuals in tough times gives us tools for dealing with stress and can ward off loneliness (Cacioppo & Patrick, 2008). For instance, people who report greater social support show a smaller increase in cortisol when performing a speech in front of two evaluators (Eisenberger, Taylor, Gable, Hilmert, & Lieberman, 2007).

What determines whether others will increase or decrease stress? What matters is the context of the social interaction. When it has potential to reflect badly on the self, social interaction can be stressful, but when it provides support and comfort, social interaction can protect us from the negative effects of stress. Using neuroendocrinology by measuring hormonal changes in the body has helped researchers better understand how social factors impact our body and ultimately our health.

Conclusions

Human beings are intensely social creatures – our lives are intertwined with other people and our health and well-being depend on others. Social neuroscience helps us to understand the critical function of how we make sense of and interact with other people. This module provides an introduction to what social neuroscience is and what we have already learned from it, but there is much still to understand. As we move forward, one exciting future direction will be to better understand how different parts of the brain and body interact to produce the numerous and complex patterns of social behavior that humans display. We hinted at some of this complexity when we reviewed research showing that while the mPFC is involved in mentalizing, other areas such as the STS, amygdala, and TPJ are as well. There are likely additional brain areas involved as well, interacting in ways we do not yet fully understand. These brain areas in turn control other aspects of the body to coordinate our responses during social interactions. Social neuroscience will continue to investigate these questions, revealing new information about how social processes occur, while also increasing our understanding of basic neural and physiological processes.

4.5.25: Stress and health

Learning Objectives

- Describe basic terminology used in the field of health psychology.
- Explain theoretical models of health, as well as the role of psychological stress in the development of disease.
- Describe psychological factors that contribute to resilience and improved health.
- Defend the relevance and importance of psychology to the field of medicine.

Overview

Our emotions, thoughts, and behaviors play an important role in our health. Not only do they influence our day-to-day health practices, but they can also influence how our body functions. Clearly, there is a connection between stress and health - both physical and mental. This section provides an overview of health psychology, which is a field devoted to understanding the connections between psychology and health. Discussed here are examples of topics a health psychologist might study, including stress, psychosocial factors related to health and disease, how to use psychology to improve health, and the role of psychology in medicine.

What Is Health Psychology?

Today, we face more **chronic disease** than ever before because we are living longer lives while also frequently behaving in unhealthy ways. One example of a chronic disease is coronary heart disease (CHD): It is the number one cause of death worldwide (World Health Organization, 2013). CHD develops slowly over time and typically appears midlife, but related heart problems can persist for years after the original diagnosis or cardiovascular event. In managing illnesses that persist over time (other examples might include cancer, diabetes, and long-term disability) many psychological factors will determine the progression of the ailment. For example, do patients seek help when appropriate? Do they follow doctor recommendations? Do they develop negative psychological symptoms due to lasting illness (e.g., depression)? Also important is that psychological factors can play a significant role in *who* develops these diseases, the prognosis, and the nature of the symptoms related to the illness. Health psychology is a relatively new, interdisciplinary field of study that focuses on these very issues, or more specifically, the role of psychology in maintaining health, as well as preventing and treating illness.

Figure 4.5.25.1: Health psychologists are helping people to adapt behaviors to avoid disease, reduce stress, and improve overall health. [Image: Adelphi Lab Center, https://goo.gl/N9wXon, CC BY 2.0, goo.gl/BRvSA7]

Consideration of how psychological and social factors influence health is especially important today because many of the leading causes of illness in developed countries are often attributed to psychological and behavioral factors. In the case of CHD, discussed above, psychosocial factors, such as excessive stress, smoking, unhealthy eating habits, and some personality traits can also lead to increased risk of disease and worse health outcomes. That being said, many of these factors can be adjusted using psychological techniques. For example, clinical health psychologists can improve health practices like poor dietary choices and smoking, they can teach important stress reduction techniques, and they can help treat psychological disorders tied to poor health. Health psychology considers how the choices we make, the behaviors we engage in, and even the emotions that we feel, can play an important role in our overall health (Cohen & Herbert, 1996; Taylor, 2012).

Health psychology relies on the **Biopsychosocial Model of Health**. This model posits that biology, psychology, and social factors are just as important in the development of disease as biological causes (e.g., germs, viruses), which is consistent with the World Health Organization (1946) definition of **health**. This model replaces the older **Biomedical Model of Health**, which primarily considers the physical, or pathogenic, factors contributing to illness. Thanks to advances in medical technology, there is a growing understanding of the physiology underlying the **mind–body connection**, and in particular, the role that different feelings can have on our body's function (See Figure 4.5.25.1) . Health psychology researchers working in the fields of **psychosomatic medicine** and **psychoneuroimmunology**, for example, are interested in understanding how psychological factors can "get under the skin" and influence our physiology in order to better understand how factors like stress can make us sick.

What Is stress?

It is clear that stress plays a major role in our mental and physical health, but what exactly is it? The term **stress** was originally derived from the field of mechanics where it is used to describe materials under pressure. The word was first used in a *psychological* manner by researcher Hans Selye. He was examining the effect of an ovarian hormone that he thought caused sickness in a sample of rats. Surprisingly, he noticed that almost any injected hormone produced this same sickness. He smartly realized that it was not the hormone under investigation that was causing these problems, but instead, the unpleasant experience of being handled and injected by researchers that led to high physiological arousal and, eventually, to health problems like ulcers. Selye (1946) coined the term "stressor" to label a stimulus that had this effect on the body and developed a model of the stress response called the **General Adaptation Syndrome**. Since then, psychologists have studied stress in a myriad of ways, including stress as caused by negative events (e.g., natural disasters or major life changes like dropping out of school), as caused by chronically difficult situations (e.g., taking care of a loved one with Alzheimer's), as caused by short-term hassles, as a biological fight-or-flight response, and even as clinical illness like post-traumatic stress disorder (PTSD). It continues to be one of the most important and well-studied psychological correlates of illness, because excessive stress causes potentially damaging wear and tear on the body and can influence almost any imaginable disease process.

Stress and Health

You probably know exactly what it's like to feel stress, but what you may not know is that it can objectively influence your health. Answers to questions like, "How stressed do you feel?" or "How overwhelmed do you feel?" can predict your likelihood of developing both minor illnesses as well as serious problems like future heart attack (Cohen, Janicki-Deverts, & Miller, 2007). To understand how health psychologists study these types of associations, we will describe one famous example of a stress and health study. Imagine that you are a research subject for a moment. After you check into a hotel room as part of the study, the researchers ask you to report your general levels of stress. Not too surprising; however, what happens next is that you receive droplets of *cold virus* into your nose! The researchers intentionally try to make you sick by exposing you to an infectious illness. After they expose you to the virus, the researchers will then evaluate you for several days by asking you questions about your symptoms, monitoring how much mucus you are producing by weighing your used tissues, and taking body fluid samples—all to see if you are objectively ill with a cold. Now, the interesting thing is that not everyone who has drops of cold virus put in their nose develops the illness. (Clearly this study was done long before COVID-19 because I can't see people checking into a hotel, or being intentionally exposed to a virus - even the common cold one - after the pandemic!) Studies like this one find that people who are less stressed and those who are more positive at the beginning of the study are at a decreased risk of developing a cold (Cohen, Tyrrell, & Smith, 1991; Cohen, Alper, Doyle, Treanor, & Turner, 2006) (see Figure 4.5.25.2 for an example).

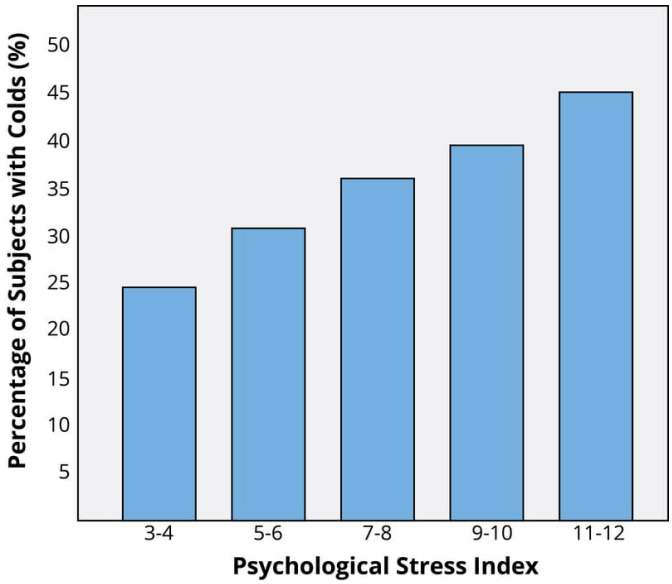

Figure 4.5.25.2: Adapted from Cohen et al. 1991. This graph indicates that the greater the psychological stress index, the greater the percent of subjects with colds. In fact, there is a 25% increase in percentage of subjects with a cold from those who report a psychological stress index of 3-4 versus those reporting a psychological stress index of 11-12.

Importantly, it is not just major life **stressors** (e.g., a family death, a natural disaster) that increase the likelihood of getting sick. Even small **daily hassles** like getting stuck in traffic or fighting with your girlfriend/boyfriend or partner can raise your blood pressure, alter your stress hormones, and even suppress your immune system function (DeLongis, Folkman, & Lazarus, 1988; Twisk, Snel, Kemper, & van Machelen, 1999).

Immune System

The immune system is a host defense system. It comprises many biological structures —ranging from individual white blood cells to entire organs — as well as many complex biological processes. The function of the immune system is to protect the host from pathogens (something that causes a disease) and other causes of disease such as tumor cells. To function properly, the immune system must be able to detect a wide variety of pathogens. It also must be able to distinguish the cells of pathogens from the host's own cells and also to distinguish cancerous or damaged host cells from healthy cells. In humans and most other vertebrates, the immune system consists of layered defenses that have increased specificity for particular pathogens or tumor cells. The layered defenses of the human immune system are usually classified into two subsystems called the innate immune system and the adaptive immune system.

Innate Immune System

Any discussion of the innate immune response usually begins with the physical barriers that prevent pathogens (which are bacteria, viruses or other microorganisms that case diseases) from entering the body, destroy them after they enter, or flush them out before they can establish themselves in the hospitable environment of the body's soft tissues. Barrier defenses are part of the body's most basic defense mechanisms. The barrier defenses are not a response to infections, but they are continuously working to protect against a broad range of pathogens.

The phagocytes are the body's fast acting first line of immunological defense against organisms that have breached barrier defenses and have entered the vulnerable tissues of the body. For example, certain leukocytes (white blood cells) engulf and destroy pathogens they encounter in the process called phagocytosis. The body's response against a pathogen's breach is also called inflammation. Inflammation is discussed in detail again a few paragraphs later.

Adaptive Immune System

The adaptive immune system is activated if pathogens successfully enter the body and manage to evade the general defenses of the innate immune system. An adaptive response is specific to the particular type of pathogen that has invaded the body or to cancerous cells. It takes longer to launch a specific attack, but once it is underway, its specificity makes it very effective. An

adaptive immune response is set in motion by antigens that the immune system recognizes as foreign. Unlike an innate immune response, an adaptive immune response is highly specific to a particular pathogen (or its antigen).

An important function of the adaptive immune system that is not shared by the innate immune system is the creation of immunological memory or immunity. This occurs after the initial response to a specific pathogen. It allows a faster, stronger response on subsequent encounters with the same pathogen, usually before the pathogen can cause symptoms of illness. An adaptive response also usually leads to immunity. This is a state of resistance to a specific pathogen due to the ability of the adaptive immune system to “remember” the pathogen and immediately mount a strong attack tailored to that particular pathogen if it invades again in the future.

Lymphatic System

The lymphatic system is a human organ system that is a vital part of the adaptive immune system. It is also part of the cardiovascular system and plays a major role in the digestive system

The primary function of the lymphatic system is to host defense as part of the immune system. This function of the lymphatic system is centered on the production, maturation, and circulation of lymphocytes. Lymphocytes are leukocytes that are involved in the adaptive immune system. They are responsible for the recognition of, and tailored defense against, specific pathogens or tumor cells. Lymphocytes may also create a lasting memory of pathogens so they can be attacked quickly and strongly if they ever invade the body again. In this way, lymphocytes bring about long-lasting immunity to specific pathogens.

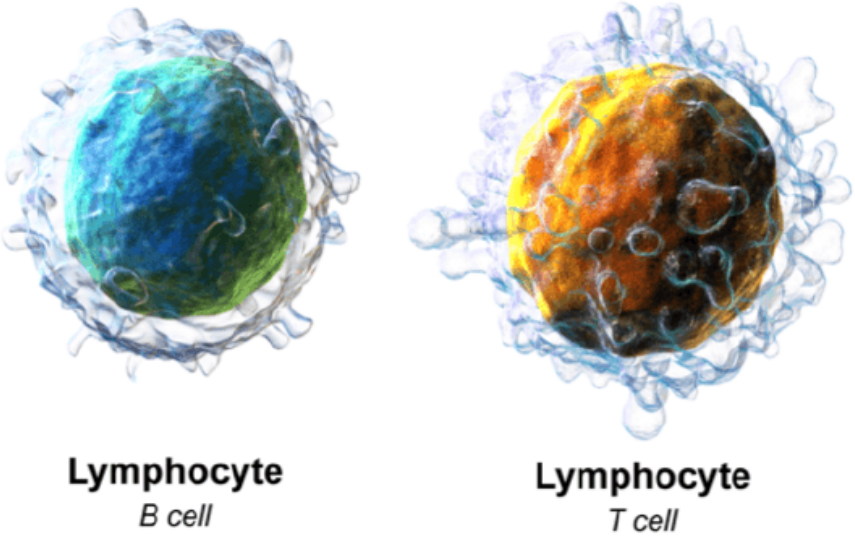

Figure 4.5.25.3: These are Lymphocytes - B nd T cells - Notice the large nucleus in the center of these relatively round cells.

.

Lymphocytes are leukocytes that arise and mature in organs of the lymphatic system, including the bone marrow and thymus. There are two main types of lymphocytes involved in adaptive immune responses, called T cells and B cells which are illustrated in Figure 4.5.25.3. Both B cells and T cells are involved in the adaptive immune response, but they play different roles. T cells destroy infected cells or release chemicals that regulate immune responses. B cells secrete antibodies that bind with antigens of pathogens so they can be removed by other immune cells or processes.

T Cells

There are multiple types of T cells or T lymphocytes. Major types are killer (or cytotoxic) T cells and helper T cells. Both types develop from immature T cells that become activated by exposure to an antigen. T cells must be activated. After the pathogen is phagocytized and digested by macrophages, a part of the pathogen is displayed on the surface of the macrophage. Helper T cells are more easily activated than killer T cells. Activation of killer T cells is strongly regulated and may require additional stimulation from helper T cells.

B Cells and B Cell Activation

B cells, or B lymphocytes, are the major cells involved in the creation of antibodies that circulate in blood plasma and lymph. Antibodies are large, Y-shaped proteins used by the immune system to identify and neutralize foreign invaders. Besides producing antibodies, B cells may also function as antigen-presenting cells or secrete cytokines that help control other immune cells and responses.

Self vs. Non-Self

Both innate and adaptive immune responses depend on the ability of the immune system to distinguish between self and non-self molecules. Self molecules are those components of an organism's body that can be distinguished from foreign substances by the immune system.

Antigens and Antibodies

Many non-self molecules comprise a class of compounds called antigens. Antigens, which are usually proteins, bind to specific receptors on immune system cells and elicit an adaptive immune response. Some adaptive immune system cells (B cells) respond to foreign antigens by producing antibodies. An antibody is a molecule that precisely matches and binds to a specific antigen. This may target the antigen (and the pathogen displaying it) for destruction by other immune cells.

Antigens on the surface of pathogens are how the adaptive immune system recognizes specific pathogens. Antigen specificity allows for the generation of responses tailored to the specific pathogen. It is also how the adaptive immune system "remembers" the same pathogen in the future.

Immune Surveillance

Another important role of the immune system is to identify and eliminate tumor cells. This is called immune surveillance. The transformed cells of tumors express antigens that are not found on normal body cells. The main response of the immune system to tumor cells is to destroy them. This is carried out primarily by aptly named killer T cells of the adaptive immune system.

Inflammation and Fever

The inflammatory response, or inflammation, is triggered by a cascade of chemical mediators and cellular responses that may occur when cells are damaged and stressed or when pathogens successfully breach the physical barriers of the innate immune system. Although inflammation is typically associated with negative consequences of injury or disease, it is a necessary process insofar as it allows for recruitment of the cellular defenses needed to eliminate pathogens, remove damaged and dead cells, and initiate repair mechanisms. Excessive inflammation, however, can result in local tissue damage and, in severe cases, may even become deadly.

A fever is an inflammatory response that extends beyond the site of infection and affects the entire body, resulting in an overall increase in body temperature. Body temperature is normally regulated and maintained by the hypothalamus, an anatomical section of the brain that functions to maintain homeostasis in the body. However, certain bacterial or viral infections can result in the production of pyrogens, chemicals that effectively alter the "thermostat setting" of the hypothalamus to elevate body temperature and cause fever. Pyrogens may be exogenous or endogenous. For example, the endotoxin lipopolysaccharide (LPS), produced by gram-negative bacteria, is an exogenous pyrogen that may induce the leukocytes to release endogenous pyrogens such as interleukin-1 (IL-1), IL-6, interferon-γ (IFN-γ), and tumor necrosis factor (TNF). In a cascading effect, these molecules can then lead to the release of prostaglandin E2 (PGE_2) from other cells, resetting the hypothalamus to initiate fever (Figure $4.5.25.4$:).

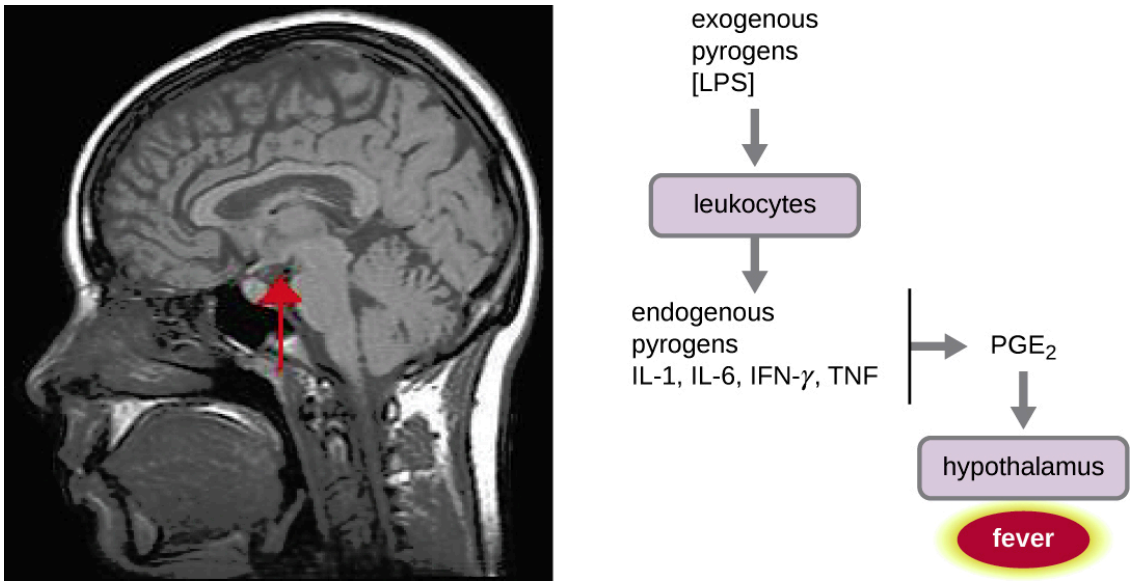

Figure 4.5.25.4:Macrophages recognize pathogens in an area and release cytokines that trigger inflammation. The cytokines also send a signal up the vagus nerve to the hypothalamus.

Inflammation and Fever by Openstax, licensed CC BY 4.0

Like other forms of inflammation, a fever enhances the innate immune defenses by stimulating leukocytes to kill pathogens. The rise in body temperature also may inhibit the growth of many pathogens since human pathogens are mesophiles with optimum growth occurring around 35 °C (95 °F). In addition, some studies suggest that fever may also stimulate release of iron-sequestering compounds from the liver, thereby starving out microbes that rely on iron for growth.

During fever, the skin may appear pale due to vasoconstriction of the blood vessels in the skin, which is mediated by the hypothalamus to divert blood flow away from extremities, minimizing the loss of heat and raising the core temperature. The hypothalamus will also stimulate shivering of muscles, another effective mechanism of generating heat and raising the core temperature.

The crisis phase occurs when the fever breaks. The hypothalamus stimulates vasodilation, resulting in a return of blood flow to the skin and a subsequent release of heat from the body. The hypothalamus also stimulates sweating, which cools the skin as the sweat evaporates.

Although a low-level fever may help an individual overcome an illness, in some instances, this immune response can be too strong, causing tissue and organ damage and, in severe cases, even death. The inflammatory response to bacterial superantigens is one scenario in which a life-threatening fever may develop. Superantigens are bacterial or viral proteins that can cause an excessive activation of T cells from the specific adaptive immune defense, as well as an excessive release of cytokines that overstimulates the inflammatory response. For example, *Staphylococcus aureus* and *Streptococcus pyogenes* are capable of producing superantigens that cause toxic shock syndrome and scarlet fever, respectively. Both of these conditions can be associated with very high, life-threatening fevers in excess of 42 °C (108 °F).

Stress and Immune Function

It is widely believed that stress suppresses immune function and increases susceptibility to infections and cancer. Paradoxically, stress is also known to exacerbate allergic, autoimmune, and inflammatory diseases. These observations suggest that stress may have bidirectional effects on immune function, being immunosuppressive (deterring the immune system) in some instances and immunoenhancing (enhancing the immune system) in others. It has recently been shown that in contrast to chronic stress that suppresses or dysregulates immune function, acute stress can be immunoenhancing. Acute stress enhances dendritic cell, neutrophil, macrophage, and lymphocyte trafficking, maturation, and function and has been shown to augment innate and adaptive immune responses. Acute stress experienced prior to novel antigen exposure enhances innate immunity and memory T-cell formation and results in a significant and long-lasting immunoenhancement. Acute stress experienced during antigen reexposure enhances secondary/adaptive immune responses. Therefore, depending on the conditions of immune activation and

the immunizing antigen, acute stress may enhance the acquisition and expression of immunoprotection or immunopathology. In contrast, chronic stress dysregulates innate and adaptive immune responses by changing the type 1-type 2 cytokine balance and suppresses immunity by decreasing leukocyte numbers, trafficking, and function. Chronic stress also increases susceptibility to skin cancer by suppressing type 1 cytokines and protective T cells while increasing suppressor T-cell function. The adaptive purpose of a physiological stress response may be to promote survival, with stress hormones and neurotransmitters serving as beacons that prepare the immune system for potential challenges (eg, wounding or infection) perceived by the brain (eg, detection of an attacker). However, this system may exacerbate immunopathology (diseases/malfunction of the immune system) if the enhanced immune response is directed against innocuous or self-antigens or dysregulated following prolonged activation, as seen during chronic stress (see Figure 4.5.25.5). In view of the ubiquitous nature of stress and its significant effects on immunoprotection and immunopathology, it is important to further elucidate the mechanisms mediating stress-immune interactions and to meaningfully translate findings from laboratory bench to hospital bedside.

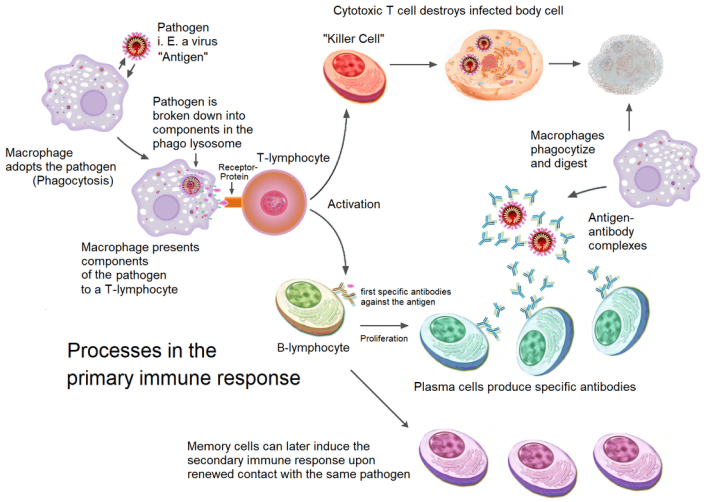

Figure 4.5.25.5: Macrophages break down a pathogen (virus) and present the components to a T-cell which activates killer cells that destroy the infected body cell, and flag the antigens, and also trigger B cells which create antibodies for those antigens as well as memory cells for future reference. (Copyright;Processes in the primary immune response by: Sciencia58 an the makers of the single images Domdomegg, [1], Fæ, Petr94, Manu5, CC BY-SA 4.0, via Wikimedia Commons)

An important function of physiological mediators released under conditions of acute psychological stress may be to ensure that appropriate leukocytes are present in the right place and at the right time to respond to an immune challenge that might be initiated by the stress-inducing agent (eg, attack by a predator, invasion by a pathogen, etc.). The modulation of immune cell distribution by acute stress may be an adaptive response designed to enhance surveillance and increase the capacity of the immune system to respond to challenge in compartments (such as the skin, lung, gastrointestinal and urinary-genital tracts, mucosal surfaces, and lymph nodes), which serve as defense barriers for the body. Thus, neurotransmitters and hormones released during stress may increase immunosurveillance and help enhance immune preparedness for potential (or ongoing) immune challenge. Stress-induced immunoenhancement may increase immunoprotection during surgery, vaccination, or infection but may also exacerbate immunopathology during inflammatory (asthma, allergy, dermatitis, cardiovascular disease, gingivitis) or autoimmune (psoriasis, arthritis, multiple sclerosis) diseases that are known to be exacerbated by stress (Amkraut et al, 1971; Ackerman, 2002; Al'Abadie et al, 1994; Garg, 2001; Wright et al, 1998; Wright, 2001).

Protecting Our Health

An important question that health psychologists ask is: What keeps us protected from disease and alive longer? When considering this issue of **resilience** (Rutter, 1985), five factors are often studied in terms of their ability to protect (or sometimes harm) health. They are:

1. Coping
2. Control and Self-Efficacy
3. Social Relationships
4. Dispositions and Emotions

Coping Strategies

How individuals cope with the stressors they face can have a significant impact on health. Coping is often classified into two categories: problem-focused coping or emotion-focused coping (Carver, Scheier, & Weintraub, 1989). **Problem-focused coping** is thought of as actively addressing the event that is causing stress in an effort to solve the issue at hand. For example, say you have an important exam coming up next week. A problem-focused strategy might be to spend additional time over the weekend studying to make sure you understand all of the material. **Emotion-focused coping**, on the other hand, regulates the emotions that come with stress. In the above examination example, this might mean watching a funny movie to take your mind off the anxiety you are feeling. In the short term, emotion-focused coping might reduce feelings of stress, but problem-focused coping seems to have the greatest impact on mental wellness (Billings & Moos, 1981; Herman-Stabl, Stemmler, & Petersen, 1995). That being said, when events are uncontrollable (e.g., the death of a loved one), emotion-focused coping directed at managing your feelings, at first, might be the better strategy. Therefore, it is always important to consider the match of the stressor to the coping strategy when evaluating its plausible benefits.

Control and Self-Efficacy

Figure 4.5.25.6: Feeling a sense of control in one's life is important. Something as simple as having control over the care of a houseplant has been shown to improve health and longevity. [Image: JJ Harrison, https://goo.gl/82FsdV, CC BY-SA 2.5, goo.gl/SRAIwa]

Another factor tied to better health outcomes and an improved ability to cope with stress is having the belief that you have **control** over a situation. For example, in one study where participants were forced to listen to unpleasant (stressful) noise, those who were led to believe that they had control over the noise performed much better on proofreading tasks afterwards (Glass & Singer, 1972). In other words, even though participants *did not* have actual control over the noise, the control *belief* aided them in completing the task. In similar studies, perceived control benefited immune system functioning (Sieber et al., 1992) (See Figure 4.5.25.6)Outside of the laboratory, studies have shown that older residents in assisted living facilities, which are notorious for low control, lived *longer* and showed *better* health outcomes when given control over something as simple as watering a plant or choosing when student volunteers came to visit (Rodin & Langer, 1977; Schulz & Hanusa, 1978). In addition, feeling in control of a threatening situation can actually change stress hormone levels (Dickerson & Kemeny, 2004). Believing that you have control over your own behaviors can also have a positive influence on important outcomes like smoking cessation, contraception use, and weight management (Wallston & Wallston, 1978). When individuals do not believe they have control, they do not try to change. **Self-efficacy** is closely related to control, in that people with high levels of this trait believe they can complete tasks and reach their goals. Just as feeling in control can reduce stress and improve health, higher self-efficacy can reduce stress and negative **health behaviors**, and is associated with better health (O'Leary, 1985).

Social Relationships

Research has shown that the impact of social isolation on our risk for disease and death is similar in magnitude to the risk associated with smoking regularly (Holt-Lunstad, Smith, & Layton, 2010; House, Landis, & Umberson, 1988). In fact, the importance of social relationships for our health is so significant that some scientists believe our body has developed a physiological system that encourages us to seek out our relationships, especially in times of stress (Taylor et al., 2000). **Social integration** is the concept used to describe the number of social roles that you have (Cohen & Wills, 1985), as well as the lack of isolation. For example, you might be a daughter, a basketball team member, a Humane Society volunteer, a coworker, and a student. Maintaining these different roles can improve your health via encouragement from those around you to maintain a healthy lifestyle. Those in your social network might also provide you with **social support** (e.g., when you are under stress). This support might include emotional help (e.g., a hug when you need it), tangible help (e.g., lending you money), or advice. By helping to improve health behaviors and reduce stress, social relationships can have a powerful, protective impact on health, and in some cases, might even help people with serious illnesses stay alive longer (Spiegel, Kraemer, Bloom, & Gottheil, 1989).

Dispositions and Emotions: What's Risky and What's Protective?

Negative dispositions and personality traits have been strongly tied to an array of health risks. One of the earliest negative trait-to-health connections was discovered in the 1950s by two cardiologists. They made the interesting discovery that there were common behavioral and psychological patterns among their heart patients that were not present in other patient samples. This pattern included being competitive, impatient, hostile, and time urgent. They labeled it **Type A Behavior**. Importantly, it was found to be associated with *double* the risk of heart disease as compared with **Type B Behavior** (Friedman & Rosenman, 1959). Since the 1950s, researchers have discovered that it is the **hostility** and competitiveness components of Type A that are especially harmful to heart health (Iribarren et al., 2000; Matthews, Glass, Rosenman, & Bortner, 1977; Miller, Smith, Turner, Guijarro, & Hallet, 1996). Hostile individuals are quick to get upset, and this angry arousal can damage the arteries of the heart. In addition, given their negative personality style, hostile people often lack a heath-protective supportive social network.

Positive traits and states, on the other hand, are often health protective. For example, characteristics like positive emotions (e.g., feeling happy or excited) have been tied to a wide range of benefits such as increased longevity, a reduced likelihood of developing some illnesses, and better outcomes once you are diagnosed with certain diseases (e.g., heart disease, HIV) (Pressman & Cohen, 2005). Across the world, even in the most poor and underdeveloped nations, positive emotions are consistently tied to better health (Pressman, Gallagher, & Lopez, 2013). Positive emotions can also serve as the "antidote" to stress, protecting us against some of its damaging effects (Fredrickson, 2001; Pressman & Cohen, 2005; see Figure 4.5.25.7:). Similarly, looking on the bright side can also improve health. Optimism has been shown to improve coping, reduce stress, and predict better disease outcomes like recovering from a heart attack more rapidly (Kubzansky, Sparrow, Vokonas, & Kawachi, 2001; Nes & Segerstrom, 2006; Scheier & Carver, 1985; Segerstrom, Taylor, Kemeny, & Fahey, 1998).

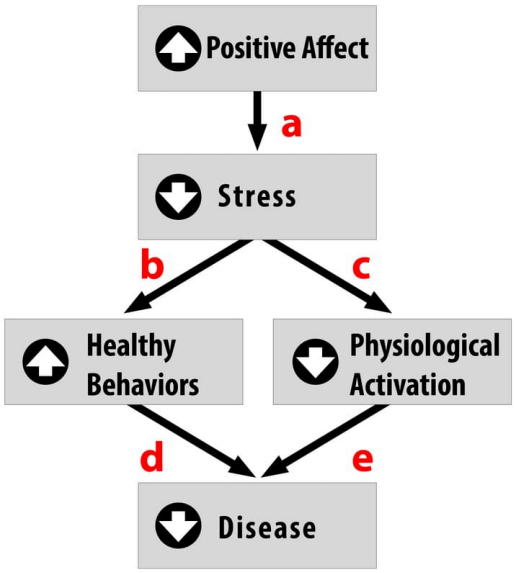

Figure 4.5.25.7:This figure illustrates one possible way that positive affect protects individuals against disease. Positive affect can reduce stress perceptions (a), thereby improving health behaviors (b) and lowering physiological stress responses (c) (e.g., decreased cardiovascular reactivity, lower stress hormones, non-suppressed immune activity). As a result, there is likely to be less incidence of disease (d, e). (Adapted from Pressman & Cohen, 2005)

Stress Management

About 20 percent of Americans report having stress, with 18–33 year-olds reporting the highest levels (American Psychological Association, 2012). Given that the sources of our stress are often difficult to change (e.g., personal finances, current job), a number of interventions have been designed to help reduce the aversive responses to duress. For example, relaxation activities and forms of meditation are techniques that allow individuals to reduce their stress via breathing exercises, muscle relaxation, and mental imagery. Physiological arousal from stress can also be reduced via **biofeedback**, a technique where the individual is shown bodily information that is not normally available to them (e.g., heart rate), and then taught strategies to alter this signal. This type of intervention has even shown promise in reducing heart and hypertension risk, as well as other serious conditions (e.g., Moravec, 2008; Patel, Marmot, & Terry, 1981). But reducing stress does not have to be complicated! For example, exercise is a great stress reduction activity (Salmon, 2001) that has a myriad of health benefits.

The Importance Of Good Health Practices

As a student, you probably strive to maintain good grades, to have an active social life, and to stay healthy (e.g., by getting enough sleep), but there is a popular joke about what it's like to be in college: you can only pick two of these things (see Figure 4.5.25.8 : for an example). The busy life of a college student doesn't always allow you to maintain all three areas of your life, especially during test-taking periods. In one study, researchers found that students taking exams were more stressed and, thus, smoked more, drank more caffeine, had less physical activity, and had worse sleep habits (Oaten & Chang, 2005), all of which could have detrimental effects on their health. Positive health practices are *especially* important in times of stress when your immune system is compromised due to high stress and the elevated frequency of exposure to the illnesses of your fellow students in lecture halls, cafeterias, and dorms.

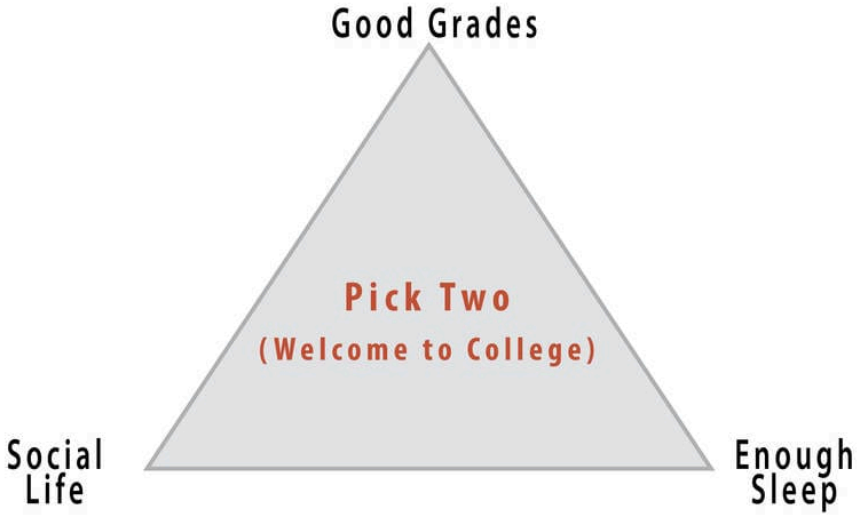

Figure 4.5.25.8: A popular joke about how difficult it is to stay balanced and healthy during college.

Psychologists study both **health behaviors** and health habits. The former are behaviors that can improve or harm your health. Some examples include regular exercise, flossing, and wearing sunscreen, versus negative behaviors like drunk driving, pulling all-nighters, or smoking. These behaviors become *habits* when they are firmly established and performed automatically. For example, do you have to think about putting your seatbelt on or do you do it automatically? Habits are often developed early in life thanks to parental encouragement or the influence of our peer group.

While these behaviors sound minor, studies have shown that those who engaged in more of these protective habits (e.g., getting 7–8 hours of sleep regularly, not smoking or drinking excessively, exercising) had fewer illnesses, felt better, and were less likely to die over a 9–12-year follow-up period (Belloc & Breslow 1972; Breslow & Enstrom 1980). For college students, health behaviors can even influence academic performance. For example, poor sleep quality and quantity are related to weaker learning capacity and academic performance (Curcio, Ferrara, & De Gennaro, 2006). Due to the effects that health behaviors can have, much effort is put forward by psychologists to understand *how* to change unhealthy behaviors, and to understand *why* individuals fail to act in healthy ways. Health promotion involves enabling individuals to improve health by focusing on behaviors that pose a risk for future illness, as well as spreading knowledge on existing risk factors. These might be genetic risks you are born with, or something you developed over time like obesity, which puts you at risk for Type 2 diabetes and heart disease, among other illnesses.

Psychology And Medicine

There are many psychological factors that influence medical treatment outcomes. For example, older individuals, (Meara, White, & Cutler, 2004), women (Briscoe, 1987), and those from higher socioeconomic backgrounds (Adamson, Ben-Shlomo, Chaturvedi, & Donovan, 2008) are all *more* likely to seek medical care. On the other hand, some individuals who need care might avoid it due to financial obstacles or preconceived notions about medical practitioners or the illness. Thanks to the growing amount of medical information online, many people now use the Internet for health information and 38% percent report that this influences their decision to see a doctor (Fox & Jones, 2009) (see Figure 4.5.25.9). Unfortunately, this is not always a good thing because individuals tend to do a poor job assessing the credibility of health information. For example, college-student participants reading online articles about HIV and syphilis rated a physician's article and a college student's article as *equally* credible if the participants said they were familiar with the health topic (Eastin, 2001). Credibility of health information often means how accurate or trustworthy the information is, and it can be influenced by irrelevant factors, such as the website's design, logos, or the organization's contact information (Freeman & Spyridakis, 2004). Similarly, many people post health questions on online, unmoderated forums where *anyone* can respond, which allows for the possibility of inaccurate information being provided for serious medical conditions by unqualified individuals.

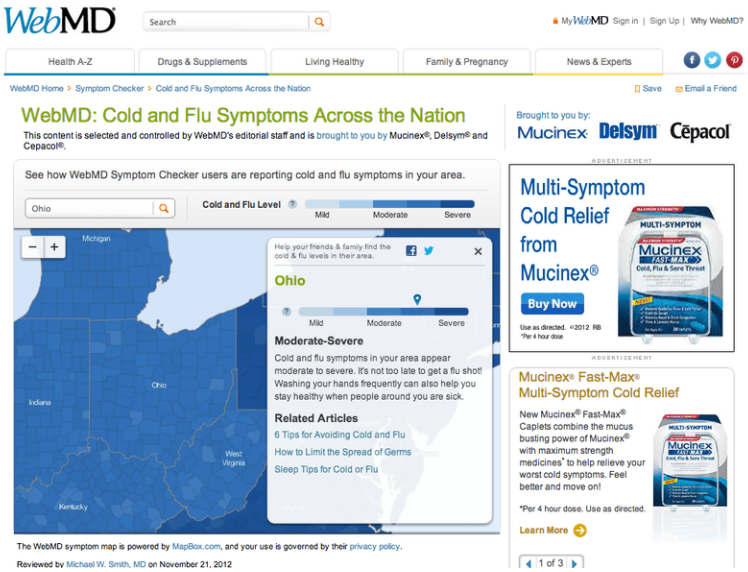

Figure 4.5.25.9: While the Internet has increased the amount of medical information available to the public and created greater access, there are real concerns about how people are making decisions about their health based on that information. [Image: Mapbox, https://goo.gl/UNhmx5, CC BY 2.0, goo.gl/BRvSA7]

After individuals decide to seek care, there is also variability in the information they give their medical provider. Poor communication (e.g., due to embarrassment or feeling rushed) can influence the accuracy of the diagnosis and the effectiveness of the prescribed treatment. Similarly, there is variation following a visit to the doctor. While most individuals are tasked with a health recommendation (e.g., buying and using a medication appropriately, losing weight, going to another expert), not everyone *adheres* to medical recommendations (Dunbar-Jacob & Mortimer-Stephens, 2010). For example, many individuals take medications inappropriately (e.g., stopping early, not filling prescriptions) or fail to change their behaviors (e.g., quitting smoking). Unfortunately, getting patients to follow medical orders is not as easy as one would think. For example, in one study, over one third of diabetic patients failed to get proper medical care that would prevent or slow down diabetes-related blindness (Schoenfeld, Greene, Wu, & Leske, 2001)! Fortunately, as mobile technology improves, physicians now have the ability to monitor **adherence** and work to improve it (e.g., with pill bottles that monitor if they are opened at the right time). Even text messages are useful for improving treatment adherence and outcomes in depression, smoking cessation, and weight loss (Cole-Lewis, & Kershaw, 2010).

Being A Health Psychologist

Training as a clinical health psychologist provides a variety of possible career options. Clinical health psychologists often work on teams of physicians, social workers, allied health professionals, and religious leaders. These teams may be formed in locations like rehabilitation centers, hospitals, primary care offices, emergency care centers, or in chronic illness clinics. Work in each of these settings will pose unique challenges in patient care, but the primary responsibility will be the same. Clinical health psychologists will evaluate physical, personal, and environmental factors contributing to illness and preventing improved health. In doing so, they will then help create a treatment strategy that takes into account all dimensions of a person's life and health, which maximizes its potential for success. Those who specialize in health psychology can also conduct research to discover new health predictors and risk factors, or develop interventions to prevent and treat illness. Researchers studying health psychology work in numerous locations, such as universities, public health departments, hospitals, and private organizations. In the related field of **behavioral medicine**, careers focus on the application of this type of research. Occupations in this area might include jobs in occupational therapy, rehabilitation, or preventative medicine. Training as a health psychologist provides a wide skill set applicable in a number of different professional settings and career paths.

The Future of Health Psychology

Much of the past medical research literature provides an incomplete picture of human health. "Health care" is often "illness care." That is, it focuses on the management of symptoms and illnesses as they arise. As a result, in many developed countries, we are faced with several health epidemics that are difficult and costly to treat. These include obesity, diabetes, and cardiovascular disease, to name a few. The National Institutes of Health have called for researchers to use the knowledge we have about risk

factors to design effective interventions to reduce the prevalence of *preventable* illness. Additionally, there are a growing number of individuals across developed countries with *multiple* chronic illnesses and/or lasting disabilities, especially with older age. Addressing their needs and maintaining their quality of life will require skilled individuals who understand how to properly treat these populations. Health psychologists will be on the forefront of work in these areas.

With this focus on prevention, it is important that health psychologists move beyond studying risk (e.g., depression, stress, hostility, low socioeconomic status) in isolation, and move toward studying factors that confer resilience and protection from disease. There is, fortunately, a growing interest in studying the positive factors that protect our health (e.g., Diener & Chan, 2011; Pressman & Cohen, 2005; Richman, Kubzansky, Maselko, Kawachi, Choo, & Bauer, 2005) with evidence strongly indicating that people with higher positivity live longer, suffer fewer illnesses, and generally feel better. Seligman (2008) has even proposed a field of "Positive Health" to specifically study those who exhibit "above average" health—something we do not think about enough. By shifting some of the research focus to identifying and understanding these health-promoting factors, we may capitalize on this information to improve public health.

Innovative interventions to improve health are already in use and continue to be studied. With recent advances in technology, we are starting to see great strides made to improve health with the aid of computational tools. For example, there are hundreds of simple applications (apps) that use email and text messages to send reminders to take medication, as well as mobile apps that allow us to monitor our exercise levels and food intake (in the growing mobile-health, or m-health, field). These m-health applications can be used to raise health awareness, support treatment and compliance, and remotely collect data on a variety of outcomes. Also exciting are devices that allow us to monitor physiology in real time; for example, to better understand the stressful situations that raise blood pressure or heart rate. With advances like these, health psychologists will be able to serve the population better, learn more about health and health behavior, and develop excellent health-improving strategies that could be specifically targeted to certain populations or individuals. These leaps in equipment development, partnered with growing health psychology knowledge and exciting advances in neuroscience and genetic research, will lead health researchers and practitioners into an exciting new time where, hopefully, we will understand more and more about how to keep people healthy.

What first comes to mind when you think of the word “drug”? Historically, drugs have been associated with medicine - substances that help prevent, treat, or cure disease. However, even life-saving medicines can be dangerous if used incorrectly. Furthermore, not all drugs are used for medicinal or therapeutic purposes. Many drugs are used recreationally or to deliberately alter one's mood or state of consciousness. Certain drugs with addictive properties, such as cocaine and heroin, are considered controlled substances and are strictly regulated by the government. However, many commonly used legal psychoactive drugs, including nicotine and alcohol, also pose a high risk for addiction. Caffeine, a drug you likely encounter every day, is one of the most widely used psychoactive drugs in the world. As you can imagine, the term “drug” can take on many different connotations depending on the context.

In this chapter, we will broadly define a drug as any non-food chemical substance, be it naturally derived or synthetic, with the ability to alter an organism’s physiology or behavior. You will be introduced to the basics of Psychopharmacology, which is the study of how drugs affect mood, cognition, and behavior. We will also explore concepts relevant to the field of Neuropsychopharmacology, an interdisciplinary research area that combines the principles of psychopharmacology and neuroscience to examine the underlying neurobiological mechanisms that contribute to drug-induced changes in physiology and behavior.

5.1.2: Basic Principles of Pharmacology

Learning Objectives

By the end of this section, you should be able to

- 14.1.1 List the factors that contribute to bioavailability and describe how they can influence an individual's response to a drug.
- 14.1.2 Describe how drugs impact neuronal signaling via their interaction with receptors and the neurotransmitter life cycle.

The physiological and behavioral effects of drugs, also known as pharmacodynamics, are a result of their molecular interactions with receptors located throughout the body. To reach these receptors, the drug must enter the body and cross into the blood circulatory system. However, the amount of drug consumed or administered does not always equal the amount of drug that is available to bind and produce an effect. The proportion of the drug that ultimately reaches the circulation system, referred to as bioavailability, is a key variable in predicting an individual's response to the drug. The range of doses in which a drug is effective without causing adverse effects is known as the therapeutic window. Lower plasma concentrations of a drug are more likely to be ineffective, whereas higher concentrations run the risk of being toxic or even lethal. The ideal drug has a large therapeutic window, meaning there is a large range of concentrations in which the drug is both safe and effective.

Factors affecting drug availability

The bioavailability of a particular drug is influenced by pharmacokinetics or the movement of the drug throughout the body. Factors such as route of administration, and the rate of absorption, distribution, metabolism, and excretion all have the potential to impact drug bioavailability.

Route of administration

The route of administration refers to how a drug is introduced to the body. Although there are several different methods for drug administration, they fall broadly into two categories: enteral administration, which involves the gastrointestinal system, and parenteral administration, which does not. The route of administration plays an important role in determining the onset of action, or the amount of time it takes to experience a drug's effect. In general, enteral administration is associated with slower onset compared to parenteral administration. Furthermore, the route of administration is often dependent on the chemical structure of the drug since certain formulations may only be effective when delivered a specific way. A few of the more common routes of administration are discussed below and diagrammed in Figure 14.2.

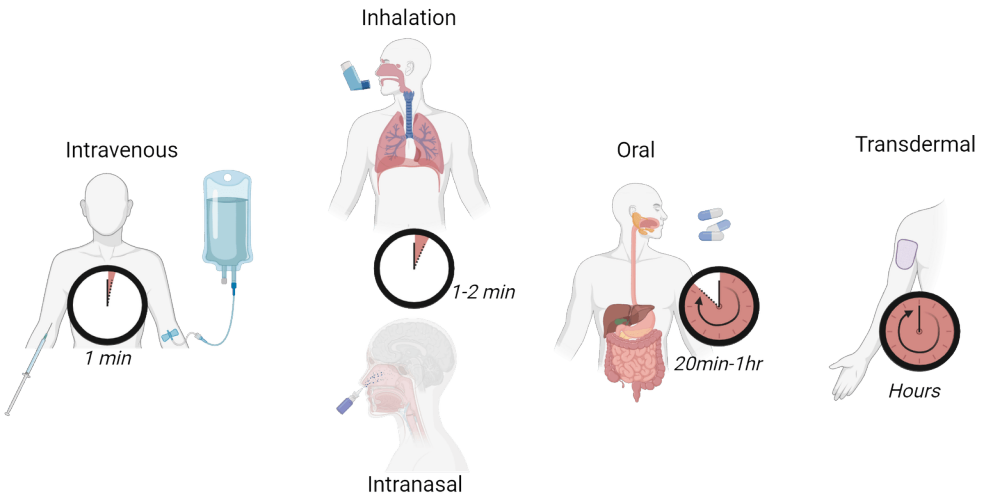

Figure 14.2 Routes of drug administration and time of action onset

Oral administration is one of the most frequently used forms of drug administration because it is generally safe, simple, and convenient to self-administer. Drugs designed for oral administration are often formulated as capsules, pills, or tablets, but can also be delivered through a liquid solution. Once ingested, the drug moves through the stomach into the small intestines where it is absorbed into the portal vein and passed through the liver before entering the main circulatory system. This process is known as first-pass metabolism. Enzymes in the liver can chemically alter the drug, resulting in less of it reaching the binding site. Certain protein-based drugs, such as insulin, are destroyed by gastric acids in the stomach before even being absorbed into the portal vein. This is why insulin is typically administered via a subcutaneous (under the skin) injection. The onset of action for orally administered drugs typically ranges from 20 minutes to an hour.

Intravenous (IV) administration is the delivery of a drug directly into the bloodstream via a hypodermic needle. In contrast to oral administration, IV administration has a very rapid onset of action (within 1 minute). Furthermore, bioavailability is essentially 100% seeing as this route of administration bypasses the gastrointestinal system and first-pass metabolism. While this is certainly advantageous when fast effects are needed, this form of administration can also lead to overdoses or other adverse effects if the drug is impure or if the dose is not calculated correctly. IV drug use can also pose additional health hazards when done without sterile equipment.

Inhalation is a route of administration that allows the drug to be absorbed into the circulatory system via the lungs. For this method of delivery, the drug must be burned to create smoke (such as with a cigarette) or volatilized into a vapor. The inhaled smoke or vapor passes through the lungs and is absorbed by the surrounding pulmonary capillaries, which quickly carry the drug into the circulatory system. For this reason, drug delivery by inhalation also produces a fairly rapid onset of action. However, inhalation of non-gaseous particles can cause damage to the airways and lungs.

Intranasal drug delivery is achieved by inhaling a substance through the nostrils or directly applying the drug to the mucous membranes of the nasal passage. The drug is then absorbed into the blood vessels that line the nasal cavity and carried into the circulatory system. Oxytocin, a peptide hormone involved in social bonding and reproduction (see Chapter 11 Sexual Behavior and Development), is sometimes delivered intranasally through a spray to facilitate breastfeeding after childbirth. Although this route of administration also results in a rapid onset of action, contaminants present in the drug may irritate the nasal passage and lead to tissue damage.

Transdermal administration delivers drugs through the skin's surface into the underlying blood vessels via a skin patch or ointment. This route is unique from topical administration, in which the drug is intended to remain on the skin surface. Hormonal contraceptives that contain estrogen and progesterone can be administered transdermally through a skin patch. This route of administration allows for a sustained diffusion of drugs over an extended time, which eliminates the need to remember to take a daily pill or injection. Although transdermal administration has a slow onset of action, it can provide extended periods of drug delivery (up to a week in some cases). The utility of this route of administration is limited by the fact that only certain types of drugs can penetrate the skin.

Absorption and distribution

As discussed earlier, a drug must be absorbed into the bloodstream and distributed throughout the body to reach its target binding site. The speed at which this occurs depends on the route of administration. Drugs delivered directly into the bloodstream will be absorbed and distributed much faster than drugs that must travel through the gastrointestinal system. For enteral methods of administration, most drug absorption occurs in the small intestines. Therefore, the time it takes the drug to reach the bloodstream is heavily dependent on how long it takes for the stomach to empty into the small intestines. The absorption process can also be affected by food being digested in the stomach. For example, calcium molecules found in dairy products, such as milk, yogurt, and cheese, can bind to certain antibiotics and prevent them from being absorbed. Similarly, medications used to treat hypothyroidism, such as levothyroxine, need to be taken on an empty stomach to enhance absorption.

One factor that can impact absorption and distribution in the brain is the blood-brain barrier (BBB), a lining of cells that acts as a border between blood vessels and extracellular fluid in the brain (Figure 14.3) (see Chapter 1 Structure and Function of the Nervous System: Cells and Anatomy).

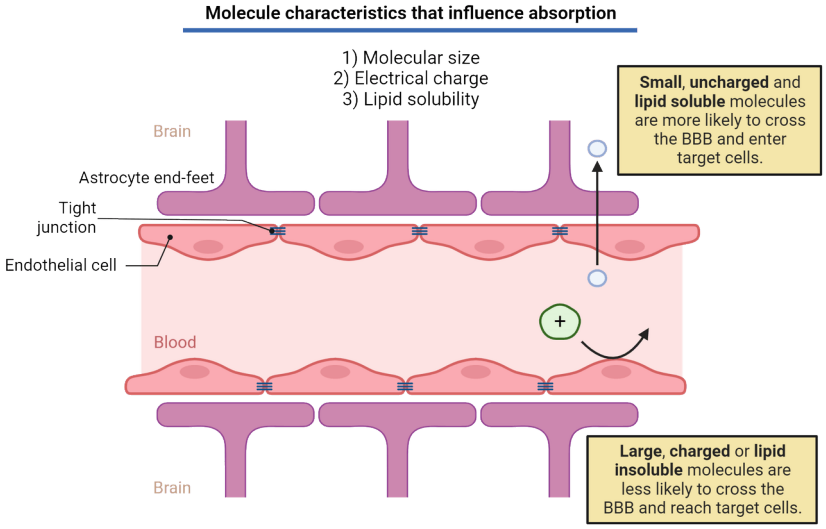

Figure 14.3 Molecule characteristics that influence absorption across the blood-brain barrier

The relatively impermeable nature of the BBB prevents the vast majority of molecules from diffusing into the brain since most compounds found in the blood are large, electrically charged or lipid insoluble. The BBB tightly regulates the entry of select nutrients and molecules into the brain via passive and active transport channels. This selectivity helps to protect the central nervous system (CNS) from pathogens that could cause systemic infection but can also prevent certain drugs from reaching the brain. Drugs with high lipid-solubility, or the ability to dissolve through the cell membrane, are more likely to cross the BBB. Many psychoactive drugs (e.g. cocaine, nicotine, fentanyl) are highly lipid-soluble molecules, a property which allows them to penetrate the BBB and interact with their targets in the brain. The BBB continues to present a challenge for developing pharmaceutical treatments for central nervous system (CNS) disorders since pharmaceutical drugs cannot always be designed as small or lipid-soluble molecules.

Metabolism

Drugs can be chemically altered by enzymes located throughout the body, although the majority of drug metabolism takes place in the liver and gastrointestinal tract. The rate of metabolism for a particular drug is influenced by how quickly these enzymes alter the drug, which differs depending on genetics, age, sex, and body weight. This process can potentially inactivate the drug, thereby reducing bioavailability. For example, alcohol is broken down in the stomach and liver by alcohol dehydrogenase enzymes which transform the drug first into acetaldehyde and then into acetic acid. In contrast, prodrugs are drugs that are inactive until they are metabolized by the body. Codeine, an opiate drug derived from the opium poppy, has very little drug effect until it is metabolized by the liver to produce morphine, a much more potent drug.

There are several ways that changes in liver enzyme function can alter drug metabolism and thereby end up changing how a drug ultimately impacts a person. Liver damage or dysfunction can lead to unpredictable changes in drug clearance and metabolism,

for example. Using a drug chronically can increase the number of liver enzymes that degrade it, which over time may reduce the amount of drug that is absorbed into the bloodstream. The administration of multiple drugs at the same time can cause drug-drug interactions, in which one drug impacts the activity of another. In addition, increased levels of one or more of the drugs may accumulate in the bloodstream if they are metabolized by the same enzyme. This phenomenon is known as competitive enzyme inhibition. Essentially, the enzyme that would be helping to break down and clear one drug is too busy breaking down the other drug. For example, cisapride, a drug used to treat gastroesophageal reflux disease, and ketoconazole, an antifungal medication, are both metabolized by cytochrome P450 (CYP) liver enzymes. When these drugs are taken together, blood levels of cisapride can reach toxic levels, which may increase the risk of adverse side effects.

Excretion

The primary way that drugs and their metabolites are removed from the body is via the kidney, which filters the blood and excretes waste materials through urine. Drugs can also be excreted from the body through feces, sweat and saliva. The amount of time it takes for the blood concentration of a drug to reach 50% of its original value is commonly referred to as the half-life. The half-life of a drug can be influenced by the route of administration. Drugs that are taken orally enter and exit the bloodstream more slowly than those injected directly into a blood vessel. A drug with a short half-life may have to be administered multiple times a day to maintain its effects, whereas the effects of a drug with a long half-life may persist for over a day with only a single administration. A long half-life may seem ideal for therapeutic purposes. However, it may also prolong unwanted or dangerous side effects of the drug. These factors, along with absorption and distribution, contribute to the drug plasma concentration over time (Figure 14.4). The length of time a drug remains at a therapeutic or effective concentration is considered the duration of action.

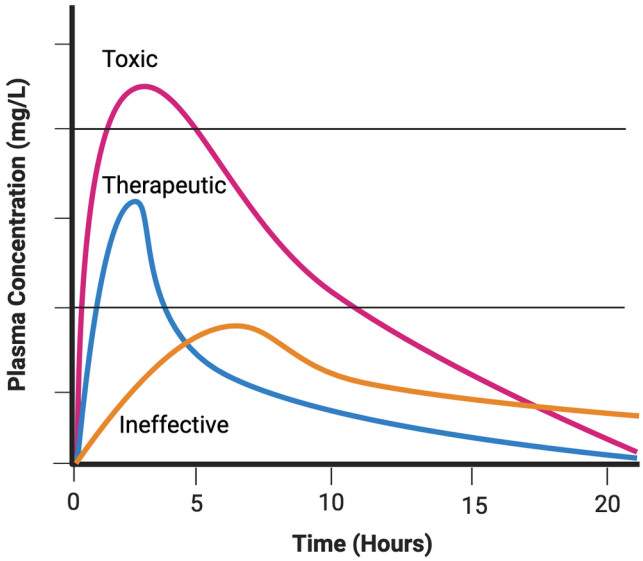

Figure 14.4 Plasma concentration over time Each curve shows the plasma concentration of a drug over time, revealing different absorption rates. Only the middle (blue) curve shows plasma concentrations within the therapeutic range without inducing toxic effects.

Drug interactions with neurotransmitter lifecycle

In addition to their interactions with receptors, drugs can also impact neuronal functioning indirectly by interfering with different stages of synaptic transmission (Figure 14.5) (see Chapter 3 Basic Neurochemistry).

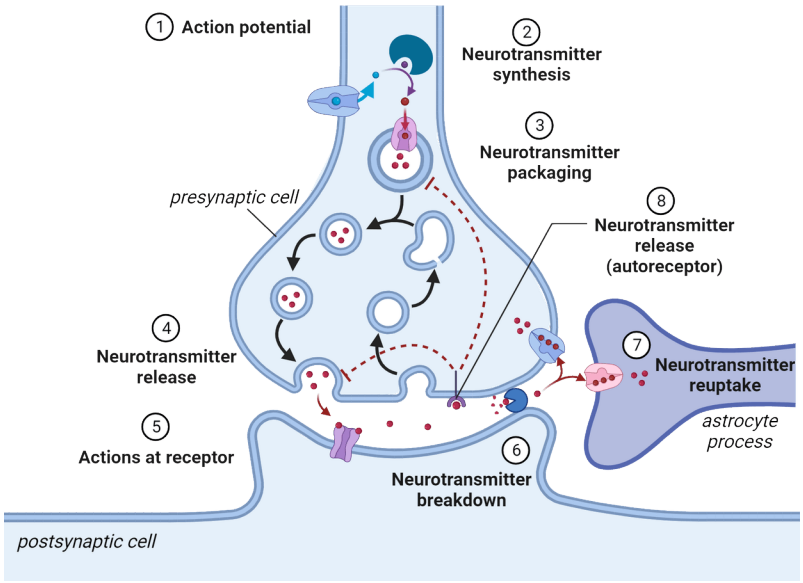

Figure 14.5 Sites of drug action

At the root of synaptic transmission is the arrival of an action potential, a step that can be altered by drugs (step 1 in Figure 14.5). For example, lidocaine, a local anesthetic, can inhibit the propagation of an action potential by blocking voltage-gated sodium channels, and ultimately prevent neurotransmitter release.

Neurotransmitters must also be synthesized to be available at the synapse. During the synthesis stage, enzymes catalyze reactions between precursor molecules to create the final neurotransmitter. Drugs that impact synthesis can either reduce or enhance the level of neurotransmitters produced in the brain (step 2 in Figure 14.5). For example, metyrosine, a drug used to treat hypertension, is known to inhibit tyrosine hydroxylase, an enzyme that is necessary for the synthesis of catecholamines like dopamine, norepinephrine, and epinephrine. Within the peripheral nervous system, elevated levels of norepinephrine and epinephrine contribute to increased heart rate and blood pressure. Thus, the depletion of these neurotransmitters can help treat high blood pressure.

After the synthesis process, neurotransmitters are then packaged into a vesicle and stored in the axon terminal. The influx of calcium from voltage-gated calcium channels following an action potential promotes vesicle docking and fusion at the axon terminal, which ultimately leads to the release of neurotransmitters. Several classes of psychoactive drugs act by altering packaging (step 3 in Figure 14.5) and/or release (step 4 in Figure 14.5) of neurotransmitters. For example, methamphetamine interferes with the functioning of dopamine transporter proteins on synaptic vesicles, which results in the escape of dopamine molecules into the cytosol. Methamphetamine also reverses dopamine transporter proteins located on the axon terminal, ultimately leading to increased dopamine release in the synaptic cleft.

To end signaling to the postsynaptic cell, neurotransmitters are either broken down in the synaptic cleft or brought back into the presynaptic cell via reuptake (steps 6 and 7 in Figure 14.5). Drugs that prevent termination may enhance postsynaptic signaling. For example, selective serotonin reuptake inhibitors (SSRIs), a class of antidepressant drugs, prevent the reuptake of serotonin into the presynaptic terminal, thereby elevating concentrations of serotonin in the synaptic cleft.

Drug-receptor interactions

Some drugs impart their neurobiological effects through interaction with receptors located on target cells in the CNS (step 5 in Figure 14.5). Most receptors are transmembrane proteins that contain an extracellular surface with a binding site where neurotransmitters, hormones, drugs, or other molecules can bind. Broadly, any molecule that can bind to a receptor's binding site is referred to as a ligand. Drug-receptor interactions can also be characterized by the binding affinity or strength of the interaction. A high-affinity ligand tends to bind to a particular receptor more than a low-affinity ligand.

Receptors

There are two main categories of ligand-binding receptors, both shown in Figure 14.6 (see Chapter 3 Basic Neurochemistry).

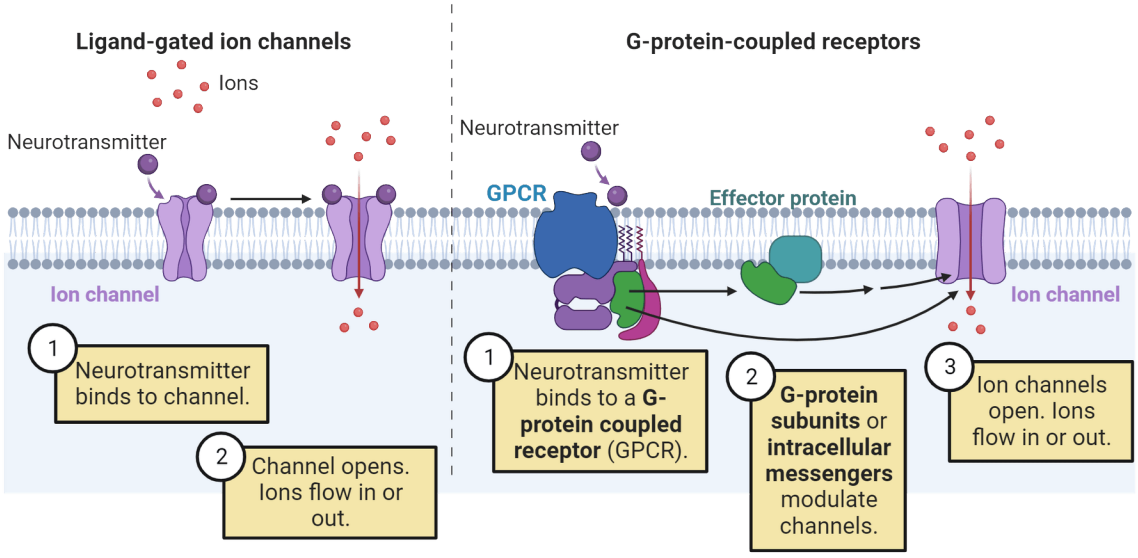

Figure 14.6 Ionotropic vs metabotropic receptors

Ligand-gated channels (also known as ionotropic receptors) are ion channels composed of proteins embedded in the cell membrane. When a ligand binds to the binding site, the membrane-spanning portions of the receptor open to form a channel that allows specific ions to cross into the cell. If the receptor is on a neuron, which is often the case for psychoactive drugs, this movement can result in either excitation or inhibition of the neuron. This response usually occurs within a millisecond of the ligand binding.

Metabotropic receptors (also known as G protein-coupled receptors) also have an extracellular active site, but these receptors do not form an ion channel. Instead, they are composed of seven transmembrane proteins that are physically linked to intracellular proteins called G proteins. When a ligand binds to the active site, the G protein disassociates from the receptor complex. Once unbound, the G protein can go on to open or close ion channels located on the cell membrane or activate or inhibit intracellular signaling cascades. Because metabotropic receptors are indirectly linked with ion channels and signaling transduction, compared to ionotropic receptors, their effects on neuronal activity occur at a slower pace and can persist for a longer period.

Receptor ligands

Ligands can be naturally produced within the body or derived from a source outside of the body. For example, endocannabinoids are neurotransmitters that are produced within the central and peripheral nervous system and bind to cannabinoid (CB) receptors (see Chapter 3 Basic Neurochemistry). Because they are synthesized within the brain, endocannabinoids are considered the endogenous ligand for CB receptors. The primary psychoactive chemical in cannabis (THC) also binds to CB receptors. However, it is derived from a plant and is thus considered an exogenous ligand.

A dose-response curve plots the relationship between the level of receptor response and the dose of the drug (Figure 14.7).

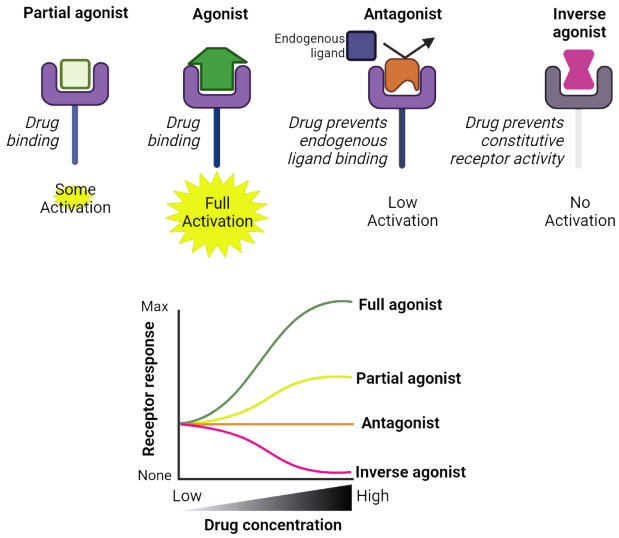

Figure 14.7 Ligand receptor interactions

A full agonist is a ligand or drug that is capable of binding to and activating a receptor with maximal efficacy. Epinephrine is an example of a full agonist at the adrenergic receptor. A partial agonist also can activate a receptor upon binding. However, it elicits a reduced receptor response compared to a full agonist, even with increasing concentration of the ligand. Buprenorphine, an opioid drug used to treat opioid use disorder, is a partial agonist at the mu-opioid receptor (MOR). Buprenorphine's reduced efficacy at the MOR decreases the risk of overdose.

In some cases, a receptor can produce a biological response in the absence of an agonist binding. This phenomenon is referred to as constitutive activity. An inverse agonist is a drug that inhibits the same binding site as a full agonist but reduces activity in a receptor that would otherwise be constitutively active. For example, certain histamine receptors exhibit agonist-independent activity, which is thought to contribute to many allergy symptoms. Antihistamines, drugs used to alleviate allergy symptoms, bind to histamine receptors and reduce their biological response instead of increasing it, thereby making them inverse agonists.

An antagonist is a ligand that blocks the activation of the receptor by preventing agonists from binding. In contrast to the inverse agonist, an antagonist does not have any intrinsic activity on the receptor itself, it simply blocks agonists from interacting with the receptor. For example, caffeine is an antagonist at adenosine receptors, which typically induce drowsiness when activated by their endogenous ligand.

Another type of agonist interaction sometimes seen with G protein-coupled receptors is biased agonism or functional selectivity. This occurs when the unique structure of a ligand allows it to preferentially activate certain intracellular signaling cascades over others. A major goal in drug development research is to design ligands that induce signaling cascades that promote the therapeutic effects of drugs while minimizing the activation of cascades associated with adverse side effects. In 2020, the Food and Drug Administration (FDA) approved the first biased mu-opioid receptor agonist for the treatment of severe pain. When tested in clinical studies, this drug produced a similar degree of analgesia (pain relief) but less nausea and respiratory depression compared to morphine (DeWire et al., 2013).

Certain ligands, called allosteric modulators, can regulate receptor activity without interacting with a receptor's orthosteric site, the location where an agonist would typically bind. Instead, allosteric modulators bind to a different part of the receptor (referred to as the allosteric site), which can ultimately alter the effects of ligands that bind to the orthosteric site. Positive allosteric modulators increase the efficacy of agonists that bind to the receptor, whereas negative allosteric modulators reduce the ability of agonists to activate the receptor. Benzodiazepines, drugs used to treat anxiety disorders, are an example of positive allosteric modulators of the $GABA_A$ receptor (Figure 14.8). When both GABA and benzodiazepines are bound to the $GABA_A$ receptor, the ion channel opens more frequently or for a longer period, allowing more chloride ions to enter the cell. This results in a greater inhibitory effect compared to when only GABA is present. In contrast to an agonist, benzodiazepines have no effect on $GABA_A$ receptor activation on their own.

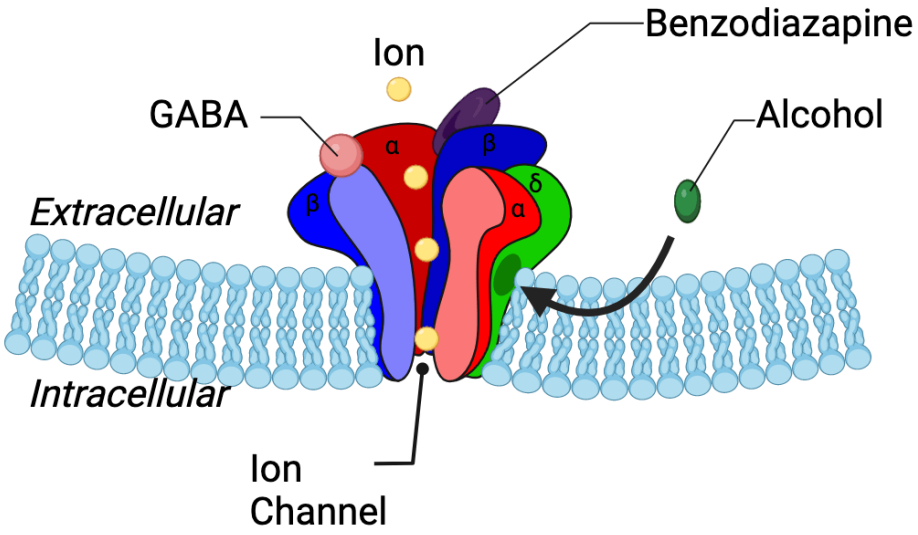

Figure 14.8 $GABA_A$ receptor agonists Many sedatives work by binding to and activating $GABA_A$ receptors.

Drug Approval Process in the United States

The U.S. Food and Drug Administration (FDA) is a federal agency within the Department of Health and Human Services that is tasked with ensuring the safety and efficacy of food, drugs, and biomedical products among other things in the U.S. The FDA's Center for Drug Evaluation and Research is specifically responsible for reviewing new drugs before they can be sold to consumers.

Before a new drug can reach the store shelf it must pass through multiple stages of testing and evaluation. First, the drug must be tested in multiple animal models to determine its safety and pharmacological profile, and whether it is effective. Next, the pharmaceutical company must submit an Investigational New Drug (IND) application, which includes the results of the initial rounds of animal testing, information on the drug composition and manufacturing, and a detailed plan for how the drug will be tested in humans. Once the FDA reviews and approves the IND, the pharmaceutical company can begin conducting clinical trials in humans.

There are generally three stages of clinical testing: Phase 1, Phase 2, and Phase 3. The main goals of Phase 1 are to evaluate the safety of the drug, identify any adverse side effects, and determine how the drug is metabolized. These trials are made up entirely of healthy volunteers. Phase 2 trials include patients who have the disease or condition that the new drug is proposed to treat. The main goal of this phase is to determine how the drug performs compared to a placebo (a substance that has no therapeutic action) or a different drug that is already approved for treatment. Both Phase 1 and Phase 2 trials tend to have a small number of participants (100 or less). In contrast, Phase 3 trials are considered large-scale studies and typically recruit over 1000 participants. The main goal of this phase is to gather more information on the safety and efficacy of the drug across different populations.

Following the completion of clinical testing, which can take several years, the analyses of all the data collected from both animal and human studies are submitted to the FDA as a New Drug Application (NDA). An independent team made up of physicians and scientists carefully reviews the submitted data to determine if the health benefits of the drug outweigh the risks. If the drug meets these criteria, the FDA will grant approval for marketing the drug in the U.S. The review process for approving an NDA can take up to 6-10 months to complete. However, in the case of public health emergencies, such as the Covid-19 epidemic, the FDA can enact its Emergency Use Authorization to allow non-FDA-approved medications to be used in certain conditions.

5.1.3: Psychotherapeutics

Learning Objectives

By the end of this section, you should be able to

- 14.2.1 Identify the neurotransmitter systems that are impacted by benzodiazepines, SSRIs, ketamine, antipsychotics and psychostimulants.
- 14.2.2 Discuss how placebos might produce therapeutic effects in the absence of drug activity.

Psychotherapeutics are drugs used primarily in a clinical context to treat mental illnesses (see Chapter 13 Emotion and Mood). While these drugs on their own are not a cure, they can help to reduce symptoms or make non-pharmacological treatments, such as psychotherapy, more effective. Psychotherapeutics work through a variety of mechanisms, but in general, act to alter neurotransmitter signaling in brain circuits that underlie emotion and mood regulation. Table 14.1 shows some common psychotherapeutics in the 4 major categories we will discuss below.

Category	Example	Drug class	Common use
Anxiolytic	Alprazolam (Xanax) Lorazepam (Ativan)	Benzodiazepine	Generalized anxiety disorder, post-traumatic stress disorder, panic disorder
Anti-depressant	Citalopram (Celexa) Fluoxetine (Prozac)	Selective serotonin reuptake inhibitor	Depression, post traumatic stress disorder, panic disorder
	Esketamine (Spravato)	Psychedelic	
Anti-psychotic	Chlorpromazine (Thorazine) Fluphenazine (Prolixin)	Conventional	Schizophrenia
	Clozapine (Clozaril) Risperidone (Risperdal)	Atypical	
Psycho-stimulant	Methylphenidate (Ritalin) Amphetamine (Adderall)	Stimulant	Attention-deficit/hyperactivity disorder (ADHD)

Table 14.1

Treatment of anxiety

Anxiety disorders are one of the most prevalent forms of mental illness. Approximately 31% of American adults will be diagnosed with an anxiety disorder at some point in their lifetime (Harvard Medical School, 2007). Although most people experience some degree of anxiety from time to time, anxiety disorders are characterized by a constant anticipation of threat that is severe enough to disrupt daily functioning. There are several types of anxiety disorders, but they fall broadly into three main categories: generalized anxiety disorder (GAD), panic disorder, and phobia-related disorders. GAD is associated with persistent feelings of excessive dread or worry. Panic disorders are characterized by recurring panic attacks, which are sudden periods of autonomic hyperactivity (i.e. increased heart rate, sweating, shortness of breath) that can occur without any clear stimulus or trigger. Lastly, phobia-related disorders involve irrational or excessive worry about encountering a specific object or situation.

Anxiolytics, psychotherapeutic drugs used primarily to prevent or reduce anxiety symptoms, are the main pharmacological treatment currently used for treating most anxiety disorders. The most commonly prescribed anxiolytics belong to a class of

drugs called benzodiazepines (BZDs). BZDs are positive allosteric modulators that bind to $GABA_A$ receptors (a subtype of GABA receptor that is highly expressed throughout the limbic system) and increase the efficacy of GABA binding (Figure 14.8). These drugs are highly effective in reducing anxiety symptoms. However, BZDs may produce adverse outcomes when used with other psychoactive substances. For example, BZDs combined with opioids or alcohol, which also have sedative effects, can increase the risk of experiencing a coma or overdose.

Neuroscience in the lab: Mechanism of action for benzodiazepines

Animal models have been pivotal in advancing our understanding of the specific molecular mechanisms that underlie the behavioral effects of these psychotherapeutics (and others). A critical part of this research is being able to measure an animal's level of anxiety. The light-dark choice test is a commonly used behavioral assay in anxiety research that is based on a rodent's innate aversion to a brightly lit area (Figure 14.9). Rodents naturally prefer to spend more time in the dark compartment, which they perceive as safer. Treatment with an anxiolytic increases time spent in the light compartment, something researchers interpret as a sign of reduced anxiety. Animals that possess a genetic mutation in the GABA receptor that prevents benzodiazepines from binding do not exhibit any changes in behavior when given an anxiolytic (Low et al., 2000). This type of finding indicates that the anxiety-reducing effects of benzodiazepines are mediated by activity at the GABA receptor.

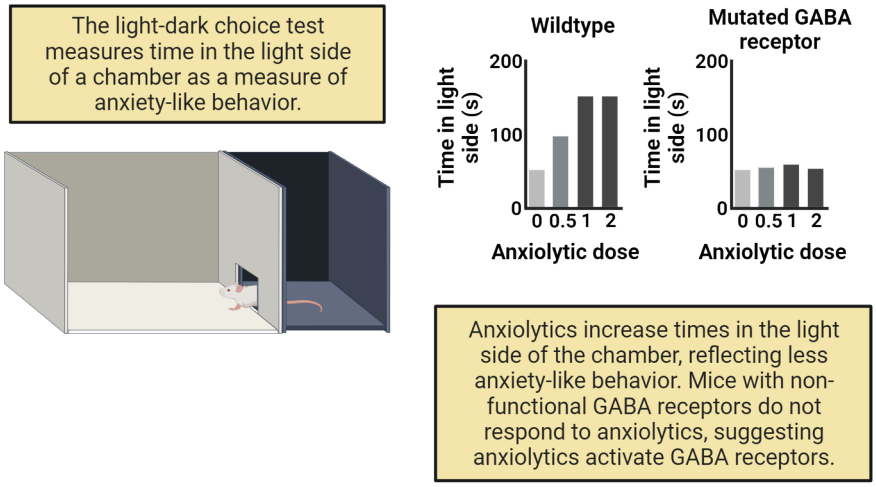

Figure 14.9 Light-dark paradigm

Treatment of depression

Major depressive disorder (MDD), also known as unipolar depression, is characterized by depressed mood and anhedonia, which is a loss of interest or pleasure in normally enjoyable pursuits. These core symptoms may also be accompanied by changes in sleep, energy, appetite, and cognition. In 2020, the past year's prevalence of MDD in the U.S. was 17%, with women being almost twice as likely to be diagnosed compared to men (SAMSHA, 2022). MDD is often reoccurring; approximately 80% of people diagnosed with MDD will experience multiple depressive episodes over time. Moreover, MDD is highly comorbid, or diagnosed simultaneously, with other mental illnesses, including anxiety and substance use disorders. Collectively, these factors have led to MDD being one of the leading causes of disability worldwide.

SSRIs

Antidepressants are psychotherapeutic drugs used to treat or prevent recurrent depressive episodes. They can also be used to treat anxiety disorders. The most frequently prescribed class of antidepressants is selective serotonin reuptake inhibitors (SSRIs). These medications block the reuptake of serotonin into presynaptic axon terminals, resulting in increased serotonin signaling in the postsynaptic neuron (Figure 14.10).

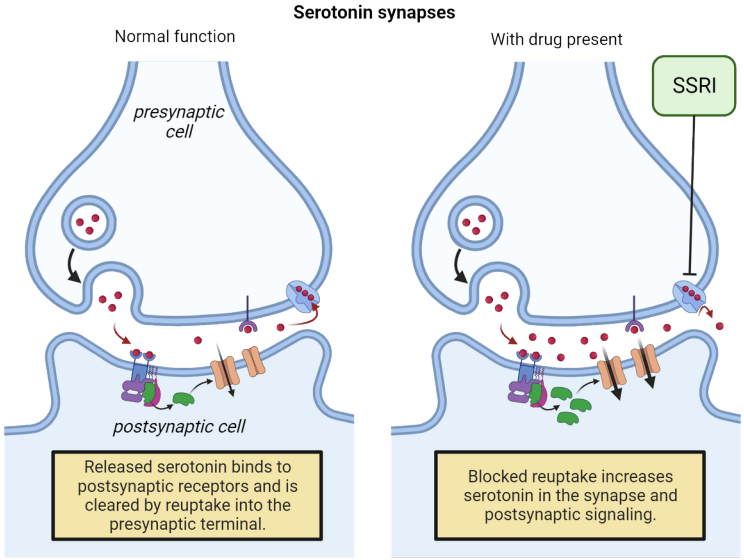

Figure 14.10 SSRI mechanism of action

Other molecular mechanisms likely contribute to antidepressant action since clinically significant therapeutic effects are typically not observed until 2-3 weeks after the start of treatment despite a rapid increase in serotonin availability. One potential mechanism is that SSRI-mediated elevations in serotonin levels increase hippocampal neurogenesis, which is believed to play a role in regulating mood. Chronic SSRI treatment is associated with increased neurogenesis in humans (Boldrini et al., 2009; Boldrini et al., 2013) and rodent models (Wang et al., 2008; David et al., 2009).In comparison to older types of antidepressants, such as monoamine oxidase inhibitors (MAOIs) and tricyclics, SSRIs tend to have a better safety profile and fewer adverse side effects. For this reason, SSRIs are often used as first-line medications, meaning they are the first choice for prescribing.

Science as a process: Monoamine hypothesis of depression

The monoamine hypothesis posits that depression is caused by a functional deficit in cortical and limbic monoamine transmitters, specifically serotonin and norepinephrine. The demonstrated efficacy of medications that increase synaptic levels of norepinephrine or serotonin helped support this hypothesis. Evidence from a handful of small clinical studies also suggested that temporarily reducing serotonin levels by depleting tryptophan, a precursor to serotonin, exacerbates depressive symptoms in individuals in remission from a depressive episode (Moreno et al., 1999; Moreno et al., 2000). Lastly, a genetic variant in the gene that codes for the serotonin transporter has been associated with an increased risk of developing MDD following stressful life events (Caspi et al., 2003).

While the monoamine hypothesis has been the prevailing theory of depression for several decades, there are many limitations. For one, not all patients respond clinically to SSRIs, and drugs that do not act through the monoamine system are effective for some patients. Furthermore, a recent systematic review of the clinical literature surrounding depression found no consistent evidence that depression is linked to lowered serotonin levels in the brain (Moncrieff et al., 2022).

Current perspectives on the etiology of depression adopt a more comprehensive view that takes into consideration the interaction of biological, psychological, and environmental factors. For example, the neurotrophic model proposes that depression is caused by stress-induced neuronal atrophy in limbic brain regions, such as the hippocampus, that mediate mood and stress response. Both physical and social stressors have been shown to reduce brain-derived neurotrophic factor (BDNF), a molecule highly implicated in neurogenesis and neuroplasticity. Moreover, chronic antidepressant treatment is associated with an upregulation of BDNF.

Ketamine

For most individuals, SSRIs are effective in attenuating symptoms or preventing relapse. However, it is estimated that SSRIs are ineffective in 10-30% of people diagnosed with MDD. Patients who do not respond to two or more different types of antidepressants are considered to have treatment-resistant depression (TRD). In 2019, the FDA approved the use of intranasal ketamine for the treatment of TRD. Ketamine is an anesthetic regularly used in veterinary and emergency medicine. It is

also used recreationally for its dissociative properties, which can induce hallucinations and feelings of detachment from one's body or environment. Ketamine's antidepressant effects occur at sub-anesthetic doses and do not depend on its psychoactive effects. However, additional research is needed to understand how ketamine's long-term efficacy and safety compare to first-line antidepressant treatments.

Ketamine's therapeutic effects are thought to be mediated in part by its antagonistic activity at NMDA receptors located on the axon terminal of GABAergic interneurons which synapse onto glutamate-releasing neurons (Figure 14.11). Under normal conditions, NMDA receptor activation results in increased GABA release from the GABAergic interneuron. This in turn inhibits activity in the presynaptic glutamate-releasing neuron and prevents the stimulation of AMPA receptors on the postsynaptic cell. Ketamine blocks the activation of NMDA receptors, thus inhibiting GABA release onto the presynaptic glutamatergic neuron. Consequently, there is more glutamate release and increased activation of AMPA receptors on the postsynaptic cell.

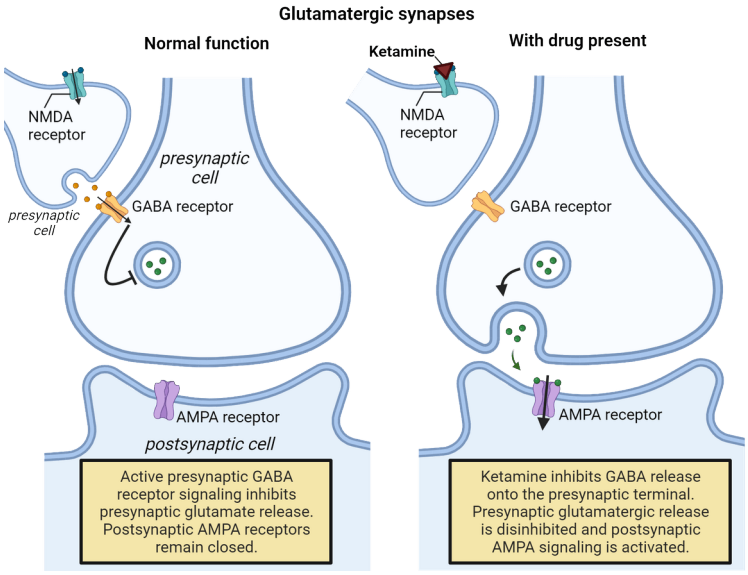

Figure 14.11 Ketamine mechanism of action

AMPA receptor signaling is highly implicated in synaptic plasticity, which is thought to underlie the antidepressant effects of ketamine. In contrast to SSRIs, which have a therapeutic lag of multiple weeks, a single intravenous injection of ketamine has been shown to reduce depressive symptoms within 24 hours (Murrough et al., 2013) (Figure 14.12). Moreover, intranasal ketamine combined with an oral antidepressant, such as an SSRI, significantly delays relapse (Daly et al., 2019).

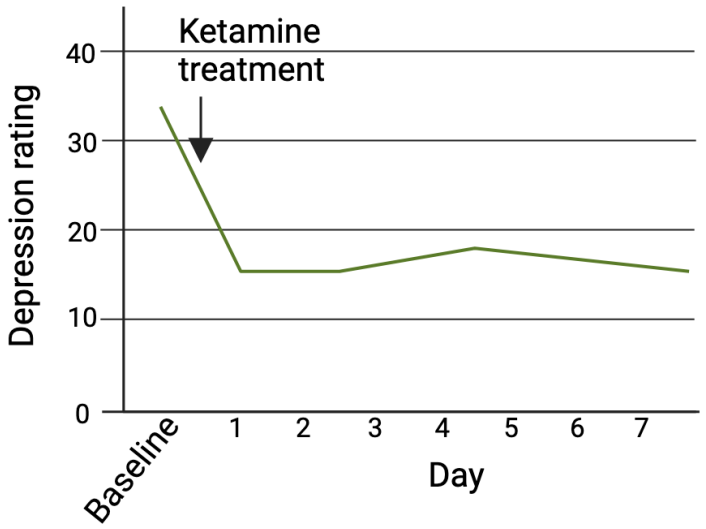

Figure 14.12 Ketamine effects on depression A single administration of ketamine can lead to reduced depressive symptoms within 1 day.

Neuroscience in the lab: Rodent models of depression

While there is no single test that can fully recapitulate the complex symptomatology of MDD, scientists have developed different animal models of depression based on certain physiological or behavioral symptoms seen in humans. A widely used paradigm for inducing depressive and/or anxiety-like behavior in rodents is the unpredictable chronic mild stress (UCMS) model. The procedure involves exposing animals to a randomized sequence of mild stressors (i.e. wet bedding, change of cage mate, white noise) over several weeks. The accumulation of mild but uncontrollable stressors is meant to model long-term stress which is highly associated with the development of depression in humans (see Chapter 12 Stress).

Rodent studies have shown that some animals that undergo UCMS exhibit a reduced preference for a sweetened solution. Diminished motivation for a food reward that the animal would normally seek out is interpreted as anhedonic behavior. Similar to humans, some rodents may be more sensitive to the effects of stress than others. Animals who exhibit behavioral changes following UCMS are considered stress-vulnerable, while those who do not are considered stress-resilient. UCMS was found to impair BDNF activity and dendritic morphology in the hippocampus of stress-vulnerable animals only, suggesting that this mechanism may underlie vulnerability to stress in rats (Tornese et al., 2019). Remarkably, a single administration of ketamine reversed many of the UCMS-induced behavioral and molecular changes in the stress-vulnerable animals within 24 hours. This finding suggests that restoration of synaptic homeostasis may underlie ketamine's rapid-acting antidepressant effects.

People behind the science: Dr. Helen Mayberg

The most robust experimental design for testing the therapeutic effects of a drug in humans is a randomized, placebo-controlled study.A placebo is an inert substance designed to look identical to the experimental drug but has no active ingredients or therapeutic value. In some cases, an individual's interaction with a healthcare provider or perception of treatment alone may be sufficient to alter responses. This is known as the placebo effect. Thus, to determine the true therapeutic value of a drug, it is necessary to discriminate what percentage of the clinical response is due to the drug versus placebo effects.

Although placebo effects have historically been considered a nuisance, they raise the question of whether an individual's beliefs and expectations about treatment can influence neurobiological functioning, and if so, whether these mechanisms can be harnessed to enhance treatment efficacy. Dr. Helen Mayberg, Professor of Neurology, Psychiatry, and Neuroscience at Mount Sinai, explored these questions in the context of the treatment of depression. In a seminal neuroimaging study, Dr. Mayburg found a significant degree of overlap in limbic brain regions that were activated following exposure to a placebo versus an SSRI, suggesting that changes in activity in these areas facilitate therapeutic effects (Mayberg et al., 2002) (Figure 14.13). Interestingly, individuals treated with the SSRI exhibited additional activity changes in subcortical brain regions that were not seen in the placebo group. Thus, changes unique to the treatment group may underlie the actual drug response. These findings highlight the complex neurobiological and psychosocial interactions that regulate mood and behavior.

Clinical use of psychedelics

Psychedelics are a class of psychoactive drugs that are capable of producing hallucinations or altered states of consciousness. This includes ketamine, lysergic acid diethylamide (LSD), and psilocybin, a chemical derived from fungi. While psychedelic substances have been used in spiritual and cultural contexts throughout human history, scientific research into the therapeutic potential of psychedelics first peaked between the 1950s and 1960s. These initial studies provided some promising preliminary results. However, growing societal concerns about recreational drug use led to the creation of government regulations that strictly limited access to psychedelics. In the 1970s, Congress passed the Controlled Substances Act, which made psychedelics illegal to use for all purposes.

The search for novel targets for the treatment of psychiatric disorders has led to a recent revival in psychedelic research. Although psychedelics are still considered controlled substances, the FDA has approved several clinical trials investigating their efficacy in treating anxiety, depression, and substance use disorders. For example, a single dose of psilocybin has been shown to reduce anxiety and depressive symptoms in patients with life-threatening cancer for up to 6 months (Griffiths et al., 2016; Ross et al., 2016).

The neurobiological mechanisms underlying the antidepressant properties of psychedelics are not fully understood. However, there is evidence that their therapeutic effects may be mediated in part through interactions with the serotonergic system. A recent study in a mouse model demonstrated that psilocybin promotes cortical dendritic growth via the activation of intracellular serotonin receptors (Vargas et al., 2023). These neuroplastic changes were associated with a reduction in depressive-like behavior.

Treatment of schizophrenia

Approximately 1% of people in the United States meet the diagnostic criteria for schizophrenia (Ringeisen et al., 2023), a rare mental disorder characterized by disorganized behavior and recurring episodes of psychosis, or severely altered perceptions of reality (see Chapter 19 Attention and Executive Function). The onset of schizophrenia typically occurs between late adolescence and young adulthood (early thirties) (McGrath et al., 2008). Schizophrenia symptoms are commonly divided into two broad categories: positive symptoms, which are indicative of excessive functioning, and negative symptoms, which are indicative of reduced or impaired functioning. Positive symptoms include hallucinations (perceiving something that is not there) and delusions (a false belief not grounded in reality). Negative symptoms include reduced speech, reduced expression of emotion, reduced motivation for or interest in normally enjoyable activities, and cognitive impairments. It is important to note that the

presentation of symptoms often varies between individuals, and there is no single symptom that uniformly occurs in all people with schizophrenia.

Antipsychotics (also known as neuroleptics) are a class of drugs used to treat the symptoms of schizophrenia. First-generation antipsychotics, also known as conventional antipsychotics were first developed in the 1950s, and act as dopamine D2 receptor antagonists. These drugs are effective in reducing the positive symptoms of schizophrenia. This finding has lent support to the dopamine hypothesis of schizophrenia, which proposes that the disorder is caused by overactive dopamine signaling in the brain. However, conventional antipsychotics are less effective in managing negative symptoms, suggesting that other neurotransmitter systems are likely involved in the pathophysiology of schizophrenia. Atypical (second-generation) antipsychotics were developed in the 1970s. In contrast to conventional antipsychotics that primarily target the dopamine system, atypical antipsychotics have been shown to interact with dopamine, serotonin, adrenergic, and cholinergic receptors (Miyamoto et al., 2005). While both conventional and atypical antipsychotics can improve positive symptoms, atypical antipsychotics are more effective in treating certain negative symptoms of schizophrenia. This may be due to their ability to target a broader range of neurotransmitter systems (Gardner et al., 2005). Furthermore, although both classes of antipsychotics carry a risk of adverse side effects including weight gain and sedation, the risk of debilitating motor symptoms, such as uncontrollable muscle contractions and tremors, is higher with typical antipsychotics (Pierre, 2005).

Treatment of attention-deficit/hyperactivity disorder

Attention-deficit/hyperactivity disorder, or ADHD, is characterized by persistent and disruptive inattentiveness, hyperactivity, and/or impulsivity. ADHD is one of the most prevalent childhood neurodevelopmental disorders. In the United States, approximately 10% of children aged 3-17 are diagnosed with ADHD, with boys being twice as likely to be diagnosed than girls (Bitsko et al., 2022). ADHD is typically diagnosed in school-aged children, however, in some cases, symptoms are not detected until adulthood. The estimated prevalence of ADHD in people aged 18 or older ranges between 2.5 and 4.4% (Kessler et al., 2006; Bernardi et al., 2012), although there is evidence suggesting that ADHD is likely underdiagnosed in adults (Ginsberg et al., 2014).

Two of the most commonly prescribed treatments for ADHD, methylphenidate (Ritalin) and amphetamine (Adderall), are psychostimulants, or drugs that increase the activity of the CNS. Specifically, both drugs increase dopamine and norepinephrine release in the brain. It is hypothesized that some of the executive function impairments seen in ADHD, such as increased impulsivity and difficulty focusing, may be caused by deficits in prefrontal cortex (PFC) functioning (Genro et al., 2010). Dopamine and norepinephrine signaling in the PFC is critical for regulating attention, focus, and self-control. Thus, enhancing the concentrations of these neurotransmitters in the PFC likely contributes to the overall therapeutic effects of psychostimulants on ADHD symptoms. Psychostimulants are typically prescribed at low doses, thereby reducing the chance of experiencing euphoric effects.

5.1.4: Neural Circuitry of Drug Reward

Learning Objectives

By the end of this section, you should be able to

- 14.3.1 Identify the major brain regions involved in the dopamine reward pathway.
- 14.3.2 Describe three different mechanisms for how a drug can enhance dopamine release within the reward pathway.

There are certain basic physiological needs, such as food, water, and procreation, that are essential for the survival of the individual and the species. From an evolutionary perspective, it stands to reason that behaviors that promote survival would be perceived as enjoyable to encourage the continued expression of the behavior. The dopamine reward pathway is critical in mediating motivated behavior for rewarding stimuli.

Dopamine reward pathway

The most well-characterized reward circuit in the brain originates in the ventral tegmental area (VTA), which is located in the midbrain. Within the VTA are the cell bodies of dopaminergic neurons, which are cells that synthesize the neurotransmitter dopamine. VTA dopamine neurons have two major projections: the mesolimbic pathway and the mesocortical pathway. Together, these two pathways are collectively referred to as the mesocorticolimbic dopamine pathway. Figure 14.14 shows these connections for a human brain on the left. The right image shows the parallel circuitry in a mouse brain, revealing how highly conserved these connections are between species.

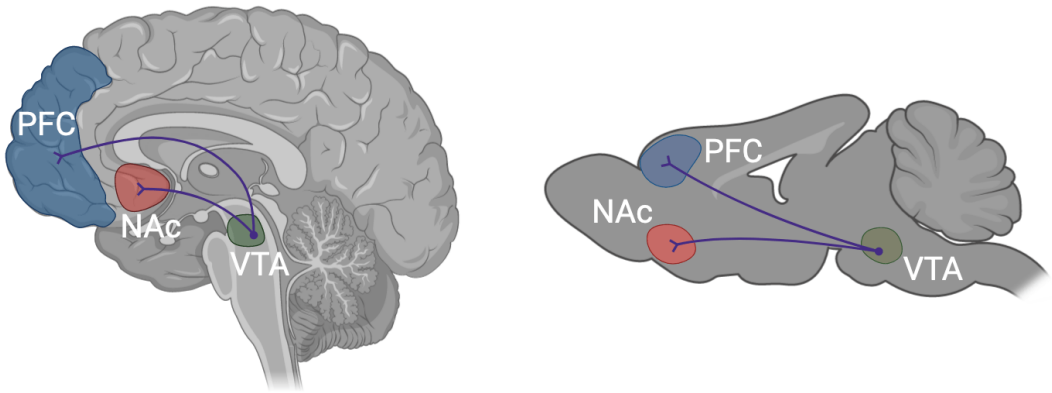

Figure 14.14 Dopaminergic pathways Dopaminergic pathways from the VTA project to PFC and NAc in both humans and rodents.

The mesolimbic pathway is composed of dopaminergic neurons that innervate cells in the nucleus accumbens (NAc), a region of the brain highly implicated in motivation and goal-directed behavior. The impact of rewarding stimuli on dopamine signaling in the NAc was first established using microdialysis, a sampling technique in which extracellular fluid is continuously collected from a probe inserted into brain tissue. The collected fluid, also known as dialysate, can then be analyzed to determine the concentration of specific neurotransmitters at different time intervals. Early microdialysis studies in rats demonstrated increased dopamine release in the NAc in response to several different types of psychoactive drugs (Di Chiara & Imperato, 1988). Similarly, positron emission tomography (PET) studies in humans show that rapid increases in dopamine concentration in the NAc are associated with the reinforcing effects of psychoactive drugs (Volkow et al., 1999).

The mesocortical pathway is made up of VTA dopamine neurons that synapse with cells in the prefrontal cortex (PFC). These dopaminergic projections play an important role in self-control, decision-making and emotional regulation. Dysregulation of this pathway is thought to contribute to the impaired self-control and compulsive behavior seen in addiction.

Although the NAc and PFC are important targets of the brain reward pathway, there are several other brain regions and neurotransmitters that mediate the cognitive processes that encode pleasurable experiences and reinforce reward-seeking

behaviors. The hippocampus and amygdala, for example, are also innervated by dopaminergic neurons that originate in the VTA and play an important role in forming memories and contextual cues associated with rewarding stimuli. To prevent the constant firing of dopaminergic neurons, GABAergic interneurons in the VTA maintain a basal tone by inhibiting dopamine release in the absence of a reward. Brain regions involved with mood regulation and stress reactivity, such as the hypothalamus and lateral habenula, can also modulate the dopamine pathway through both glutamatergic and GABAergic inputs.

Neuroscience in the Lab

Role of dopamine signaling in reward

Dopamine activity within the mesocorticolimbic pathway is a vital component of reward processing. However, the hypothesized functional role of the neurotransmitter in the brain reward system has varied throughout history. The hedonia hypothesis, first coined by Roy Wise in 1980, proposed that dopamine release directly correlates with the hedonic value, or "liking" of a pleasurable stimulus (Wise, 1980). This hypothesis was later challenged by taste reactivity studies in rodents. Similar to humans, rodents exhibit distinct facial expressions in response to appetitive versus aversive tastes. Interestingly, animals who had reduced dopamine levels in the brain reward pathway showed similar appetitive responses to a sweet taste compared to animals who had an intact dopamine system but exhibited less motivation to seek out food rewards (Berridge, Venier, & Robinson, 1989). These findings suggested that while dopamine activity is not necessary for hedonic "liking", it is important for motivational drive.

A separate series of electrophysiological experiments conducted in monkeys provided support for dopamine's involvement in reward-based associative learning as opposed to "liking". Monkeys who were presented with an unexpected appetitive stimulus exhibited increased firing of dopaminergic neurons in the VTA (Schultz, 1986). This effect was not seen when animals were presented with an aversive stimulus. After repeated pairings of an environmental cue with the appetitive stimulus, the VTA dopamine neurons began firing in response to the cue rather than the reward itself (Schultz et al., 1992). If animals were presented with the cue but did not receive the reward, VTA dopamine activity was significantly decreased compared to baseline (Schultz, Apicella, & Ljungberg, 1993).

Together, these observations gave rise to the reward prediction error hypothesis, which argues that dopamine activity encodes the error, or deviation, between predicted and experienced rewards. As illustrated in Figure 14.15, before learning, an unexpected reward elicits a strong dopamine response, which reflects a greater reward than anticipated. Once reward-based associations have been formed with the environmental cue, the cue serves as a predictor of an upcoming reward. Thus, dopamine neurons will fire in response to the cue but not the reward itself, seeing as if the reward is received there is no error between the prediction and outcome. In contrast, the presentation of a cue without the reward results in the suppression of dopamine activity, which indicates that the outcome was less than expected. These signals ultimately serve as an adaptive learning mechanism for seeking out and obtaining rewards.

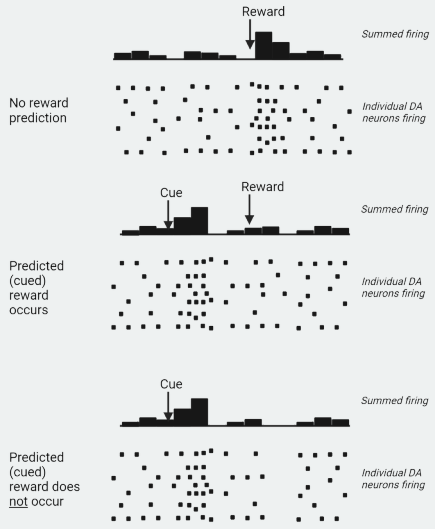

Figure 14.15 Dopamine neurons report prediction error

While the reward prediction error hypothesis helped to establish a role for dopamine in learning, more recent theories also consider the role of dopamine in modulating motivational drive in response to changing physiological and emotional states. For example, an advertisement featuring food may induce a stronger urge to seek out food in a person who is hungry compared to a person who recently consumed a meal. The magnitude of desire or "wanting" for a rewarding stimulus is referred to as incentive salience. The incentive salience theory posits that increased dopamine activity in the mesocorticolimbic pathway enhances motivational "wanting" for previously learned reward-associated cues, thereby increasing the likelihood that the reward will be sought out in the future. Building off of this, the incentive-sensitization theory of addiction hypothesizes that chronic use of psychoactive drugs, such as cocaine and heroin, dysregulates the dopamine reward pathway and enhances the incentive salience of drug-related cues to the point where they are compulsively "wanted", even in the absence of "liking" (Berridge, 2012).

Commonly used psychoactive drugs

In the United States, certain psychoactive drugs are regulated by the FDA and the Drug Enforcement Agency (DEA). These drugs are categorized into one of five schedules based on accepted medical use and potential for addiction (Table 14.2). Schedule I drugs are characterized as having the highest risk for physical and psychological dependence and no accepted medical use, whereas Schedule V drugs have the lowest potential for dependence, although these assessments do not always coincide with current scientific knowledge.

Schedule	Description	Example
Schedule 1	No currently accepted medical use in the US, lack of accepted safety, high potential for psychological and physical dependence	Heroin, LSD, marijuana, ecstasy
Schedule 2	High potential for psychological and physical dependence	Cocaine, oxycodone, fentanyl, methamphetamine
Schedule 3	Moderate to low potential for psychological and physical dependence	Buprenorphine, ketamine, anabolic steroids
Schedule 4	Low potential for psychological and physical dependence	Alprazolam (Xanax), zolpidem (Ambien), diazepam (Valium)
Schedule 5	Lower potential for psychological and physical dependence than Schedule 4	cough medicines with low doses of codeine (Robitussin AC)

Table 14.2

The most commonly used psychoactive drugs fall into four main categories, as shown in Table 14.3.

Category	Effect	Examples
Stimulant	Increases CNS activity	Amphetamine, cocaine, nicotine
Depressant	Decreases CNS activity	Alcohol, Benzodiazepines
Opioid	Pain relief, sedation, euphoria	Fentanyl, heroin, morphine
Hallucinogen	Altered sensory perception	Ketamine, LSD, psilocybin

Table 14.3

Stimulants increase levels of physiological or central nervous system activity in the body, whereas depressants reduce CNS activity. Hallucinogens are drugs that can alter your perceptions or produce changes in cognition, emotion, and consciousness to a degree that is not typically experienced with other drug categories. The term narcotics, which comes from the Greek word for "stupor", was originally used to describe any psychoactive compound with sleep-inducing properties. Nowadays, the term refers specifically to opium derivatives and synthetics. Virtually all psychoactive drugs either stimulate dopamine release or enhance dopamine receptor activity in the NAc, resulting in increased dopamine signaling within the reward pathway. Figure 14.16 shows the actions of several common classes of psychoactive drugs on the mesolimbic dopaminergic system, many of which we will describe further in the sections that follow.

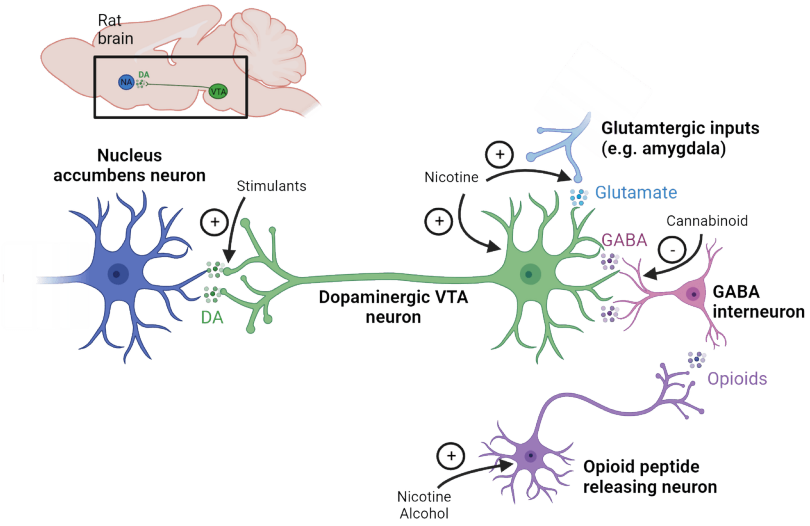

Figure 14.16 Drugs of abuse site of action summary

Opioids

The powerful analgesic and euphoric properties of opioids were recognized as early as 3400 BC. The term opiate refers to substances derived from the opium poppy plant, including morphine, codeine, and heroin (see Chapter 9 Touch and Pain). Semi-synthetic opioids, such as oxycodone and hydrocodone, are drugs that are created from natural opiates. Synthetic opioids, such as fentanyl, are manufactured entirely in a laboratory but have similar cellular and physiological effects to opiates. Opioids are most commonly administered orally via pills or injected intravenously.

Opioid receptors are inhibitory G-protein coupled receptors. Within the dopamine reward pathway, opioid receptors are primarily located on GABAergic interneurons that synapse onto dopaminergic VTA neurons. Activation of these opioid receptors hyperpolarizes the GABAergic interneurons, leading to reduced GABA release. In the absence of inhibitory input, VTA dopamine neurons become more active, resulting in increased dopamine release in the NAc. Another way to describe this mechanism is that opioids disinhibit dopamine neurons in the VTA via their inhibition of GABAergic interneurons.

Opioid receptors are also highly expressed on neurons in the brainstem that control breathing. High doses of opioids (or co-administration of opioids with other depressants) can hyperpolarize these cells, resulting in slowed or stopped breathing, also known as respiratory depression. If not treated, respiratory depression may lead to loss of consciousness, coma, or even death. Naloxone (Narcan) is an opioid receptor antagonist that rapidly blocks the effects of opioid drugs already in the body and can restore normal breathing in a person who is experiencing an overdose.

Alcohol

Alcohol, a depressant, is one of the oldest and most widely used psychoactive drugs in the world. It is produced as a byproduct of the fermentation of sugars by yeast. In 2021, 84% of Americans aged 18 or older reported drinking alcohol at some point in their lifetime (SAMHSA, 2021).

Several different receptor types and neurotransmitters in the brain are affected by alcohol. The reinforcing properties of alcohol are thought to be mediated in part by its modulation of the endogenous opioid system. Alcohol administration increases the synthesis of opioid peptides (i.e. beta-endorphin) in the brain. Similar to exogenous opioid drugs, these peptides also bind to mu-opioid receptors on GABAergic interneurons in the VTA and disinhibit dopamine release in the NAc.

As a positive allosteric modulator of the $GABA_A$ receptor, alcohol also enhances inhibitory signaling in the brain, leading to an overall reduction in arousal.Many of the sedative effects of alcohol, such as slurred speech, incoordination, and slowed reaction time, are mediated by its activity at the $GABA_A$ receptor. Alcohol also suppresses glutamate release and inhibits NMDA receptor signaling, which further reduces CNS activity and also contributes to memory loss and impaired cognitive functioning. As with all drugs, the acute behavioral and physiological effects of alcohol are heavily dependent on the amount that is absorbed

into the bloodstream. Whereas lower concentrations of alcohol may only produce mild symptoms, rapid and excessive alcohol consumption, also known as binge drinking, increases the risk of adverse effects, such as loss of consciousness, coma, or death.

Nicotine

Nicotine, a stimulant substance naturally found in tobacco leaves, is the primary psychoactive chemical in tobacco products such as cigarettes and cigars. Although inhalation is a common route of administration for nicotine, it can also be chewed, snorted, or absorbed through the skin via a patch. In 2021, 22% of Americans aged 12 or older reported using tobacco products or nicotine vaping devices (such as electronic cigarettes) in the past month (SAMHSA, 2021).

Nicotine is an exogenous ligand for the nicotinic acetylcholine receptor (nAChR), an excitatory ligand-gated ion channel expressed widely throughout the brain and peripheral nervous system, although nicotine has a higher affinity for nAChRs in the brain than those in the neuromuscular junction. The reinforcing effects of nicotine are mediated by the activation of nAChRs located within the mesolimbic dopamine pathway. Stimulation of nAChRs expressed on glutamatergic inputs to dopaminergic VTA neurons, and the VTA neurons themselves, elevates dopamine release in the NAc. Similar to alcohol, nicotine also increases the synthesis of endogenous opioid peptides. Nicotine's stimulant effects, including increased heart rate and blood pressure, are due to the activation of nAChRs on the adrenal glands which stimulate the release of epinephrine and norepinephrine. These mechanisms have also been associated with enhanced attention and cognitive performance.

Cocaine

Cocaine is a stimulant chemical derived from the coca plant, which is indigenous to South America. It first became popularized in Western medicine in the 1800s as a cure-all and continues to be used today in medical contexts as a topical analgesic. Small concentrations of cocaine can be ingested by chewing the leaves of the coca plant. However, in modern recreational usage, it is more commonly snorted, smoked, or solubilized and injected intravenously.

Rather than binding to a receptor directly, cocaine exerts its molecular effects by inhibiting reuptake transporter proteins. These proteins are located in the cell membrane and are responsible for removing neurotransmitters from the synaptic cleft by drawing the molecules back into the presynaptic axon terminal. Thus, in the presence of cocaine, dopamine can stay in the synapse longer and continue binding to its receptor on the postsynaptic neuron (Figure 14.17). Similar to nicotine, cocaine also increases physiological arousal by enhancing epinephrine and norepinephrine release in the periphery.

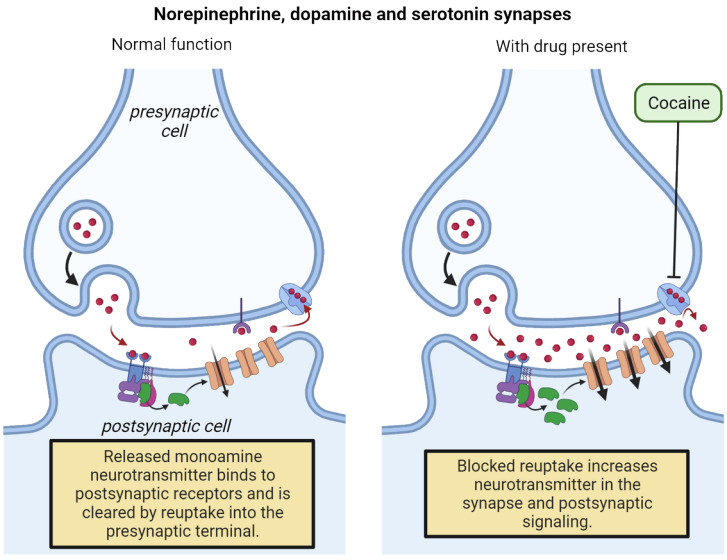

Figure 14.17 Cocaine effects at the synapse

Tetrahydrocannabinol (THC)

The primary psychoactive substance in cannabis (also known as marijuana) is the cannabinoid tetrahydrocannabinol (THC). Cannabis, which is derived from the cannabis plant, is commonly administered via inhalation, although edible formulations have

become popular. THC is the exogenous ligand for the cannabinoid (CB) receptor, a G-protein coupled receptor located throughout the body. There are two subtypes of CB receptors. The CB_1 receptor is expressed primarily in the brain, whereas CB2 receptors are found mainly within the immune system.

The reinforcing effects of THC are mediated by its activity at presynaptic CB_1 receptors located on GABAergic interneurons that innervate dopamine cells. CB_1 receptors are primarily inhibitory G-protein coupled receptors. Therefore, the binding of THC to the receptor hyperpolarizes the GABAergic interneuron and disinhibits dopamine release in the NAc. At low doses, THC can enhance mood and increase relaxation. Higher doses of THC may distort sensory perceptions and induce paranoia, though these effects appear to be rare and may be dependent on the strain, or genotype, of the plant. Cannabidiol (CBD) is another type of cannabinoid found in cannabis that also binds to CB_1 receptors. However, in contrast to THC, CBD does not have any intoxicating effects. This may be because CBD is a negative allosteric modulator of the CB_1 receptor and thus suppresses receptor activation.

At the federal level, cannabis and its derivatives are currently classified as a Schedule 1 drug, although there is strong evidence that cannabinoids are effective in treating certain medical conditions (Whiting et al., 2015). As of 2023, 38 states have legalized the use of cannabis for medical purposes and 23 states and Washington D.C. have legalized cannabis for recreational use by people 21 or older.

5.1.5: Neurobiology of Addiction

Learning Objectives

By the end of this section, you should be able to

- 14.4.1 List and describe the three stages of the addiction cycle.
- 14.4.2 Discuss the advantages and disadvantages of the brain disease model of addiction.

In 2021, over 46 million people met the criteria for having a substance use disorder (SUD) (SAMHSA, 2021). The Diagnostic and Statistical Manual of Mental Disorders (DSM) classifies a SUD as uncontrolled or hazardous substance use despite negative outcomes, such as medical and legal issues, loss of employment, or estrangement from family and friends. While "SUD" and "addiction" are often used interchangeably, SUD severity ranges from mild to severe, with the most severe forms being classified as addiction.

Neurobiological model of addiction

A well-cited neurobiological framework for studying addiction conceptualizes the condition as a repeating cycle composed of three stages that feed into each other (Wise & Koob, 2014) (Figure 14.18).

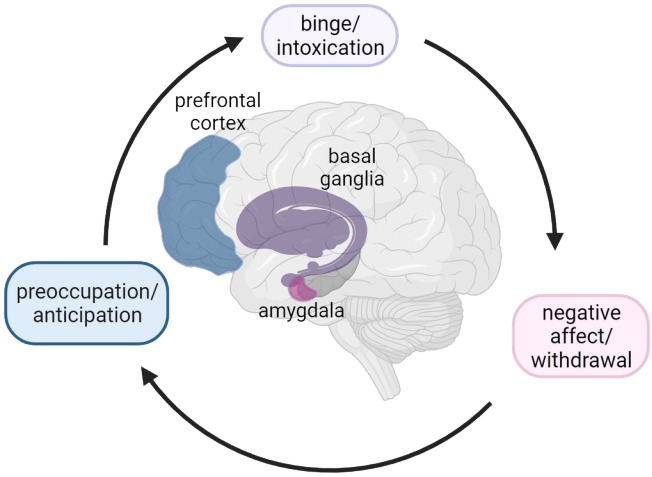

Figure 14.18 Koob model of addiction cycle

The binge/intoxication stage is associated with the initial euphoric effects elicited by many psychoactive drugs, which serve as a powerful reinforcer for continued drug use. In contrast, the withdrawal/negative affect stage is characterized by reduced positive associations with the drug. Prolonged drug use can lead to tolerance, or decreased drug effectiveness over time, in addition to diminished interest or motivation for non-drug-related rewards. Drug cessation may result in withdrawal, a constellation of highly aversive physical (i.e. sweating, vomiting, diarrhea, seizures), and psychological (i.e. anxiety, depression) symptoms. Whereas physical symptoms typically subside within a week or so, the psychological aspects of withdrawal can continue for months or longer. At this stage, drug use is typically motivated by a desire to avoid withdrawal symptoms as opposed to seeking euphoric effects. The preoccupation/anticipation stage occurs during periods of abstinence when individuals experience strong cravings for the drug and become engrossed with seeking out and obtaining the drug. Thus, one of the most challenging aspects of treating SUDs is the risk of chronic relapse or a repeated pattern of returning to drug use after a period of abstinence. The proposed neurobiological mechanisms that contribute to these distinct stages are described below.

Binge/Intoxication

As discussed earlier in the chapter, almost all psychoactive drugs enhance activity in the mesocorticolimbic dopamine system. Importantly, these drug-induced increases in dopamine signaling often occur faster and to a larger and more prolonged extent compared to natural stimuli (Figure 14.19). This extra strong stimulation of the mesolimbic dopamine system is thought to induce neuroplastic changes, such as increased dendritic spines or insertion of receptors into the synapse, within the larger basal ganglia system which regulates complex processes including motivation, decision-making, and emotions. The activation of brain circuits that mediate reward-based learning ultimately increases the incentive salience, or motivational drive, for the drug and drug-associated environmental cues (i.e. specific people, places, or items that have previously been paired with drug use).

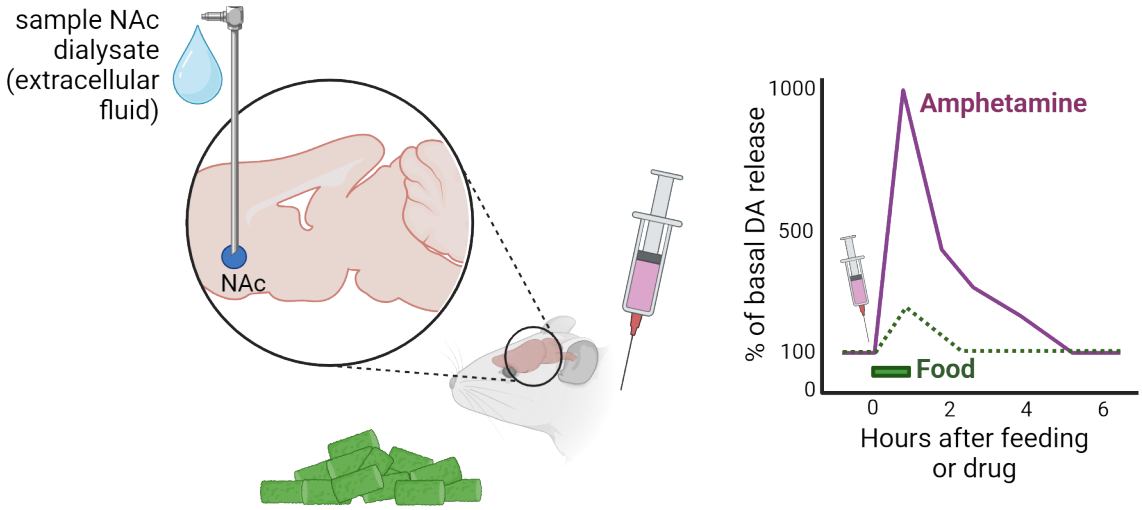

Figure 14.19 NAc dopamine release with food vs amphetamine

Negative Affect/Withdrawal

Drug dependence refers to a physical and/or psychological state in which drug use is necessary to avoid withdrawal. It is typically preceded by the development of tolerance, in which increasingly higher doses of the drug are required to achieve the original effect (Figure 14.20).

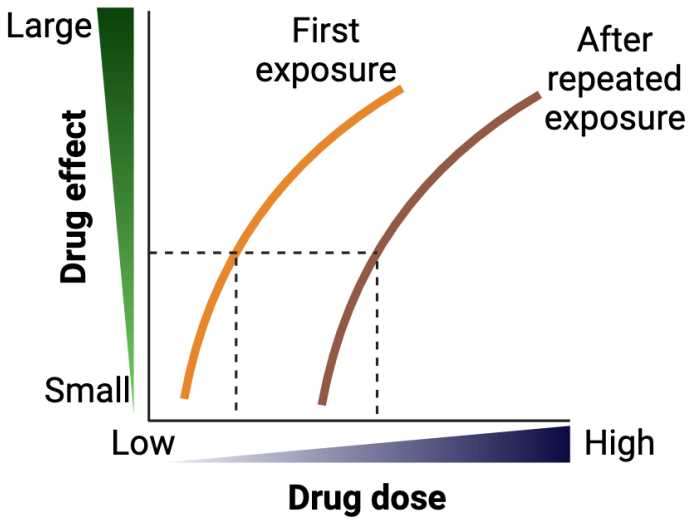

Figure 14.20 Tolerance Repeated use of a drug can lead to a shift in response, such that more drug is needed to achieve the same effect.

Tolerance can arise through several different mechanisms. Drug-induced changes in metabolism, such as elevated liver enzyme activity, can lead to faster degradation and clearance of the drug, resulting in reduced bioavailability. Alternatively, tolerance may be caused by changes in cellular responses to the drug following repeated exposure. For example, whereas initial drug use enhances dopamine release, chronic drug exposure reduces dopamine release and downregulates the expression of dopamine receptors within the dopamine reward pathway (Volkow et al., 1997; Martinez et al., 2004) (Figure 14.21). With less neurotransmitter and receptor availability comes less receptor binding and signaling, ultimately leading to reduced drug effects.

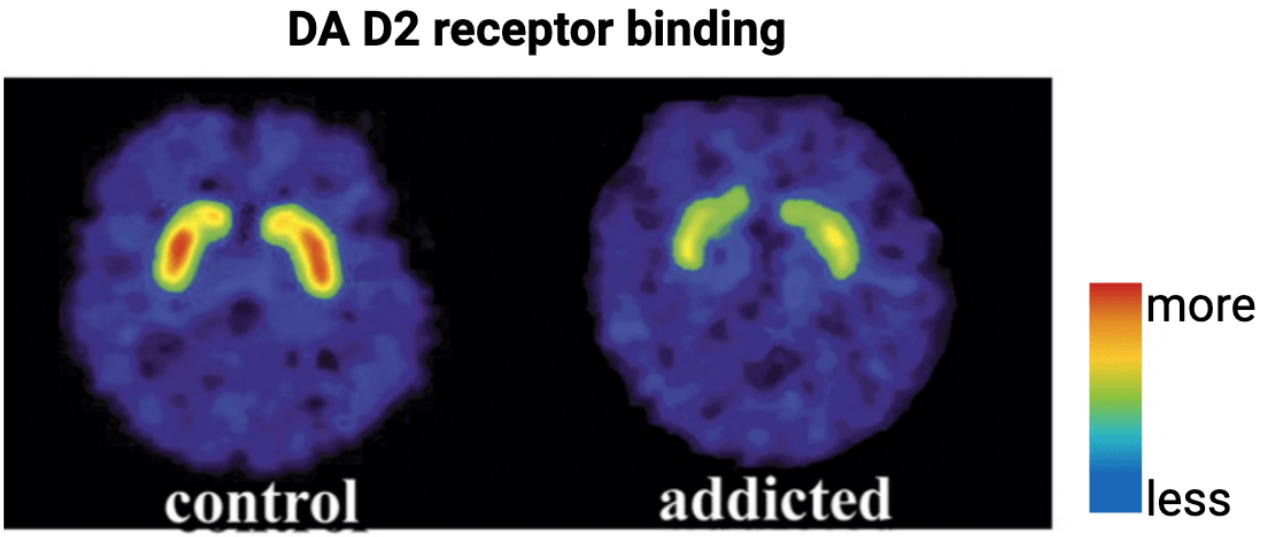

Figure 14.21 Dopamine (DA) D2 receptor binding Position emission topography (PET) scan studies demonstrate reduced expression of D2 dopamine receptors within the basal ganglia of participants with cocaine use disorder compared to controls. Image credit: 1993 Wiley-Liss, Inc. Image reused with permission: Volkow, N.D., Fowler, J.S., Wang, G.-J., Hitzemann, R., Logan, J., Schlyer, D.J., Dewey, S.L. and Wolf, A.P. (1993), Decreased dopamine D2 receptor availability is associated with reduced frontal metabolism in cocaine abusers. Synapse, 14: 169-177. doi.org/10.1002/syn.890140210.

Tolerance can also manifest from conditioned behavioral responses to environmental cues associated with drug use (Siegel, 1999). Drug users who were presented with drug preparation materials and asked to self-inject experienced significantly fewer physiological responses to the drug compared to drug users who received a passive infusion of the drug (Ehran et al., 1992). This finding suggests that the mere anticipation of drug administration may be sufficient to induce compensatory physiological mechanisms that weaken the drug's effects. While drug dependence is highly associated with SUDs, it does not necessarily equate to addiction. For instance, a person who drinks caffeinated beverages daily may become dependent on caffeine and experience withdrawal symptoms (e.g. headache, fatigue, irritability) if they skip a day, but it is highly unlikely that they would develop the pathological behaviors that characterize SUDs.

The negative psychological symptoms associated with chronic drug use and withdrawal are mediated by increased activation of brain stress systems and impaired functioning of reward circuits. While the mechanisms underlying these effects are not well understood, they are thought to be caused by drug-induced neuroadaptations that sensitize circuits involved in stress response. Several rodent studies have demonstrated that withdrawal from chronic drug exposure increases stress hormone activity in the extended amygdala, an anatomical region including the amygdala and bed nucleus of the stria terminalis (BNST) that is highly implicated in both stress response and emotional processing (Koob, 2008) (see Chapter 12 Stress). On the other hand, the blockade of stress hormone signaling prevents the manifestation of anxiety-like behavior following drug cessation. Collectively, these mechanisms are believed to contribute to the aversive psychological components of drug withdrawal that act as a negative reinforcement for continued drug use.

Preoccupation/Anticipation

Increased preoccupation, or fixation on seeking out and obtaining drugs, may be caused by drug-induced alterations in neuronal processes within the hippocampus and prefrontal cortex (PFC). Neuroimaging studies in humans have demonstrated increased hippocampal activation during cue-elicited craving (Volkow, Fowler, & Wang, 2004). Furthermore, individuals diagnosed with a SUD exhibit abnormal activity in the PFC and impaired performance in cognitive tasks that are dependent on the PFC (Bolla et al., 2003). As proposed by the incentive-sensitization theory of addiction, drug-induced dysregulation of reward-based learning

pathways may cause drugs and drug-associated cues to become hyper-salient, leading to intense cravings during abstinence. This, coupled with impaired impulse control and self-regulation mechanisms, may explain why factors such as environmental cues or stress can reinstate uncontrollable drug-seeking behavior in individuals who are in recovery.

Neuroscience across species: Intravenous self-administration

The brain reward system is remarkably conserved across species (see Chapter 4 Comparative Neuroscience). Rodents, in particular, share many of the same brain regions, neurotransmitters, receptors, and genes found in humans. Furthermore, rodents exhibit similar behavioral and neurobiological responses to psychoactive drugs, making them an excellent translational model for investigating the neural mechanisms underlying the different stages of addiction.

Intravenous self-administration (IVSA) is considered the gold standard for studying drug-seeking behavior in an animal model (Figure 14.22). Using IVSA, researchers can examine the variables that contribute to different levels of responding to a drug reward. In this procedure, a catheter is surgically implanted into the jugular vein of a mouse or rat. The catheter is connected to a syringe containing the drug of interest. The rodent is then trained in an operant chamber to press a lever to receive an intravenous delivery of the drug. Often drug delivery is paired with an auditory or visual cue, such as a tone or light.

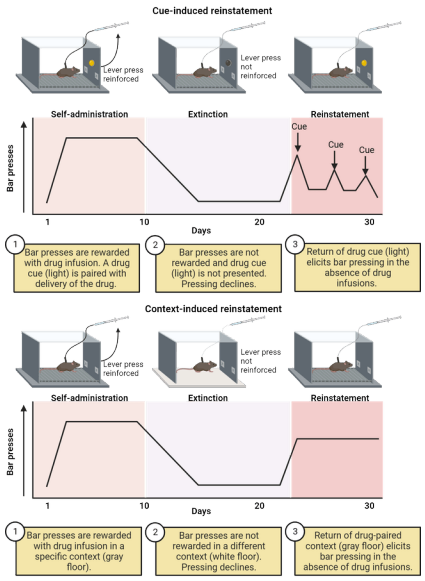

Figure 14.22 Self-administration paradigm

To investigate how much effort an animal will exert to receive the drug, the experimenter can manipulate the ratio schedule, which is the number of lever presses required to receive the drug reward. In a fixed ratio schedule, the animal must perform a predetermined number of lever presses to receive a single delivery of the drug. For example, in a fixed ratio 1 schedule (FR1), the animal receives one delivery for each lever press within a session, whereas a fixed ratio 5 schedule (FR5) requires the animal to perform at least 5 lever presses to receive a single dose. In contrast, a progressive ratio schedule requires escalating responses for a single delivery within a session. In this scenario, the animal may initially only need to lever press a few times to receive one delivery, but over time may need to lever press over a hundred times to receive the same reward. The highest ratio schedule achieved within a certain time period before the animal stops responding is referred to as the breakpoint. A high breakpoint is indicative of increased motivational desire or “wanting” of the drug.

During extinction, the drug and drug-associated cues are removed, or the chamber context is changed (different wall pattern, floor texture, odor, etc.). Over time, the lack of reinforcement leads to a reduction in lever pressing. However, drug-seeking behavior (i.e. lever pressing) can be quickly restored by either exposing the animal to a drug-associated context or cue, a stressor (i.e. footshock), or an injection of the drug itself before testing. This phenomenon is referred to as reinstatement and closely mimics relapse behavior in humans. The top of Figure 14.22 shows this experimental paradigm coupled with cue-induced reinstatement while the bottom shows context-induced reinstatement. Note in both cases that bar pressing increases during self-administration when lever pressing is reinforced by drug infusions, decreases during extinction when the drug and associated cue or context is removed, and increases again when either the drug-associated cue or context is returned in the absence of reinforcement from drug infusions.

History of neuroscience: Opioid crisis

In 2017, the opioid crisis was declared a public health emergency in the United States. The history of this epidemic is often characterized by three distinct waves of opioid-related overdose deaths, with the first wave beginning in the 1990s. This first wave can be traced to a change in how pain was treated medically. In 1996, the American Pain Society instituted pain as the fifth vital sign (in addition to body temperature, heart rate, respiration rate, and blood pressure). Consequently, healthcare institutions revised their guidelines to prioritize pain assessment and management. Around the same time, the pharmaceutical company Purdue Pharmaceutical released OxyContin, a sustained-release opioid painkiller. OxyContin was aggressively marketed to physicians and pain management professionals as a non-addictive opioid, even though these claims were never substantiated with clinical evidence. This marketing campaign led to the overprescription of opioids and the subsequent rise in prescription opioid overdoses between the late 1990s to 2010.

In response to these deaths, state and federal agencies began monitoring the distribution of prescription opioids, and physicians were issued guidelines on more conservative prescribing of opioids. The second wave of the opioid epidemic coincided with the increased availability of heroin in the United States. Many individuals who had become dependent on prescription opioids switched to heroin because it was cheaper and easier to obtain. Consequently, heroin-related overdoses increased fivefold between 2010 and 2016.

The third wave of the opioid epidemic began in 2013 and was driven by the import of synthetic opioids, such as fentanyl, into the drug market. Fentanyl is significantly more potent than heroin, which makes it more addictive, but also increases the risk of overdose. The emergence of the Covid-19 pandemic in 2020 and subsequent disruptions in health care combined with social and economic stressors further exacerbated the opioid crisis. Synthetic opioids are currently the leading cause of drug overdose deaths. In 2018, the National Institutes of Health launched the HEAL (Helping to End Addiction Long-term) Initiative to address the opioid crisis. The initiative seeks to develop more effective and evidence-based approaches to treating opioid use disorder and enhancing pain management.

Risk/protective factors

Many people use drugs with high addictive potential without ever developing an addiction. However, several genetic and environmental factors have been associated with an increased risk of developing a substance use disorder (SUD). At the individual level, biological or genetic predispositions can contribute to an increased likelihood of drug misuse. Genome-wide association studies (GWAS) have helped to identify genetic variants that are associated with certain SUDs. For example, a mutation in the gene that codes for the mu-opioid receptor (OPRM1 A118G) is associated with higher susceptibility to developing opioid dependence in certain populations (Bond et al., 1998). In addition to potential heritable factors, a family history of drug use can compound risk by increasing access to or availability of the drug. Early-life drug use (during childhood or adolescence) can alter brain development, which may contribute to long-term behavioral and cognitive issues in addition to an increased risk of developing a SUD later in life (Moustafa et al., 2021). Certain personality traits, such as impulsivity, have been linked to an increased risk of addiction (Ersche et al., 2010). Furthermore, mental health disorders, including anxiety, depression, attention deficit hyperactivity disorder (ADHD), and post-traumatic stress disorder (PTSD), are often comorbid with SUDs.

Many psychosocial and environmental variables can serve as protective factors by either reducing the likelihood that the individual develops an addiction in the first place or enhancing access to treatment in the case they are diagnosed with a SUD.Protective factors include supportive social structures, participation in community-based initiatives, treatment availability, and access, educational campaigns, beneficial economic conditions, and insurance coverage to name a few.

People behind the science: Dr. Yasmin Hurd

The past few decades have witnessed a significant shift in policies surrounding the medical and recreational use of cannabis at the state level. With the increased prevalence of cannabis products across the country, concerns have been raised about the potentially harmful long-term effects of cannabis use. Dr. Yasmin Hurd, a neuroscientist at the Icahn School of Medicine at Mount Sinai (Figure 14.23), is well known for her contributions to enhancing our understanding of the neurodevelopmental effects of early-life THC (the active ingredient in cannabis) exposure. Her laboratory uses both preclinical (involving animal models) and clinical studies to better understand the neurobiological mechanisms that underlie addiction and other neuropsychiatric disorders. This approach to science is known as translational research since the goal is to convert basic science findings into information that can ultimately benefit humans.

Figure 14.23 Dr. Yasmin Hurd Image from: By Droldn, CC BY-SA 4.0, https://commons.wikimedia.org/w/inde...curid=64216948

In an innovative study combining both animal and human research, Dr. Hurd and her colleagues investigated postmortem fetal brain samples that had either been exposed to cannabis during gestation or had no prenatal exposure (DiNieri et al., 2011). They found that gestational exposure to cannabis was associated with decreased dopamine receptor expression in the nucleus accumbens (NAc), a brain region highly implicated in reward processing.

To further examine the effects of cannabis on the developing brain, Dr. Hurd's research team developed a rodent model in which pregnant rats were treated with daily intravenous injections of either THC or an inactive solution throughout gestation. To control for the potential effects of drug exposure on maternal behavior, offspring of THC-exposed rats were fostered by rats that had no drug exposure. Brain samples were collected on postnatal day 2 (a developmental period comparable to the second trimester of a human pregnancy) and at 8 weeks, which is considered young adulthood in rodents. Similar to the human fetal brain samples, rats prenatally exposed to THC exhibited reduced dopamine receptor expression in the NAc compared to non-exposed controls shortly after birth. Strikingly, this effect was still observed at the 8-week time point. Furthermore, adult rats who had previously been exposed to THC demonstrated increased sensitivity to opioid rewards. Taken together, these findings suggest that early-life THC exposure has long-lasting effects on dopamine receptor function within the mesocorticolimbic pathway, which may increase vulnerability to the reinforcing effects of psychoactive drugs later in life.

Science as a process: Is addiction a brain disease?

The brain disease model of addiction characterizes addiction as a chronic and relapsing condition that arises from drug-induced neuroplastic changes in the reward and mood circuits of the brain. Sensitization of brain reward systems causes drugs and drug-associated stimuli to become compulsively "wanted", leading to a persistent craving. Over time, the development of tolerance and recruitment of "anti-reward" brain systems reduces the amount of pleasure gained from the drug and increases negative affect in the absence of the drug. Collectively, these neuroadaptations are thought to underlie behavioral shifts from constrained to compulsive drug use which can overcome the will to abstain from drug use.

The brain disease model has been influential in the development of evidence-based treatments for addiction, such as medication for reducing craving and withdrawal, and cognitive behavioral therapies for improving self-regulation. Classifying addiction as a disease has helped inform public health policy, such as the Mental Health Parity and Addiction Equity Act of 2008, which required that health insurance plans provide the same level of benefits for SUD treatment as other medical illnesses. Additionally, proponents argue that the brain disease model helps to reduce the stigmatization of addiction as a moral failing, which in turn reduces barriers to seeking out treatment.

Although the brain disease model has grown in popularity over the last few decades, several issues have been raised regarding this theory. Opponents of the brain disease model argue that it overemphasizes biological processes while downplaying the influence of societal, psychosocial and environmental factors. There are concerns that this may lead to an over-reliance on biomedical approaches at the expense of more holistic public health strategies. Furthermore, some argue that labeling addiction as a disease diminishes personal agency and motivation to change behaviors. Alternative theories propose that rather than a

pathological state, addiction is a natural learned response to rewarding environmental stimuli that can be overcome by behavioral and cognitive modifications.

Factors such as the route of administration and the rate of absorption, metabolism, and excretion can impact the ultimate concentration of a drug that ends up in the circulatory system. Drugs that can cross the blood-brain barrier can interact with neurotransmitters and receptors in the brain through a variety of mechanisms that can ultimately impact neuronal signaling. Understanding the pharmacodynamic and pharmacokinetic profile of drugs is essential for predicting their effects on mood, cognition and behavior.

14.2 Psychotherapeutics

Psychotherapeutics are prescription drugs used for the treatment of mental disorders. Benzodiazepines, a class of drugs commonly used to treat anxiety, alleviate symptoms by increasing GABAergic signaling in the brain. SSRIs are first-line treatments for depression that increase serotonin levels by blocking the reuptake of serotonin, though their therapeutic effects likely involve other neurotransmitter systems. Recent research investigating the therapeutic effects of psychedelics has revealed novel mechanisms for antidepressant effects. Antipsychotics that block dopamine D2 receptors reduce positive symptoms of schizophrenia, whereas the modulation of multiple neurotransmitter systems appears to be more effective in treating negative symptoms. Lastly, psychostimulants help increase attention and focus in patients with ADHD by enhancing dopamine signaling in the prefrontal cortex.

14.3 Neural Circuitry of Drug Reward

The mesocorticolimbic dopamine reward pathway plays a crucial role in the reward-related cognitive processes that reinforce pleasurable stimuli and experiences. Consequently, the anticipation of these positive emotions contributes to motivation to seek out the rewarding stimulus. The majority of commonly used psychoactive drugs activate the mesocorticolimbic dopamine system in some manner. Enhanced dopamine release in the nucleus accumbens is believed to underlie the reinforcing effects of these drugs.

14.4 Neurobiology of Addiction

There are many different reasons why an individual may initiate drug use. However, a single or even a few exposures to a drug rarely result in a SUD. The transition from controlled to compulsive drug use is likely mediated by drug-induced neuroplastic changes in brain reward and stress response circuits that enhance incentive salience for drug-related cues and generate negative emotional states in the absence of the drug. Although the neurobiological framework for studying addiction has helped to advance our understanding of the biological mechanisms that mediate drug-seeking behavior, it is important to also consider the societal, social, psychological, and environmental factors that contribute to the overall risk of developing a SUD.

5.1.7: Key Terms

14.1 Basic Principles of Pharmacology

pharmacodynamics, bioavailability, therapeutic window, pharmacokinetics, enteral, parenteral, onset of action, oral, first-pass metabolism, intravenous, inhalation, intranasal, transdermal, blood-brain barrier, lipid-solubility, prodrugs, drug-drug interactions, competitive enzyme inhibition, half-life, duration of action, binding site, ligand, binding affinity, ligand-gated ion channels, metabotropic receptors, endogenous ligand, exogenous ligand, dose-response curve, full agonist, partial agonist, constitutive activity, inverse agonist, antagonist, biased agonism, allosteric modulator

14.2 Psychotherapeutics

Psychotherapeutics, benzodiazepines, light-dark choice test, major depressive disorder (MDD), anhedonia, comorbid, selective serotonin reuptake inhibitors, first-line medications, monoamine hypothesis, neurotrophic model, brain-derived neurotrophic factor, treatment-resistant depression, unpredictable chronic mild stress, placebo, placebo effect, psychosis, positive symptoms, negative symptoms, conventional antipsychotics, atypical antipsychotics, psychostimulants

14.3 Neural Circuitry of Drug Reward

ventral tegmental area, mesolimbic pathway, mesocortical pathway, mesocorticolimbic dopamine pathway, nucleus accumbens, microdialysis, prefrontal cortex, hedonia hypothesis, reward prediction error hypothesis, incentive salience theory, stimulants, depressants, hallucinogens, narcotics, opiate, respiratory depression, naloxone, binge drinking, nicotinic acetylcholine receptor, cannabinoid receptor

14.4 Neurobiology of Addiction

substance use disorder, tolerance, withdrawal, chronic relapse, dependence, intravenous self-administration, fixed ratio schedule, progressive ratio schedule, breakpoint, extinction, reinstatement, genome-wide association studies, brain disease model of addiction

This page titled 5.1.7: Key Terms is shared under a CC BY-NC 4.0 license and was authored, remixed, and/or curated by Ivette Merced via source content that was edited to the style and standards of the LibreTexts platform.

- 14.7: Key Terms by OpenStax is licensed CC BY 4.0. Original source: https://openstax.org/books/introduction-behavioral-neuroscience.

5.1.9: Multiple Choice

14.1 Basic Principles of Pharmacology

1.
In some situations, it is preferable for medication to be active only during certain times of the day. Which characteristic of the drug would be most useful in preventing unwanted extended effects of the drug?

a. A drug delivered via transdermal patch
b. A drug with a short half-life
c. A drug with a long half-life
d. A large dose of a drug

2 .
First pass-metabolism occurs with which route of administration?

a. Inhalation
b. Intranasal
c. Intravenous
d. Oral

3.
Which route of administration results in the fastest onset of action?

a. Oral
b. Intranasal
c. Intravenous
d. Transdermal

4 .
What type of drug is most likely to cross the blood-brain barrier?

a. Large molecule
b. Positively charged molecule
c. Small molecule
d. Non-lipid soluble

5.
Which type of receptor is primarily responsible for fast synaptic transmission?

a. Ionotropic receptor
b. Metabotropic receptor
c. G-protein coupled receptor
d. Kinase receptor

6 .
Which of the following would have the lowest receptor response with increasing dose?

a. Full agonist
b. Inverse agonist
c. Antagonist
d. Partial agonist

7.
What does the term binding affinity refer to?

a. The concentration of neurotransmitter in the synapse

b. The ability of a drug to cross the blood-brain barrier
c. The rate at which a drug is metabolized in the body
d. The strength of the interaction between a drug and target receptor

8 .
Which of the following best describes the therapeutic window of a drug?

a. The range of doses in which a drug is both safe and effective
b. The time it takes for a drug to completely metabolize in the body
c. The minimum tolerated dose of a drug
d. The time it takes for a drug to produce its maximum effect

9.
Which of the following statements about g-protein coupled receptors is false?

a. When activated they can stimulate intracellular signaling
b. They are also known as metabotropic receptors
c. The receptor itself is an ion channel that is activated by the binding of a ligand
d. The effects of receptor activation are slow-acting

14.2 Psychotherapeutics

10 .
What does the microdialysis technique allow you to measure?

a. The electrical activity of neurons
b. The amount of neurotransmitter release
c. The structural integrity of white matter
d. The expression of a specific genes

11.
Where in the brain are dopamine-producing neurons located?

a. Hippocampus
b. Amygdala
c. Ventral tegmental area
d. Nucleus accumbens

12 .
Which theory proposes that dopamine activity encodes the difference between expected rewards and actual outcomes?

a. Incentive salience theory
b. Hedonia hypothesis
c. Reward prediction error hypothesis
d. Arousal theory

13.
Which of the following is considered a depressant drug?

a. Ketamine
b. Alcohol
c. Cocaine
d. Cannabis

14 .
Which of the following drugs increase dopamine signaling in the nucleus accumbens by blocking transporters in the presynaptic membrane?

a. Cocaine

b. Alcohol
c. Opioids
d. Nicotine

14.3 Neural Circuitry of Drug Reward

15.
Which of the following is considered a risk factor for developing a substance use disorder?

a. Biological or genetic predispositions
b. Family history of drug use
c. Early-life drug use
d. All of the above

16 .
Which of the following best characterizes drug dependence?

a. An increase in the effective of a drug after prolonged use
b. The development of allergic reactions to a drug
c. A physical or psychological need for a drug accompanied by withdrawal symptoms upon cessation
d. The occasional use of a drug

17.
Which of the following best characterizes the third wave of the opioid epidemic in the United States?

a. Increased availability of synthetic opioids (i.e. fentanyl)
b. Over prescription of OxyContin
c. Increased availability of heroin
d. The inclusion of pain as the fifth vital sign

18 .
Which is not a stage in the addiction cycle?

a. Recovery/remission
b. Preoccupation/anticipation
c. Negative affect/withdrawal
d. Binge/intoxication

14.4 Neurobiology of Addiction

19.
Which of the following is considered a first-line medication for the treatment of depression?

a. Lithium
b. Ketamine
c. Selective serotonin reuptake inhibitors (SSRIs)
d. Benzodiazepines

20 .
Which of the following statements about the neurotrophic model is true?

a. It proposes that reduced levels of BDNF in the brain contribute to the development of depression
b. It proposes that increased levels of neurotrophins contributes to the development of depression
c. It proposes that depression is primarily caused by chemical imbalances in the brain
d. It proposes that genetics play a minimal role in depression

21.
What is the primary mechanism of action for benzodiazepines?

a. Inhibits serotonin reuptake
b. Blocks NMDA receptors
c. Increases activation of GABA receptors
d. Increases activation of dopamine receptors

22 .
Which of the following drugs is not considered a psychedelic?

a. Psilocybin
b. Nicotine
c. LSD
d. Ketamine

23.
Which of the following statements best describes the placebo effect?

a. The unintended negative side effects of a placebo treatment
b. The process of comparing the effects of an experimental drug to a placebo treatment
c. The phenomenon in which a person experiences physiological and psychological effects due their belief in the effectiveness of a drug
d. The tendency for participants to report false symptoms

24 .
Which is not a mechanism by which drugs are known to alter synaptic transmission?

a. Blocking reuptake mechanisms
b. Inhibiting enzymes that degrade neurotransmitter
c. Increasing or decreasing rates of neurotransmitter synthesis
d. All of the above are known mechanisms

5.1.10: Fill in the Blank

14.1 Basic Principles of Pharmacology

1.
_____ refers to the physiological and behavioral effects of drugs, whereas _____ refers to the movement of the drug throughout the body.
2 .
An _____ is a ligand that prevents the activation of the receptor by blocking the binding of the agonist.

14.2 Psychotherapeutics

3.
Dopaminergic neurons synthesize the neurotransmitter dopamine and their cell bodies are located in the _____.
4 .
_____ activate mu-opioid receptors on GABAergic VTA interneurons, leading to inhibition of GABA neurons and increased dopamine release onto the NAc.

14.3 Neural Circuitry of Drug Reward

5.
The _____ stage of addiction is associated with the euphoric effects of many psychoactive drugs.

14.4 Neurobiology of Addiction

6 .
_____ block reuptake of serotonin into presynaptic terminals, leading to increased postsynaptic serotonin signaling.

5.2: Psychopharmacology and Psychoactive Drug Classification

Learning Objectives

1. Describe the general principles of psychopharmacology.
2. Explain the criteria for psychoactive drugs and the various types of classification systems.
3. Differentiate drug types based on their neurochemical effects on neurotransmission and behavioral impacts.

Overview

Psychopharmacology is the study of how drugs affect how we think, feel, or behave most often through their actions on the nervous system. Understanding some of the basics about psychopharmacology can help us better explain a wide range of issues that interest psychologists and others. For example, the pharmacological treatment of certain neurodegenerative diseases such as Parkinson's and Alzheimer's disease tells us something about the disease itself. The pharmacological treatments used to treat psychiatric conditions such as schizophrenia or depression have undergone amazing development since the 1950s, and the drugs used to treat these disorders provide clues to what is happening in the brain of individuals with these conditions. Finally, understanding something about the actions of drugs of abuse on the nervous system and the way they are processed by the body can help us understand why some psychoactive drugs are so likely to be abused. In this chapter, we will provide an overview of some of these topics as well as discuss some current controversial areas in the field of psychopharmacology.

Psychopharmacology

Psychopharmacology, the study of how drugs affect the brain and behavior, is a relatively new science, although people have probably been taking drugs to change how they feel from early in human history (consider the eating of fermented fruit, ancient beer recipes, chewing on the leaves of the cocaine plant for stimulant properties as just some examples). The word *psychopharmacology* itself tells us that this is a field that bridges our understanding of behavior, brain function, and pharmacology. Additionally, the topics included within this field are extremely broad including the influence of expectations of drug effects, how the drug is processed by the body, and ultimately, to how the drug impacts various systems, particularly the central nervous system.

Psychoactive Drugs

If a drug changes the way you feel, think, or behave it is often doing so by acting on your brain and other parts of your nervous system. We call these ***psychoactive* drugs,** and almost everyone has used them at some point (yes, caffeine counts). Virtually all psychoactive drugs cause psychological or behavioral changes by altering how neurons communicate with each other. It is important to recall that neurons communicate with each other by releasing **neurotransmitters** across the **synapse**. When the neurotransmitter crosses the synapse, it binds to a postsynaptic receptor (protein) on the receiving neuron and the message may then be transmitted onward. Neurotransmission is far more complicated than this, but the first step is understanding that virtually all **psychoactive drugs** alter how neurons communicate with each other in one way or another. While some drugs, such as most antidepressants and many stimulants, have well-defined effects at the level of the neuron, others, like alcohol, have more widespread and less-clear effects.

Some of the most important in terms of psychopharmacological treatment and drugs of abuse are outlined in Table 1. The neurons that release these neurotransmitters, for the most part, are localized within specific circuits of the brain that mediate specific types of behaviors.

Table 1: Key Neurotransmitters and Highlights of Their Neural, Behavioral, and Psychological Effects

Neurotransmitter	Abbreviation	Behaviors or Diseases Related to These Neurotransmitters
Acetylcholine	ACh	Learning and memory; Alzheimer's disease; Voluntary muscle movement in the peripheral nervous system
Dopamine	DA	Reward circuits; Motor control; Parkinson's disease; Schizophrenia
Norepinephrine	NE	Arousal; Depression
Serotonin	5-HT	Depression; Aggression; Schizophrenia
Glutamate	GLU	Learning; Major excitatory neurotransmitter in the brain
GABA	GABA	Anxiety disorders; Epilepsy; Major inhibitory neurotransmitter in the bran
Endogenous Opioids	Endorphins, Enkephalins	Pain; Analgesia; Reward

Psychoactive drugs can either increase the typical effect of neurotransmitters at the synapse (these are called **agonists**) or decrease it (**antagonists**). It is important to remember that the "typical" effect of a neurotransmitter can be either excitatory or inhibitory depending on the type of receptor it binds to. For example, stimulant drugs, such as amphetamine, methamphetamine, or ADHD medications like Adderall are agonists for dopamine and norepinephrine systems and can increase the "typical" *excitation* that occurs at certain dopamine or norepinephrine receptors. Other agonistic drugs, such as morphine and fentanyl will increase the typical *inhibitory* effect at many of our endogenous opioid (endorphin) synapses. In other words, acting as an agonist at an inhibitory receptor will cause even more inhibition than without the drug present. Antagonists for these same systems will have the opposite effects, such as the effect of the opioid receptor blocker, naloxone (Narcan) which results in less inhibition at endogenous opioid synapses. Yes, this is complicated, but you just need to remember that agonist drugs increase and antagonist drugs decrease whatever the typical effect is at a particular synapse, be it excitatory or inhibitory.

There are various ways that drugs can effect the steps of synaptic communication and, thus produce their agonistic and antagonistic effects. Some of these are more intuitive than others. For example, antidepressants such as Prozac or Celexa are selective serotonin reuptake inhibitors (commonly referred to as SSRIs) are agonists for the serotonin system. However, they achieve increased serotonin activity at the synapse by *blocking* the reuptake of serotonin back into the presynaptic axon terminal from which it was released. In other words, they increase serotonin activity by interfering with the mechanism that normally turns its activity off (i.e., reuptake). As you can see, the basic distinction of whether a drug is an agonist or antagonist can get quite complicated very quickly. More examples of agonists and antagonists for various neurotransmitter systems are presented in Table 2. For each example, the drug's trade name, which is the name of the drug provided by the drug company, and generic name (in parentheses) are provided.

Table 2 provides examples of drugs and their primary mechanism of action, but it is very important to realize that drugs can also have effects on other neurotransmitters or even hormones. Sometimes these varied effects can change the potency and/or effectiveness of a drug. This could prove useful when trying to find just the right combination of transmitter action to treat an individual's psychological disorder. Or it could be problematic if it leads to unwanted side effects. The reality is that most drugs currently available work only where we would like them to in the brain or only on a specific neurotransmitter. In many cases, individuals are sometimes prescribed one drug but then may also have to take additional drugs to reduce the side effects. Sometimes individuals stop taking medication because the side effects are so profound.

Table 2: Drug function and mechanism

Drug	Mechanism	Use	Agonist/ Antagonist
Seroquel (quetiapine)	Blocks DA and 5-HT receptors	Schizophrenia, bipolar disorder	Antagonist for DA, 5-HT
L-dopa	Increase synthesis of DA	Parkinson's disease	Agonist for DA
Prozac (fluoxetine)	Blocks removal of 5-HT from synapse (prevents reuptake)	Depression, obsessive compulsive disorder	Agonist 5-HT
Aricept (donepezil)	Blocks removal of ACh from synapse	Alzheimer's disease	Agonist for ACh

Drug	Mechanism	Use	Agonist/ Antagonist
Revia (naltrexone)	Blocks opioid post-synaptic receptors	Alcoholism, opioid addiction	Antagonist (for opioids)
Adderall (mixed salts amphetamine)	Increase release of DA, NE	ADHD	Agonist for DA, NE
Ritalin (methylphenidate)	Blocks removal of DA, NE, and lesser (5-HT) from synapse	ADHD	Agonist for DA, NE mostly

Drug Classifications

Art in a Cup

Who knew that a cup of coffee could also be a work of art? A talented barista can make coffee look as good as it tastes. If you are a coffee drinker, you probably know that coffee can also affect your mental state. It can make you more alert and may improve your concentration. That's because the caffeine in coffee is a psychoactive drug. In fact, caffeine is the most widely consumed psychoactive substance in the world. In North America, for example, 90 percent of adults consume caffeine daily.

Figure 5.2.1: Murano Coffee with decoration on the surface.

Besides caffeine, other examples of psychoactive drugs include anti-anxiety medications (Xanax, Valium), antidepressants (Prozac, Celexa), alcohol, tobacco, marijuana, cocaine, psilocybin, oxycodone, and morphine. Organizing the wide range of different drugs into distinct categories is no easy task. One of the challenges is their various and, sometimes overlapping, pharmacological effects and mechanisms of action. Another challenge is that psychoactive drugs may be used for a variety of purposes, including therapeutic, ritual, and/or recreational.

In addition, many of these drugs may be legal prescription medications (e.g., oxycodone and morphine), legal nonprescription drugs (e.g., alcohol and tobacco), or illegal drugs (cocaine and psilocybin). To further complicate matters, some of these drugs, legal or not can be both therapeutic and abused. The status of cannabis (or marijuana), for example, is in flux, at least in the United States. Depending on where you are, cannabis may be used recreationally and/or medically, and it may be either legal or illegal. Legal prescription medications, such as opioids are also used illegally by alarmingly large numbers of people, resulting in a tragically high number of overdose deaths.

Although classification of psychoactive drugs is clearly complicated, there are some general categorizations that can prove useful.

Classification Based on Psychopharmacological Effects

Psychoactive drugs can be divided into different classes according to their psychopharmacological effects. Several classes are listed below, along with examples of commonly used drugs in each class.

- ***Stimulants***: Stimulate the brain and increase alertness and wakefulness. Examples of stimulants include caffeine, nicotine, cocaine, and amphetamines.
- ***Depressants***: Calm the brain, reduce anxious feelings, and induce sleepiness. Examples of depressants include ethanol (in alcoholic beverages) and opioids such as oxycodone and heroin.
- ***Anxiolytics***: Have a tranquilizing (calming) effect and inhibit anxiety. Examples of anxiolytic drugs include benzodiazepines such as diazepam (Valium), barbiturates such as phenobarbital, opioids, cannabis, and antidepressant drugs such as sertraline (Zoloft).
- ***Euphoriants***: Cause a state of euphoria, or intense feelings of well-being and happiness. Examples of euphoriants include the so-called club drug MDMA (ecstasy), amphetamines, ethanol, and opioids such as morphine.
- ***Hallucinogens***: Cause hallucinations and other perceptual anomalies. They also cause subjective changes in thoughts, emotions, and consciousness. Examples of hallucinogens include LSD, mescaline, nitrous oxide, and psilocybin.
- ***Empathogens***: Produce feelings of empathy, or sympathy with other people. Examples of empathogens include MDMA (Ectasy).

Figure 5.2.2: Ecstasy (MDMA) is most commonly taken in tablet form, like the colorful and decorated tablets shown

Many psychoactive drugs have multiple effects so they may be placed in more than one class. For example, many stimulants also have euphoriant properties, such as MDMA (Ectasy). Furthermore, MDMA may also act as an empathogen or hallucinogen. As of 2016, MDMA had no accepted medical uses, but is undergoing testing for use in the treatment of post-traumatic stress disorder and certain other types of anxiety disorders (Mitchell et al., 2021). As you can tell, drug classification can get a bit complicated.

Classification Based on Synaptic Mechanisms of Action

As previously stated, psychoactive drugs generally produce their effects by affecting brain chemistry, which in turn may cause changes in a person's mood, thinking, perception, and/or behavior. Each drug tends to have a specific action on one or more neurotransmitters or neurotransmitter receptors in the brain. Generally, they act as either agonists or antagonists.

- **Agonists** are drugs that mimic or increase the activity of particular neurotransmitters. They might act by promoting the synthesis of the neurotransmitters, reducing their reuptake from synapses, or mimicking their action by binding to receptors for the neurotransmitters.
- **Antagonists** are drugs that decrease the activity of particular neurotransmitters. They might act by interfering with the synthesis of the neurotransmitters or by blocking their receptors so the neurotransmitters cannot bind to them.

Consider the example of the neurotransmitter GABA. This is one of the most common neurotransmitters in the brain, and it normally has an inhibitory effect on cells. GABA *agonists,* which increase its effect at the synapse, include ethanol, depakote (anti-convulsant/bipolar medication), benzodiazepines (anti-anxiety medication), and other psychoactive drugs. All of these drugs work in different ways at the synapse, but ultimately increase the postsynaptic effect of GABA in the brain.

Classification Based on Type of Use

You may have been prescribed psychoactive drugs by your doctor. For example, you may have been prescribed a drug to treat anxiety or depression or an opioid, drug such as codeine for pain (most likely in the form of Tylenol with added codeine). You may also use nonprescription psychoactive drugs, such as caffeine for mental alertness or cannabis (CBD or Marijuana) to treat pain or anxiety. These are just some of the many possible uses of psychoactive drugs.

Medical Uses

Figure 5.2.3: This child is being prepared to receive a general anesthetic prior to surgery

Medical uses of psychoactive drugs include general anesthesia, in which pain is blocked and unconsciousness is induced. General anesthetics are most often used during surgical procedures and may be administered in gaseous form. General anesthetics include the drugs halothane and ketamine. Other psychoactive drugs are used to manage pain without affecting consciousness. They may be prescribed either for acute pain in cases of trauma such as broken bones; or for chronic pain such as pain caused by arthritis, cancer, or fibromyalgia. Most often, the drugs used for pain control are opioids, such as morphine and codeine. Their pain inhibitory actions rest with their ability to enhance our endogenous opioid activity in the brain, which ultimately will lead to a reduction of incoming pain signals from the body.

Many psychiatric disorders are also managed with psychoactive drugs. For example, antidepressants such as Sertraline or Celexa are used to treat depression, anxiety, and eating disorders. These drugs act as agonists for serotonin systems in key circuits of the brain which play an important role in mood regulation. Anxiety disorders may also be treated with anxiolytic drugs, such as buspirone and diazepam. Diazepam is from the benzodiazepine class of drugs which are agonists of the GABA system and can inhibit limbic areas of the brain involved with the anxiety and fear response.

Stimulants such as amphetamines are agonists for monamine transmitters and can be effective treatments for attention deficit disorder and certain sleep disorders. Antipsychotics such as clozapine and risperidone, as well as mood stabilizers such as lithium, are used to treat schizophrenia and bipolar disorder. These drugs act on a variety of transmitter systems in order to treat a variety of symptoms. Although controversial, relatively recent studies on the therapeutic, controlled use of hallucinogens such as MDMA and Psilocybin to treat disorders such as PTSD have been conducted.

Ritual Uses

Certain psychoactive drugs, particularly hallucinogens, have been used for ritual purposes since prehistoric times. For example, Native Americans have used the mescaline-containing peyote cactus (pictured below) for religious ceremonies for as long as 5,700 years. In prehistoric Europe, the mushroom *Amanita muscaria*, which contains a hallucinogenic drug called muscimol, was used for similar purposes. Various other psychoactive drugs — including jimsonweed, psilocybin mushrooms, and cannabis — have also been used by various peoples for ritual purposes for millennia.

Figure 5.2.4: The peyote cactus contains a hallucinogenic drug that is still used by some Native Americans for religious rituals.

Recreational Uses

The most typical recreational uses of psychoactive drugs have the purpose of altering one's consciousness and creating a feeling of euphoria commonly called a "high." Some of the drugs used most commonly for these purposes include cannabis, ethanol, opioids, and stimulants such as nicotine, amphetamine, or cocaine. Hallucinogens are also used recreationally, primarily for the alterations in thinking and perception that they cause.

Some investigators have suggested that the urge to alter one's state of consciousness is a universal human drive, similar to the drive to satiate thirst, hunger, or sexual desire. They think that the drive to alter one's state of mind is even present in children, who may attain an altered state by repetitive motions such as spinning or swinging. Some nonhuman animals also exhibit a drive to experience altered states. For example, they may consume fermented berries or fruit and become intoxicated. The way cats respond to catnip (Figure 5.2.6) is another example.

A variety of information on specific drugs used for recreational purposes is provided in section 6.3: Drugs of Abuse.

Figure 5.2.5: This cat is holding a catnip toy and apparently enjoying its psychoactive effects.

Summary

It is probably clear now that psychoactive drugs can have profound and quite varied effects on how we think, feel, perceive the world, and behave. This range of effects depends on a multitude of factors including the particular neurotransmitter systems affected, the general pharmacology of the drug, and it's specific synaptic effects. As described, the ability for drugs to act as either agonists or antagonists at synapses and the role of receptor subtypes (i.e. excitatory or inhibitory) have a major impact on the ultimate outcome to the individual. These synaptic effects and the influence of physiological effects that occur prior to drugs reaching the brain will be explored further in the next section of this chapter.

Supplemental Resources

Learn more about psychiatric drugs that are being researched to treat mental health disorders. In this inspiring TED talk, neurobiologist David Anderson explains how modern psychiatric drugs treat the chemistry of the whole brain and why a more nuanced view of how the brain functions could lead to targeted psychiatric drugs that work better and avoid side effects.

5.3: Mechanisms of Psychoactive Drug Action

Learning Objectives

1. Describe the key elements of pharmacokinetics and their relationship to drug action.
2. Compare and contrast the various drug administration methods in terms of potency, latency of action, and abuse potential.
3. Describe the key elements of pharmacodynamics, particularly drug effects on steps of synaptic transmission and major neural circuitry
4. Differentiate the major structures of the mesolimbic, "reward" pathway and the role of dopamine in its function.

Overview

Do drugs affect the body or does the body affect drugs? This may seem like either a very easy or a very odd question. Of course, the answer is drugs affect the body, right? For example, you take a certain drug and then your heart rate changes or you feel energized to move around a lot. In terms of psychoactive drugs, the brain, which is part of the body, is definitely affected by drugs. As we will see, neurotransmitters can be become more active and the receptors that these neurotransmitters bind to may trigger either increased or decreased communication with other neurons, glands, or muscles. These examples should make it clear that drugs definitely affect the body. However, even before these effects on the body occur, the *body* is able to affect incoming drugs in profound ways. Thus, the answer to the earlier question is that the body affects drugs and drugs affect the body.

This section will review the basics on how both of these processes occur with a general review of the concepts of **pharmacokinetics** (how the body affects drugs) and **pharmacodynamics** (how drugs affect the body, or more specifically the brain). In covering these topics we will address various physiological processes, such as drug metabolism and elimination and the influence of drug administration methods on a drug's impact. In addition, we will go into the specifics of how drugs interact with the process of synaptic communication and then zoom out to see how they alter the activity of major circuits and structures of the brain, such as the so-called, "reward pathway."

Pharmacokinetics: What Is It – Why Is It Important?

Pharmacokinetics refers to how the body processes drugs as they enter the body. While this section may sound more like pharmacology, it is important to realize how important pharmacokinetics can be when considering the ultimate effects of psychoactive drugs. As mentioned previously, psychoactive drugs exert their effects on behavior by altering neuronal communication in the brain, and the majority of drugs reach the brain by traveling in the blood.

The acronym **ADME** is often used to specify the processes of**:**

- **A - A**dministration **and A**bsorption (how the drug gets into the blood),
- **D - D**istribution (how the drug gets to the organ of interest – in this case, the brain),
- **M - M**etabolism (how the drug is broken down so it no longer exerts its psychoactive effects), and
- **E - E**limination (how the drug leaves the body).

We will focus on some of these processes to show their importance in determining the effects of psychoactive drugs.

Drug Administration and Absorption

Figure 5.3.1: A drug delivered by IV reaches the brain more quickly than if the drug is taken orally. While rapid delivery has advantages, there are also risks involved with IV administration. (CC BY-SA 3.0; Calleamanecer via Wikimedia Commons)

Before a drug can be absorbed by the body it needs to be administered in some way (i.e., the drug has to get into the body). There are many ways to take drugs, and these routes of drug administration can have a significant impact on how quickly that drug reaches brain.

The most common route of administration is **oral administration,** which begins in the mouth and continues in the digestive system. This route is relatively **slow** and – perhaps surprisingly – often the most variable and complex route of administration. Drugs enter the stomach and then get absorbed by the blood supply and capillaries that line the small intestine. The rate of absorption can be affected by a variety of factors including the quantity and the type of food in the stomach (e.g., fats vs. proteins). This is why the medicine label for some drugs (like antibiotics) may specifically state foods that you should or should not consume within an hour of taking the drug because they can affect the rate of absorption.

Two of the most **rapid** routes of administration include **inhalation** (i.e., smoking or gaseous anesthesia) and **intravenous (IV)** in which the drug is injected directly into the vein and hence the blood supply. Both of these routes of administration can get the drug to brain in less than 10 seconds. IV administration also has the distinction of being the most dangerous because if there is an adverse drug reaction, there is very little time to administer any antidote, as in the case of an IV heroin overdose.

Key Elements of Drug Routes of Administration (Keys)

Route of Administration	Typical Methods Used	Speed of Absorption in Blood	Advantages / Disadvantages
Oral (PO)	Pill, Liquid, Edibles	**SLOWEST**	Convenient, Gradual onset, Relatively safe / Variable blood levels due to individual differences in absorption and metabolism
Subcutaneous	Injection into skin	↓	Gradual onset, Avoids 1st pass metabolism / Only small volumes can be given, Possible localized irritation, tissue damage, infection
Intramuscular (IM)	Injection into muscle	↓	Steady absorption rates, Avoids 1st pass metabolism, Extended release possible / Only small volumes can be given, Possible localized irritation, tissue damage, infection

Route of Administration	Typical Methods Used	Speed of Absorption in Blood	Advantages / Disadvantages
Rectal	Rectal Suppository		Useful in those with digestive issues or unconscious, Mostly avoids 1st pass metabolism, Relatively high blood levels / Invasive, Unpredictable absorption rates
Sublingual	Under tongue		Direct & fast absorption, Avoids 1st pass metabolism, Quick termination possible
Inhalation	Smoke, Vape, Huff, Inhaler, Intranasal		Rapid absorption, Useful for emergency applications or localized effect (i.e. asthma), Reaches brain quickly / Variable dose & absorption, Relatively high abuse potential w/ certain drugs
Intravenous	Injected into vein	**FASTEST**	Very rapid absorption (~instantly), Avoids 1st pass metabolism, Useful for emergency applications, Accurate dosing / High abuse potential and risk for overdose with certain drugs

Why might knowing how quickly a drug gets to the brain be important? If we are considering therapeutic drugs, such as those used to treat anxiety, depression, or psychotic disorders, the time it takes to begin to relieve symptoms and how long this lasts can be critical information. For example, if treating an acute panic attack you would want a drug to act fast, whereas, if you want to prevent non-specific anxiety from occurring on a daily basis, you may use a different drug that acts more gradually but sticks around longer.

When considering potential drugs of abuse, administration and absorption rates are important for other reasons. Although there are multiple non-pharmacological risk factors for drug craving and substance use disorders, the phamacokinetics of a drug can play a significant role. For example, if a drug activates the reward circuits in the brain and reaches these areas quickly, the drug may have a relatively high risk for abuse and psychological dependence. Psychostimulants like amphetamine or cocaine are examples of drugs that have high risk for abuse in part because they are agonists at dopamine neurons involved in reward and because these drugs exist in forms that can be either smoked or injected intravenously. Some argue that cigarette smoking is one of the hardest addictions to quit, and although part of the reason for this may be that smoking gets the nicotine into the brain very quickly (and indirectly acts on dopamine neurons), it is a more complicated story.

For drugs that reach the brain very quickly, not only is the drug potentially very addictive, but so are the cues associated with the drug (see Rohsenow, Niaura, Childress, Abrams, and Monti, 1990). A learned connection between drug use and the environmental elements that accompany it can complicate quitting by triggering symptoms of withdrawal and/or cravings. For an IV opioid user, this could be the sight of a container in which the drug and syringes are typically stored or other aspects of their typical drug-taking environment. For a cigarette smoker, it could be the smell of another person's smoke or even something as typical as finishing dinner or waking up in the morning (if that is when the smoker usually has a cigarette). For both the opioid user and the cigarette smoker, the cues associated with the drug may actually cause craving that is alleviated by (you guessed it) – lighting a cigarette or injecting the opioid (i.e., relapse). This is one of the reasons individuals that enroll in drug treatment programs, especially out-of-town programs, are at significant risk of relapse if they later find themselves in proximity to old "environments", including friends and situations associated with drug use. But this is much *more* difficult for a cigarette smoker. How can someone avoid eating? Or avoid waking up in the morning, etc. These examples help you begin to understand how important the route of administration can be for psychoactive drugs.

Drug Metabolism

Metabolism involves the breakdown of psychoactive drugs, and this occurs primarily in the liver. The liver produces **enzymes** (proteins that speed up a chemical reaction), and these enzymes help catalyze a chemical reaction that breaks down psychoactive drugs. Enzymes exist in “families,” and many psychoactive drugs are broken down by the same family of enzymes, the Cytochrome P450 super family. Usually, there is not a unique enzyme for each drug; rather, certain enzymes can break down a wide variety of drugs. **Tolerance** to the effects of many drugs can occur with repeated exposure; that is, the drug produces less of an effect over time, so more of the drug is needed to get the same effect. This is particularly true for sedative drugs like alcohol or opiate-based

painkillers (e.g., fentanyl, codeine). *Metabolic tolerance* is one kind of tolerance and it takes place primarily in the liver. Some drugs, such as alcohol cause **enzyme induction** – an increase in the enzymes produced by the liver. For example, chronic drinking results in alcohol being broken down more quickly, so the alcoholic needs to drink more to get the same effect – of course, until so much alcohol is consumed that it damages the liver (i.e. fatty liver or cirrhosis).

There are a variety of other ways that enzyme action can be altered by both physiological and environmental aspects of drug taking. For example, just the expectation of drug taking or the cues from the environment where drug taking regularly occurs can trigger either enzyme induction or inhibition and, thus altering the ultimate physical and/or psychological effects of the drug. These differences in response can be particularly dangerous if they involve an unexpected increase in life-threatening side effects, such as the respiratory depression seen in response to opioids.

After "surviving" the processes of absorption and initial metabolism but before being eliminated, drugs are distributed throughout the body until they reach their target. In the case of psychoactive drugs, the main target is the brain. At this point, the process shifts to *pharmacodynamics* where the roles reverse and drugs are now able to affect the body.

Pharmacodynamics

If you have a headache or muscle pain, you might take a drug like ibuprofen (Advil, Motrin) or acetaminophen (Tylenol). Part of how these drugs work is to block the production of chemicals that cause the inflammation that is responsible for the pain. Thus, their target is the location of action is where the inflammation or pain is occurring. For psychoactive drugs, including those which treat pain the target of action for their effects is the brain or nervous system. The pharmacodynamics of their effects can be divided into two general categories: Their influence on specific steps of communication at the level of the synapse and the more holistic effect on the activity of certain circuits or major structures of the nervous system.

Just about all psychoactive drugs have their initial effects on one or more of the **steps of synaptic communication: neurotransmitter synthesis, storage, release, binding, reuptake, and breakdown (See Figure 6.2.2)**. Remember, drugs can act as either agonists or antagonists of a neurotransmitter's typical effects. The drug L-dopa, for example acts as an agonist to increase the synthesis of dopamine and treat the dopamine dysfunction present in Parkinson's disease. Other agonist drugs like amphetamine and some other stimulants can increase the amount of dopamine activity by enhancing the release step. And yet others, such as cocaine can increase the synaptic activity of dopamine by blocking its reuptake. All these drugs are dopamine agonists (increase dopamine synaptic activity), but they can have very different psychological and behavioral effects due to the difference in the synaptic step targeted.

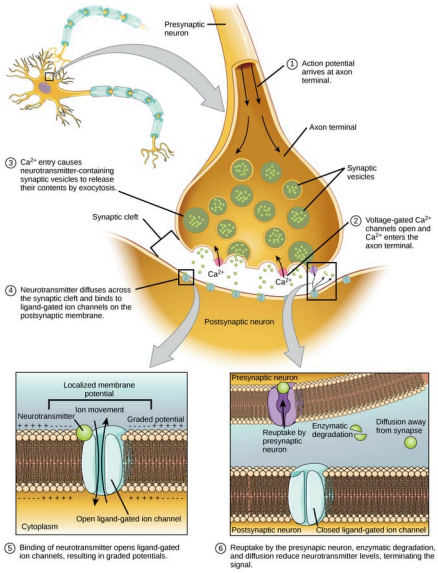

Figure 5.3.2: Steps in Synaptic Transmission starting with the arrival of the action potential and culminating in transmitter release into the synapse. Details of neurotransmitter binding and termination mechanisms in the synapse are included in insets. Psychoactive drugs can affect one or more of these steps, depending on the drug. (CC BY 4.0 by OpenStax)

Knowing these initial actions of drugs at the level of the synapse is important in order to understand how they ultimately affect our thinking, feeling, and behavior. However, the thousands or even millions of synaptic changes that occur every split second

due to drug action first need to be integrated in order to have noticeable effects. This integration is reflected in alterations of the activity of key structures and circuits of the nervous system.

Drug effects on Neural Structures and Circuits

Every distinct brain area or neural circuit can be affected in some way by the action of psychoactive drugs due to the integration process discussed above. For example, drugs that increase endorphin activity (i.e. Opioids) in certain areas of the brain can trigger changes in a major pain-inhibition pathway. Circuits involved with attention are affected by drugs that enhance norepinephrine systems and can be effective treatments for ADHD. Still other drugs, such as anti-anxiety medications (i.e. Xanax, Valium) are GABA agonists and can enhance the action of GABA throughout the brain, including the amygdala, which plays a significant role in fear and anxiety responses.

Mesolimbic "Reward" Circuitry

One of the most interesting and significant circuits that has been studied for its role in drug taking and substance use disorder is the "reward circuit" or "pleasure pathway" of the brain. This circuitry is technically called the mesolimbic circuitry and contains major dopamine pathways in addition to other transmitters which play a role in the positive feelings associated with both natural and drug rewards (See Figure 6.2.3).

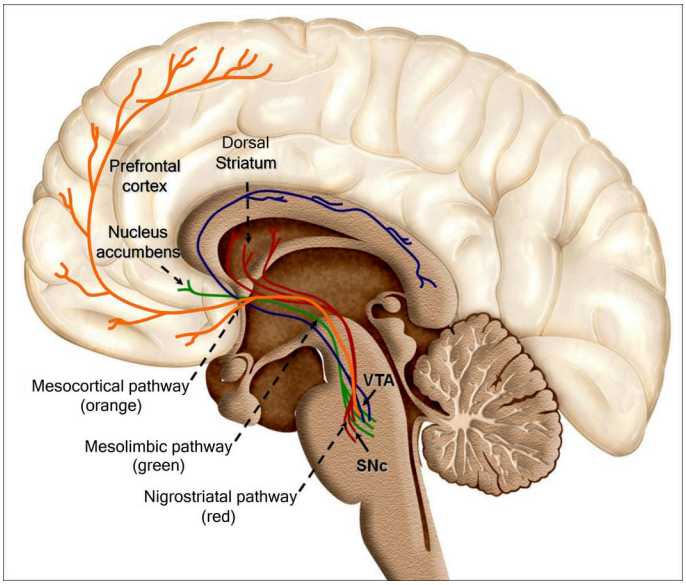

Figure 5.3.3: Mesolimbic, "Reward" Circuit and other Dopamine Pathways. These include pathways from both the Substantia Nigra (SNc) and Ventral Tegmental Area (VTA) to forebrain targets such as the Nucleus Accumbens and Prefrontal Cortex. From: Oscar Arias-Carrión1, Maria Stamelou, Eric Murillo-Rodríguez, Manuel Menéndez-González and Ernst Pöppel.Substantially modified by Seppi333, CC BY 2.0 , via Wikimedia Commons

The nucleus accumbens definitely plays a central role in the **reward circuit.** Its operation is based chiefly on two essential neurotransmitters: dopamine, which promotes desire, and serotonin, whose effects include satiety and inhibition. Many animal studies have shown that many psychoactive drugs and natural rewards increase the production of dopamine in the nucleus accumbens, while reducing that of serotonin.

But the nucleus accumbens does not work in isolation. It maintains close relations with other areas involved in pleasure and reward. One area in particular is the **ventral tegmental area (VTA)**. Located in the midbrain, at the top of the brainstem, the VTA is one of the most primitive parts of the brain. Neurons of the VTA synthesize dopamine and then send it via their axons primarily to the nucleus accumbens. The VTA is also influenced by endorphins whose receptors are targeted by opiate drugs such as heroin and morphine.

Another structure involved in pleasure mechanisms is the **prefrontal cortex**, whose role in planning and motivating action is well established. The prefrontal cortex is a significant relay in the reward circuit and also is modulated by dopamine.

The locus coeruleus, an alarm area of the brain and packed with norepinephrine, is another brain structure that plays an

important role in drug abuse. When stimulated by a lack of the drug in question, the locus coeruleus drives the user to do anything necessary to obtain more drug.

Three other structures in the limbic system also play an active part in the pleasure circuit and, consequently, in drug dependency. The first is the **amygdala**, which can provide affective or mood information in response to drugs or environmental stimuli.

The second is the **hippocampus**, which preserves the agreeable memories associated with drug taking or other non-drug behaviors and, by association, all of the details of the environment in which these behaviors occur. The memory of these details may trigger positive feelings and, in the case of drugs reawaken the desire to take the drug again contributing to the possibility of relapse.

The third structure, the most anterior portion of the **insular cortex**, or insula, is regarded as part of the limbic system that is thought to play a role in the active pleasure-seeking associated both with food and with psychoactive substances. It has been proposed that this part of the cortex tells us about the bodily states associated with our emotional experiences and then relates these feeling states to cognitive processes such as decision-making (Damasio et al., 2013).

Summary

Psychoactive drugs clearly undergo quite a journey through the body and, ultimately the brain prior to causing changes in how we think, feel, perceive the world, and behave. The pharmacokinetic steps of administration, distribution, metabolism, and elimination have a major impact on the timing and amount of drug action prior to their arrival at their targets in the nervous system. Upon arrival, pharmacodynamic actions primarily at the synapse contribute to the diverse and dynamic action of drugs on neural communication and subsequent psychological and behavioral changes. Psychoactive drugs have the potential to affect structures in all parts of the nervous system as long as the appropriate receptors are there to receive the. The structures of the Mesolimbic Reward Circuitry play a particularly critical role in the action of many psychoactive drugs, both therapeutic and recreational.

5.4: Substance Use and Addiction - Theories, Brain Mechanisms, and Treatment

Learning Objectives

1. Define addiction (substance use disorder) in terms of changes in behavior, emotion, and cognition.
2. Describe the neural mechanisms of addiction, including the role of key neurotransmitters (dopamine & endorphins), brain structures & circuits, and genetics.
3. Differentiate the actions of drugs of abuse in terms of their neurotransmitter effects, neuroanatomy of action, and abuse potential

Overview

Many people don't understand why or how other people become addicted to drugs. They may mistakenly think that those who use drugs lack moral principles or willpower and that they could stop their drug use simply by choosing to. In reality, drug addiction is a complex disease, and quitting usually takes more than good intentions or a strong will. Drugs change the brain in ways that make quitting very difficult, even for those who want to. Fortunately, researchers know more than ever about how drugs affect the brain and have found treatments that can help people recover from drug addiction and lead productive lives.

What Is Addiction?

According to the National Institute of Drug Abuse (NIDA), drug addiction is defined as the continued compulsive use of drugs despite adverse health or social consequences. People addicted to drugs have lost control of their drug use. Because of this they can become isolated from family or friends, have difficulty at work or school, engage in unhealthy behaviors, and may become involved with the criminal justice system. For a person addicted to drugs, continuing to take them becomes the primary focus in life.

The Diagnostic and Statistical Manual, 5th edition (DSM V) from the American Psychological Association has reframed addiction as **substance use disorder** (Hasin, et al., 2013). This diagnostic category views substance use on a continuum with a range of severity from mild to severe based on the presence of 11 criteria. These criteria include some of the same factors noted by the NIDA definition stated above in addition to others, such as physiological effects (i.e. withdrawal & tolerance) and psychological problems related to drug use.

Disagreements about the nature of addiction remain: namely, whether it reflects voluntary or involuntary behavior and whether it should be punished or treated as a health issue. Even though the first time a person takes a drug, it is often by choice—to achieve a pleasurable sensation or desired emotional state—we now know from a large body of research that this ability to choose can be affected by drugs. And when addiction takes hold in the brain, it disrupts a person's ability to exert control over behavior—reflecting the compulsive nature of this disease.

The human brain is an extraordinarily complex and fine-tuned communications network made up of billions of cells that govern our thoughts, emotions, perceptions, and drives. Our brains reward certain behaviors such as eating or procreating—registering these as pleasurable activities that we want to repeat. Drug addiction taps into these vital mechanisms geared for our survival. And although not a life necessity, to an addicted person, drugs become life itself, driving the compulsive use of drugs—even in the face of dire life consequences—*that is the essence of addiction*.

How Does Addiction Take Hold in the Brain?

Decades of research supported by NIDA has proven that addiction is a complex brain disease characterized by compulsive, at times uncontrollable, drug craving, seeking, and use that persist despite potentially devastating consequences. Although not the only factor, the powerful rewarding effects of most drugs of abuse play a major role in their continued use despite negative effects.

The **rewarding effects** of most drugs of abuse come mainly from large and rapid upsurges in **dopamine**, a neurochemical critical to stimulating feelings of pleasure and to motivating behavior. Increased activity of **endorphins**, our natural opiate system can also play a role in these effects. The rapid dopamine "rush" from drugs of abuse mimics but greatly exceeds in intensity and duration the feelings that occur in response to such pleasurable stimuli as the sight or smell of food, for example. Repeated exposure to large, drug-induced dopamine surges has the insidious consequence of ultimately blunting the response of the dopamine system to everyday stimuli. Thus the drug disturbs a person's normal hierarchy of needs and desires and substitutes new priorities concerned with procuring and using the drug.

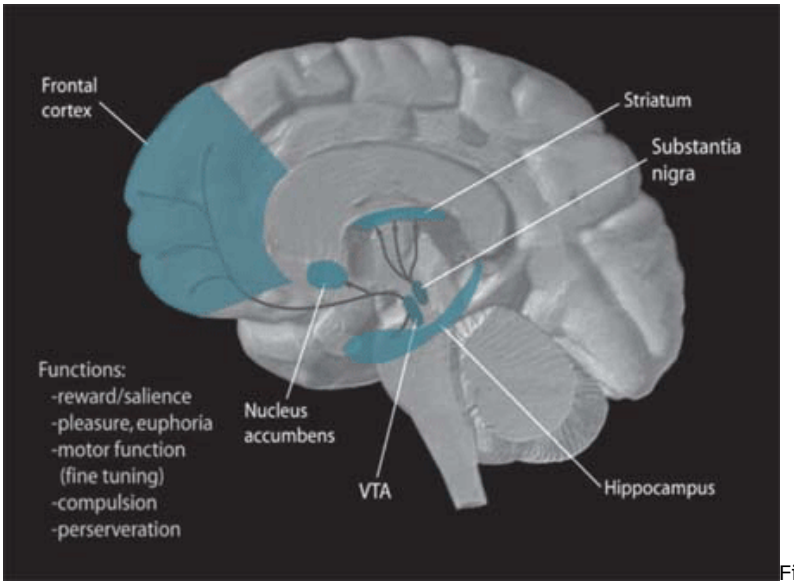

Figure 5.4.1: Dopamine Pathways. In the brain, dopamine plays an important role in the regulation of reward and movement. As part of the reward pathway, dopamine is manufactured in nerve cell bodies located within the ventral tegmental area (VTA) and is released in the nucleus accumbens and the prefrontal cortex. Its motor functions are linked to a separate pathway, with cell bodies in the substantia nigra that manufacture and release dopamine into the striatum. From: NIDA Research Report Series - Methamphetamine Abuse and Addiction (2006), PD US NIH, via Wikimedia Commons

Drug abuse also disrupts the brain circuits involved in memory and control over behavior. Memories of the drug experience can trigger craving as can exposure to people, places, or things associated with former drug use. Stress is also a powerful trigger for craving. Control over behavior is compromised because the affected frontal brain regions are what a person needs to exert inhibitory control over desires and emotions. That is why addiction is a brain disease.

As a person's **reward circuitry** becomes increasingly dulled and **desensitized** by drugs, nothing else can compete with them—food, family, and friends lose their relative value, while the ability to curb the need to seek and use drugs evaporates. Ironically and cruelly, eventually even the drug loses its ability to reward, but the compromised brain leads addicted people to pursue it, anyway; the memory of the drug has become more powerful than the drug itself.

Certain drugs, including **opioids and alcohol**, cause **strong physical reactions** in the body when drug use stops. When a person addicted to heroin stops taking heroin, they can experience a variety of symptoms ranging from watery eyes and a runny nose to irritability and loss of appetite and then diarrhea, shivering, sweating, abdominal cramps, increased sensitivity to pain, and sleep problems. In general, **withdrawal** from heroin makes people feel miserable. Withdrawal from alcohol can cause serious effects such as seizures and even death. Withdrawal from other drugs, such as cocaine and amphetamines, does not typically lead to strong physical reactions, but it may make the person feel depressed or lethargic. For most drugs, physical withdrawal symptoms can usually be controlled effectively with medications.

Even though withdrawal from some drugs does not cause the person abusing them to have physical reactions, stopping drug use is difficult because of the changes the drugs have caused in the brain. Once the drugs stop, the person will have **cravings**, or intense desire for the drugs that may lead to **relapse** of drug taking. Craving arises from the brain's need to maintain a state of homeostasis (balance) that now relies on the presence of the drug. A person may experience cravings at any stage of drug abuse or addiction, even early in the experimentation phase of drug abuse. Cravings have been shown to have a physical basis in the brain. Using PET imaging, scientists have shown that just seeing images of drug paraphernalia can stimulate the **amygdala** (part of the brain involved in emotional memory) in an addicted person.

Drugs of abuse do not merely cause short-term changes in an individual's cognitive skill and behavior. A drug "**high**" (i.e.

euphoric state) typically lasts a short time, ranging from less than an hour to 12 hours, depending on the drug, dose, and route of administration. The changes in the brain that result from continued drug use, however, can last a long time. Scientists believe that some of these changes disappear when drug use stops; some disappear within a short time after drug use stops, and other changes are potentially permanent.

One of the first changes in the brain that may occur in response to repeated drug abuse is **tolerance**. Tolerance develops when a person needs increasing doses of a drug to achieve the same high or "rush" that previously resulted from a lower dose of the drug. Two primary mechanisms underlie the development of tolerance. First, the body may become more efficient at metabolizing the drug, thereby reducing the amount that enters the brain. Second, the cells of the body and brain may become more resistant to the effect of the drug. For example, after continued cocaine use, neurons decrease the number of dopamine receptors, which results in decreasing cocaine's stimulatory effect. Opioids, on the other hand, do not typically cause a change in the number of receptors. Instead the opioid receptors become less efficient in activating associated cellular processes, thus reducing the effects of the opioids.

Why do some people become addicted to drugs while others don't?

No one factor can predict if a person will become addicted to drugs. A combination of factors influences risk for addiction. The more risk factors a person has, the greater the chance that taking drugs can lead to addiction. For example:

- **Biology**. The genes that people are born with account for about half of a person's risk for addiction. Gender, ethnicity, and the presence of other mental disorders may also influence risk for drug use and addiction.
- **Environment**. A person's environment includes many different influences, from family and friends to economic status and general quality of life. Factors such as peer pressure, physical and sexual abuse, early exposure to drugs, stress, and socioeconomic pressures can greatly affect a person's likelihood of drug use and addiction.
- **Development**. Genetic and environmental factors interact with critical developmental stages in a person's life to affect addiction risk. Although taking drugs at any age can lead to addiction, the earlier that drug use begins, the more likely it will progress to addiction. This is particularly problematic for teens. Because areas in their brains that control decision-making, judgment, and self-control are still developing, teens may be especially prone to risky behaviors, including trying drugs.

Can drug addiction be treated?

As with most other chronic diseases, such as diabetes, asthma, or heart disease, treatment for drug addiction generally isn't a cure. However, addiction is treatable and can be successfully managed. People who are recovering from an addiction will most likely be at risk for relapse for years and possibly their whole lives. Research shows that combining addiction treatment medicines with behavioral therapy ensures the best chance of success for most patients. Treatment approaches tailored to each patient's drug use patterns and any co-occurring medical, mental, and social problems can lead to continued recovery.

More good news is that drug use and addiction are preventable. Results from NIDA-funded research have shown that prevention programs involving families, schools, communities, and the media are effective for preventing or reducing drug use and addiction. Although personal events and cultural factors affect drug use trends, when young people view drug use as harmful, they tend to decrease their drug taking. Therefore, education and outreach are key in helping people understand the possible risks of drug use. Teachers, parents, and health care providers have crucial roles in educating young people and preventing drug use and addiction.

Medications and Devices used in Drug Addiction Treatment

Medications and devices can be used to manage withdrawal symptoms, prevent relapse, and treat co-occurring conditions.

Withdrawal. Medications and devices can help suppress withdrawal symptoms during detoxification. Detoxification is not in itself "treatment," but only the first step in the process. Patients who do not receive any further treatment after detoxification usually resume their drug use. One study of treatment facilities found that medications were used in almost 80 percent of detoxifications (SAMHSA, 2014). In November 2017, the Food and Drug Administration (FDA) granted a new indication to an electronic stimulation device, NSS-2 Bridge, for use in helping reduce opioid withdrawal symptoms. This device is placed behind the ear and sends electrical pulses to stimulate certain brain nerves. Also, in May 2018, the FDA approved lofexidine, a non-opioid medicine designed to reduce opioid withdrawal symptoms.

Relapse prevention. Patients can use medications to help re-establish normal brain function and decrease cravings. Medications

are available for treatment of opioid (heroin, prescription pain relievers), tobacco (nicotine), and alcohol addiction. Scientists are developing other medications to treat stimulant (cocaine, methamphetamine) and cannabis (marijuana) addiction. People who use more than one drug, which is very common, need treatment for all of the substances they use.

- ***Opioids:*** Methadone (Dolophine®, Methadose®), buprenorphine (Suboxone®, Subutex®, Probuphine® , Sublocade™), and naltrexone (Vivitrol®) are used to treat opioid addiction. Acting on the same targets in the brain as heroin and morphine, methadone and buprenorphine suppress withdrawal symptoms and relieve cravings. Naltrexone blocks the effects of opioids at their receptor sites in the brain and should be used only in patients who have already been detoxified. All medications help patients reduce drug seeking and related criminal behavior and help them become more open to behavioral treatments. A NIDA study found that once treatment is initiated, both a buprenorphine/naloxone combination and an extended release naltrexone formulation are similarly effective in treating opioid addiction. Because full detoxification is necessary for treatment with naloxone, initiating treatment among active users was difficult, but once detoxification was complete, both medications had similar effectiveness.
- ***Tobacco:*** Nicotine replacement therapies have several forms, including the patch, spray, gum, and lozenges. These products are available over the counter. The U.S. Food and Drug Administration (FDA) has approved two prescription medications for nicotine addiction: bupropion (Zyban®) and varenicline (Chantix®). They work differently in the brain, but both help prevent relapse in people trying to quit. The medications are more effective when combined with behavioral treatments, such as group and individual therapy as well as telephone quitlines.
- ***Alcohol:*** Three medications have been FDA-approved for treating alcohol addiction and a fourth, topiramate, has shown promise in clinical trials (large-scale studies with people). The three approved medications are as follows:
  - **Naltrexone** blocks opioid receptors that are involved in the rewarding effects of drinking and in the craving for alcohol. It reduces relapse to heavy drinking and is highly effective in some patients. Genetic differences may affect how well the drug works in certain patients.
  - **Acamprosate (Campral®)** may reduce symptoms of long-lasting withdrawal, such as insomnia, anxiety, restlessness, and dysphoria (generally feeling unwell or unhappy). It may be more effective in patients with severe addiction.
  - **Disulfiram (Antabuse®)** interferes with the breakdown of alcohol. Acetaldehyde builds up in the body, leading to unpleasant reactions that include flushing (warmth and redness in the face), nausea, and irregular heartbeat if the patient drinks alcohol. Compliance (taking the drug as prescribed) can be a problem, but it may help patients who are highly motivated to quit drinking.
- ***Co-occuring conditions:*** Other medications are available to treat possible mental health conditions, such as depression or anxiety, that may be contributing to the person's addiction.

More details on the addictive potential for some of the specific drugs mentioned above and others are included in the next section.

Summary

Drug addiction (i.e. Substance Use Disorder) is clearly a chronic disease characterized by drug seeking and use that is compulsive, or difficult to control, despite harmful consequences. Brain changes that occur over time with drug use challenge an individual's self-control and interfere with their ability to resist intense urges to take drugs, thus relapse is common. Most drugs affect the brain's reward circuit by flooding it with the chemical messenger dopamine. This causes the "high" that leads people to take a drug again. Over time, the brain adjusts to excess dopamine activity, which ultimately results in the effect known as tolerance, leading the user to take more of the drug in order to achieve the same high. Typically, a combination of genetic, environmental, and developmental factors influences risk for drug misuse. The more risk factors a person has, the greater the chance that taking drugs can lead to a substance use disorder. However, there is hope in that substance use disorder is both preventable and treatable.

5.5: Specific Drug Effects, Misuse, and Risks

Learning Objectives

- Identify the specific types of drugs which are commonly misused and abused
- Describe the desired and adverse effects of commonly abused drugs
- Differentiate the potential contributing factors for drug misuse and abuse of commonly abused drugs.

Overview

A wide variety of drugs both legal and illegal can lead to misuse and addiction due to several possible causal factors. As noted previously, not everyone who takes these drugs will ultimately end up with a substance use disorder. Some, in fact are used therapeutically with success or recreationally without negative consequences. However, it is also true that some pose an unusually high risk for developing abusive patterns and significant adverse physical, psychological, and behavioral effects. This section will highlight some of the most prevalent and risky drugs in terms of their potential for being abused. This selection of potential drugs of abuse and their associated effects is just a sample of the wide array of chemical substances that can result in abusive patterns of intake. More information on the effects of the drugs presented here along with several other potential drugs of abuse can be found in the links to the National Institute of Drug Abuse sites provided at the end of this section.

Prescription Drugs

Prescription drugs are often strong medications, which is why they require a prescription from a doctor or dentist. Listed below are three common types of prescription drugs along with their primary neural mechanisms of action and clinical uses.

- **Opioids**— Acts on the **endorphin** neurotransmitter system and is used to relieve pain
- **Depressants**—Acts primarily on **inhibitory** mechanisms, such as the **GABA** system and is used to relieve anxiety or help a person sleep
- **Stimulants**— Acts primarily on **excitatory** mechanisms, such as **dopamine and norepinephrine** and is used to treat attention deficit hyperactivity disorder (ADHD), narcolepsy, and other disorders.

How Prescription Drugs are Misused

Along with their clinical uses, all three of the drug types stated above are commonly abused. In the initial stages of drug misuse, people tend to take these drugs to either get “high” or achieve a state of altered consciousness. Prescription drug misuse has become a very significant public health problem primarily due to the risks and adverse effects of prescription opioids which has contributed to a recent dramatic increase in overdose deaths.

Some of the most common ways that prescription drugs are misused include the following:

- Taking someone else’s prescription medication, even if it is for a medical reason (such as to relieve pain, to stay awake, or to fall asleep).
- Taking a prescription medication (yours or someone else's) in a way other than prescribed—for instance, taking more than the prescribed dose or taking it more often, or crushing pills into powder to snort or inject the drug.
- Mixing it with alcohol or certain other drugs.

All three of these methods have an inherent set of both psychological and physiological risks which contribute to their likelihood of being abused and adverse reactions.

What Makes Prescription Drug Misuse Unsafe

Every medication has some risk for harmful effects, sometimes serious ones. Doctors and dentists consider the potential benefits and risks to each patient before prescribing medications and take into account a lot of different factors, as described below:

- **Personal information.** Before prescribing a drug, health providers consider a person's weight, how long they've been prescribed the medication, other medical conditions, and what other medications they are taking. Someone misusing prescription drugs may overload their system or put themselves at risk for dangerous drug interactions.
- **Form and dose.** Doctors know how long it takes for a pill or capsule to dissolve in the stomach, release drugs to the blood, and reach the brain. When misused, prescription drugs are sometimes taken in larger amounts or in ways that change the way the drug works in the body and brain, putting the person at greater risk for an overdose. For example, when people who misuse OxyContin® crush and inhale the pills, a dose that normally works over the course of 12 hours hits the central nervous system all at once. This effect increases the risk for addiction and overdose.
- **Side effects.** Prescription drugs are designed to treat a specific illness or condition, but they often affect the body in other ways, some of which can be uncomfortable, and in some cases, dangerous. These are called side effects. Side effects can be worse when prescription drugs are not taken as prescribed or are used in combination with other substances. Side effects for the most commonly abused prescription drugs include the following:

    - Using **opioids** like oxycodone and codeine can cause you to feel sleepy, sick to your stomach, and constipated. At higher doses, opioids can make it hard to breathe properly and can cause overdose and death.
    - Using **stimulants** like Adderall or Ritalin can make you feel paranoid. It also can cause your body temperature to get dangerously high and make your heart beat too fast. This is especially likely if stimulants are taken in large doses or in ways other than swallowing a pill.
    - Using **depressants** like barbiturates can cause slurred speech, shallow breathing, sleepiness, disorientation, and lack of coordination. People who misuse depressants regularly and then stop suddenly may experience seizures. At higher doses depressants can also cause overdose and death, especially when combined with alcohol.

Overdose Risk

More than half of the drug overdose deaths in the United States each year are caused by prescription drug misuse. Overdose deaths involving prescription drugs—including pain relievers, benzodiazepines and antidepressants—increased steadily throughout the 1990s, peaked in 2017 and then decreased steadily in 2018 and 2019, and then increased again in 2020. Increases were linked to a rise in the misuse of prescription opioid pain relievers, as well as the presence of fentanyl in the drug supply. In 2013, only 9% of deaths (1,630 deaths) involving prescription drugs also involved fentanyl. In 2019, more than 46% of deaths (10,400 deaths) involving prescription drugs also involved fentanyl.

Mixing different types of prescription drugs can be particularly dangerous. For example, benzodiazepines interact with opioids (pain relievers) and increase the risk of overdose. Also, combining opioids with alcohol can make breathing problems worse and can lead to death.

Alcohol

Alcohol is among the most used drugs, plays a large role in many societies and cultures around the world, and greatly impacts public health. More people over age 12 in the United States have used alcohol in the past year than any other drug or tobacco product, and alcohol use disorder is the most common type of substance use disorder in the United States.

Alcohol Effects on the Brain and Behavior

Alcohol is a potent depressant whose main mechanism of action is to increase inhibitory action throughout the nervous system. It's primary mode of action to accomplish this is by acting as an agonist in the GABA neurotransmitter system. This can then act to release people from inhibitions, which gives the initial appearance of alcohol being excitatory.

When people drink alcohol, they may temporarily feel elated and happy, but they should not be fooled. As blood alcohol level rises, the effects on the body—and the potential risks—multiply.

- Inhibitions and memory become affected, so people may say and do things that they will regret later and possibly not remember doing at all.
- Decision-making skills are affected, so people may be at greater risk for driving under the influence or making unwise decisions.
- Aggression can increase, potentially leading to everything from verbal abuse to physical fights.
- Coordination and physical control are also impacted. When drinking leads to loss of balance, slurred speech, and blurred vision, even normal activities can become more dangerous.

Research also suggests that drinking during the teen years could interfere with normal brain development and change the brain in various ways, including negative effects on information processing and learning and increased risk of developing alcohol use disorder later in life.

Adverse Effects and Overdose Risk

Alcohol use disorder (AUD) is a chronic relapsing brain disorder characterized by an impaired ability to stop or control alcohol use despite adverse social, occupational, or health consequences. AUD ranges from mild to severe.

Consuming a dangerously high amount of alcohol can also lead to alcohol overdose and death. When people drink too much, they may eventually pass out (lose consciousness). Reflexes like gagging and breathing can be suppressed. That means people who have had too much alcohol could vomit and choke, or just stop breathing completely. Vulnerability to overdose increases if the person is already on a sedative-hypnotic (such as Valium, Xanax, or Benadryl) or pain medication.

An alcohol overdose occurs when there is so much alcohol in the bloodstream that areas of the brain controlling basic life-support functions—such as breathing, heart rate, and temperature control—begin to shut down. Alcohol overdose can lead to permanent brain damage or death.

Symptoms of alcohol overdose may include, mental confusion, difficulty remaining conscious, vomiting, seizures, slow (fewer than 8 breaths per minute) or irregular breathing (10 seconds or more between breaths), slow heart rate, clammy skin, dulled responses, such as no gag reflex (which prevents choking).

Know the danger signals and, if you suspect that someone has an alcohol overdose, call 911 for help immediately. Do not wait for the person to have all the symptoms, and be aware that a person who has passed out can die. Don't play doctor—cold showers, hot coffee, and walking do not reverse the effects of alcohol overdose and could actually make things worse.

Marijuana

Marijuana is the dried leaves and flowers of the *Cannabis sativa* or *Cannabis indica* plant. Stronger forms of the drug include high potency strains - known as sinsemilla (sin-seh-me-yah), hashish (hash for short), and extracts.

Of the more than 500 chemicals in marijuana, *delta-9-tetrahydrocannabinol*, known as THC, is responsible for many of the drug's psychotropic (mind-altering) effects. It's this chemical that distorts how the mind perceives the world. In other words, it's what makes a person high.

The amount of THC in marijuana has increased over the past few decades. In the early 1990s, the average THC content in marijuana was less than 4 percent. It is now about 15 percent and much higher in some products such as oils and other extracts (see below). Some people adjust how they consume marijuana (by smoking or eating less) to compensate for the greater potency. There have been reports of people seeking help in emergency rooms with symptoms, including nervousness, shaking, and psychosis after consuming high concentrations of THC.

Smoking extracts and resins from the marijuana plant with high levels of THC is on the rise. These resins have 3 to 5 times more THC than the plant itself. Smoking or vaping it (also called **dabbing**) can deliver dangerous amounts of THC and has led some people to seek treatment in the emergency room. There have also been reports of people injured in fires and explosions caused by attempts to extract hash oil from marijuana leaves using butane (lighter fluid).

Marijuana Effects on the Brain and Behavior

When marijuana is smoked or vaporized, THC quickly passes from the lungs into the bloodstream, which carries it to organs throughout the body, including the brain. Its effects begin almost immediately and can last from 1 to 3 hours. This can affect decision making, concentration, and memory for days after use, especially in people who use marijuana regularly. If marijuana is consumed in "edibles," foods, or beverages the effects of THC appear later—usually in 30 minutes to 1 hour—and may last for many hours. Some people consume more and more waiting for the "high" and end up in the emergency room with uncomfortable symptoms from too much THC.

As it enters the brain, THC attaches to cells, or neurons, with specific kinds of receptors called *cannabinoid receptors*. Normally, these receptors are activated by chemicals similar to THC that occur naturally in the body. They are part of a communication

network in the brain called the *endocannabinoid system*. This system is important in normal brain development and function.

Most of the cannabinoid receptors are found in parts of the brain that influence pleasure, memory, thinking, concentration, sensory and time perception, and coordinated movement. Marijuana activates the endocannabinoid system, which causes the "high" and stimulates the release of **dopamine** in the brain's reward centers, reinforcing the behavior. Other effects include changes in perceptions and mood, lack of coordination, difficulty with thinking and problem solving, and disrupted learning and memory.

Potential Risks of Marijuana Use and Addiction

Regular marijuana use has been associated with the following risks:

- **Reduced school performance.** Students who smoke marijuana tend to get lower grades and are more likely to drop out of high school than their peers who do not use. The effects of marijuana on attention, memory, and learning can last for days or weeks.
- **Reduced life satisfaction.** Research suggests that people who use marijuana regularly for a long time are less satisfied with their lives and have more problems with friends and family compared to people who do not use marijuana.
- **Impaired driving.** Marijuana affects a number of skills required for safe driving—alertness, concentration, coordination, and reaction time—so it's not safe to drive high or to ride with someone using marijuana. Marijuana makes it hard to judge distances and react to signals and sounds on the road. Combining marijuana with drinking even a small amount of alcohol greatly increases driving danger, more than either drug alone. Learn more about what happens when you mix **marijuana and driving**.
- **Use of other drugs.** Most young people who use marijuana do not go on to use other drugs. However, those who use are more likely to use other illegal drugs. It isn't clear why some people go on to try other drugs, but researchers have a few theories. The human brain continues to develop into the early 20s. Exposure to addictive substances, including marijuana, may cause changes to the developing brain that make other drugs more appealing.
- **Severe nausea and vomiting.** Studies have shown that in rare cases, regular, long-term marijuana use can lead some people to have cycles of severe nausea, vomiting, and dehydration, sometimes requiring visits to the emergency room.

Marijuana can also be addictive---meaning users continue to use it despite negative consequences. Approximately 10 percent of people who use marijuana may develop what is called a **marijuana use disorder**—problems with their health, school, friendships, family or other conflicts in their life. The person can't stop using marijuana even though it gets in the way of daily life. People who begin using marijuana before the age of 18 are 4–7 times more likely than adults to develop a marijuana use disorder.

What causes one person to become addicted to marijuana while another does not depends on many factors—including their family history (genetics), the age they start using, if they also use other drugs, their family and friend relationships, and if they take part in positive activities like school, clubs, or sports. More research needs to be done to determine if people who use marijuana for medical reasons are at the same risk for addiction as those who use it just to get high.

People who use marijuana may feel a mild **withdrawal** when they stop using the drug, but might not recognize their symptoms as drug withdrawal. These symptoms may include, irritability, sleeplessness, lack of appetite, anxiety, and drug cravings.

These effects can last for several days to a few weeks after drug use is stopped. Relapse (returning to the drug after you've quit) is common during this period because people may crave the drug to relieve these symptoms.

Potential Therapeutic Effects

The marijuana plant itself has not been approved as a medicine by the federal government, yet several states have made it legal for recreational and/or medical use. The plant contains chemicals—called cannabinoids—that may be useful for treating a range of illnesses or symptoms. Here are some samples of cannabinoids that have been approved or are being tested as medicines:

- **THC:** The cannabinoid that can make you "high"—THC—has some medicinal properties. Two laboratory-made versions of THC, nabilone and dronabinol, have been approved by the federal government to treat nausea, prevent sickness and vomiting from chemotherapy in cancer patients, and increase appetite in some patients with AIDS.
- **CBD:** Another chemical in marijuana with potential therapeutic effects is called cannabidiol, or CBD. CBD doesn't have mind-altering effects and is being studied for its possible uses as medicine. For example, CBD oil has been approved as a possible treatment for seizures in children with some severe forms of epilepsy.
- **THC and CBD:** A medication with a combination of THC and CBD is available in several countries outside the United States

as a mouth spray for treating pain or the symptoms of multiple sclerosis.

It is important to remember that smoking marijuana can have side effects, making it difficult to develop as a medicine. Side effects might outweigh its value as a medical treatment, especially for people who are not very sick. Another problem with smoking or eating marijuana plant material is that the ingredients can vary a lot from plant to plant, so it is difficult to get an exact dose. Until a medicine can be proven safe and effective, it will not be approved by the federal government.

Tobacco, Nicotine, & Vaping (E-Cigarettes)

Tobacco is a leafy plant grown around the world, including in parts of the United States. There are many chemicals found in tobacco leaves but **nicotine** is the one that can lead to addiction. Other chemicals produced by smoking tobacco, such as tar, carbon monoxide, acetaldehyde, and nitrosamines, also can cause serious harm to the body. For example, tar causes lung cancer and other serious diseases that affect breathing, and carbon monoxide can cause heart problems.

How Tobacco and Nicotine Products Are Used

Tobacco and nicotine products come in many forms. People can smoke, chew, sniff them, or inhale their vapors.

- **Smoked tobacco products.**
  - *Cigarettes:* These are labeled as regular, light, or menthol, but no evidence exists that “lite” or menthol cigarettes are safer than regular cigarettes.
  - *Cigars and pipes:* Some small cigars are hollowed out to make room for marijuana, known as "blunts," often done to hide the fact that they are smoking marijuana.
  - *Hookahs or water pipes*: Hookah tobacco comes in many flavors, and the pipe is typically passed around in groups. A typical hookah session delivers approximately 125 times the smoke, 25 times the tar, 2.5 times the nicotine, and 10 times the carbon monoxide as smoking a cigarette.
- **Smokeless tobacco products.** The tobacco is not burned with these products:
  - *Chewing tobacco.* It is typically placed between the cheek and gums.
  - *Snuff:* Ground tobacco that can be sniffed if dried or placed between the cheek and gums.
  - *Dissolvable products:* These include lozenges, orbs, sticks, and strip.
- **Vaping/electronic cigarettes** (also called e-cigarettes, electronic nicotine delivery systems, vaping devices, e-cigs, or JUULing). Vaping products are battery-operated devices that deliver nicotine and flavorings without burning tobacco. In most products, puffing activates the battery-powered heating device, which vaporizes the liquid in the cartridge. The resulting vapor is then inhaled (called “vaping”).

Tobacco Effects on the Brain

Like many other drugs, nicotine increases levels of a neurotransmitter called **dopamine**. Dopamine is released naturally when you experience something pleasurable like good food, your favorite activity, or spending time with people you care about. When a person uses tobacco products, the release of dopamine causes similar “feel-good” effects. This effect wears off quickly, causing people who smoke to get the urge to light up again for more of that good feeling, which can lead to addiction.

A typical smoker will take 10 puffs on a cigarette over the period of about 5 minutes that the cigarette is lit. So, a person who smokes about a pack of 25 cigarettes a day gets 250 “hits” of nicotine.

When smokeless tobacco is used, nicotine is absorbed through the mouth tissues directly into the blood, where it goes to the brain. Even after the tobacco is removed from the mouth, nicotine continues to be absorbed into the bloodstream. Also, the nicotine stays in the blood longer for users of smokeless tobacco than for smokers.

Is Vaping Worse Than Smoking?

Regardless of how vaping compares to cigarette smoking, it is important to recognize that nicotine vaping has its own risks, which include addiction and other potentially harmful health effects. Research so far suggests that nicotine vaping might be less harmful than cigarettes when people who regularly smoke switch to them completely and no longer use tobacco cigarettes.

However, nicotine in any form is a highly addictive drug, and health experts have raised many questions about the safety of vaping

devices, particularly for teens:

- Testing of some vaping products found the aerosol (vapor) to contain known cancer-causing and toxic chemicals. The health effects of repeated exposure to these chemicals are not yet clear.
- Some research suggests that nicotine vaping may increase the likelihood that teens will try other tobacco products, including cigarettes. A study showed that students who have vaped nicotine by the time they start 9th grade are more likely than others to start smoking traditional cigarettes and other smoked tobacco within the next year.
- Some research suggests that certain vaping products contain metals like nickel and chromium, possibly coming from the heating of coils, that may be harmful when inhaled.

Potential Risks and Addiction

It is clear that the nicotine in tobacco is addictive. Each cigarette contains about 10 milligrams of nicotine. A person inhales only some of the smoke from a cigarette, and not all of each puff is absorbed in the lungs. The average person gets about 1 to 2 milligrams of nicotine from each cigarette.

Studies of widely used brands of smokeless tobacco showed that the amount of nicotine per gram of tobacco ranges from 4.4 milligrams to 25.0 milligrams. Holding an average-size dip in your mouth for 30 minutes gives you as much nicotine as smoking 3 cigarettes. A 2-can-a-week snuff dipper gets as much nicotine as a person who smokes 1½ packs a day.

Whether a person smokes tobacco products or uses smokeless tobacco, the amount of nicotine absorbed in the body is enough to make someone addicted. When this happens, the person continues to seek out the tobacco even though he or she understands the harm it causes. Nicotine addiction can cause:

- *Tolerance:* Over the course of a day, someone who uses tobacco products develops tolerance—more nicotine is required to produce the same initial effects. In fact, people who smoke often report that the first cigarette of the day is the strongest or the “best.”
- *Withdrawal:* When people quit using tobacco products, they usually experience uncomfortable **withdrawal** symptoms, which often drive them back to tobacco use. Nicotine withdrawal symptoms include irritability, problems with thinking and paying attention, sleep problems, increased appetite, and craving, which may last 6 months or longer, and can be a major stumbling block to quitting.

Methamphetamine

Methamphetamine is a powerful, highly addictive stimulant that affects the central nervous system. Crystal methamphetamine is a form of the drug that looks like glass fragments or shiny, bluish-white rocks. It is chemically similar to amphetamine, a drug used to treat attention-deficit hyperactivity disorder (ADHD) and narcolepsy, a sleep disorder.

People can take methamphetamine by, smoking, swallowing (pill), snorting, or injecting the powder that has been dissolved.

Because the "high" from the drug both starts and fades quickly, people often take repeated doses in a "binge and crash" pattern. In some cases, people take methamphetamine in a form of binging known as a "run," giving up food and sleep while continuing to take the drug every few hours for up to several days.

Methamphetamine Effects on the Brain and Behavior

Methamphetamine increases the amount of the natural chemical **dopamine** in the brain. Dopamine is involved in body movement, motivation, and reinforcement of rewarding behaviors. The drug’s ability to rapidly release high levels of dopamine in reward areas of the brain strongly reinforces drug-taking behavior, making the user want to repeat the experience.

Short-Term Effects

Taking even small amounts of methamphetamine can result in many of the same health effects as those of other stimulants, such as cocaine or amphetamines. These include, increased wakefulness and physical activity, decreased appetite, faster breathing, rapid and/or irregular heartbeat, and increased blood pressure and body temperature.

Long-Term Effects

Long-term methamphetamine use has many other negative consequences, including addiction, extreme weight loss, severe dental problems, anxiety, altered judgement and decision making, confusion, memory loss, sleeping problems, violent behavior, ***paranoia, and hallucinations***.

In addition, continued methamphetamine use can cause changes in brain structure and function. In particular, the brain's dopamine system is often affected, resulting in reduced coordination and impaired verbal learning. In studies of people who used methamphetamine over the long term, severe changes also affected areas of the brain involved with emotion and memory.

Although some of these brain changes may reverse after being off the drug for a year or more, other changes may not recover even after a long period of time. A recent study even suggests that people who once used methamphetamine have an increased the risk of developing Parkinson's disease, a disorder of the nerves that affects movement.

People who inject methamphetamine are at increased risk of contracting infectious diseases such as HIV and hepatitis B and C. In addition, methamphetamine use may worsen the progression of HIV/AIDS and its consequences. Studies indicate that HIV causes more injury to nerve cells and more cognitive problems in people who use methamphetamine than it does in people who have HIV and don't use the drug.

MDMA (i.e. Ecstasy or Molly)

3,4-methylenedioxy-methamphetamine (**MDMA**) is a synthetic, emphatogenic drug that alters mood and perception (awareness of surrounding objects and conditions). It is chemically similar to both stimulants and hallucinogens, producing feelings of increased energy, pleasure, emotional warmth, and distorted sensory and time perception.

MDMA was initially popular in the nightclub scene and at all-night dance parties ("raves"), but the drug now affects a broader range of people who more commonly call the drug Ecstasy or Molly.

How do people use MDMA?

People who use MDMA usually take it as a capsule or tablet, though some swallow it in liquid form or snort the powder. The popular nickname Molly (slang for "molecular") often refers to the supposedly "pure" crystalline powder form of MDMA, usually sold in capsules. However, people who purchase powder or capsules sold as Molly often actually get other drugs such as synthetic cathinones ("bath salts") instead. In addition, some people take MDMA in combination with other drugs such as alcohol or marijuana.

MDMA Effects on the Brain and Behavior

MDMA increases the activity of three brain chemicals:

- Dopamine—produces increased energy/activity and acts in the reward system to reinforce behaviors
- Norepinephrine—increases heart rate and blood pressure, which are particularly risky for people with heart and blood vessel problems
- Serotonin—affects mood, appetite, sleep, and other functions. It also triggers hormones that affect sexual arousal and trust. The release of large amounts of serotonin likely causes the emotional closeness, elevated mood, and empathy felt by those who use MDMA.

Adverse Effects

MDMA's effects last about 3 to 6 hours, although many users take a second dose as the effects of the first dose begin to fade. Negative health effects include nausea, muscle cramping, blurred vision, chills, sweating, and others. Over the course of the week following moderate use of the drug, a person may experience:

- irritability, impulsiveness and/or aggression
- depression
- sleep problems

- anxiety
- memory and attention problems
- decreased appetite
- decreased interest in and pleasure from sex

It's possible that some of these effects may be due to the combined use of MDMA with other drugs, especially marijuana.

Addictive Potential

Research results vary on whether MDMA is addictive. Experiments have shown that animals will self-administer MDMA—an important indicator of a drug's abuse potential—although to a lesser degree than some other drugs such as cocaine.

Some people report signs of addiction, including withdrawal symptoms, such as fatigue, loss of appetite, depression, and trouble concentrating.

Therapeutic Potential

MDMA was first used in the 1970s as an aid in psychotherapy (mental disorder treatment using "talk therapy"). The drug did not have the support of clinical trials (studies using humans) or approval from the U.S. Food and Drug Administration (FDA). In 1985, The U.S. Drug Enforcement Administration (DEA) labeled MDMA as an illegal drug with no recognized medicinal use. However, some researchers remain interested in its value in psychotherapy when given to patients under carefully controlled conditions. MDMA is currently in clinical trials as a possible treatment aid for post-traumatic stress disorder (PTSD); for anxiety in terminally ill patients; and for social anxiety in autistic adults. Recently, the FDA gave MDMA-assisted psychotherapy for PTSD a Breakthrough Therapy designation.

Heroin

Heroin is a very addictive drug made from morphine, a psychoactive (mind-altering) substance taken from the resin of the seed pod of the opium poppy plant. Heroin is part of a class of drugs called *opioids*. Other opioids include some prescription pain relievers, such as codeine, oxycodone, and hydrocodone.

Heroin use and overdose deaths have dramatically increased recently. This increase is related to the growing number of people misusing prescription opioid pain relievers like OxyContin and Vicodin. Some people who become addicted to those drugs switch to heroin because it produces similar effects but is cheaper and may be easier to get.

In fact, most people who use heroin report they first misused prescription opioids, but it is a small percentage of people who switch to heroin. The numbers of people misusing prescription drugs is so high, that even a small percentage translates to hundreds of thousands of heroin users.

Heroin is mixed with water and injected with a needle. It can also be sniffed, smoked, or snorted. People who use heroin sometimes combine it with other drugs, such as alcohol or cocaine (a "speedball"), which can be particularly dangerous and raise the risk of overdose.

Heroin Effects on the Brain and Behavior

When heroin enters the brain, it attaches to molecules on cells known as opioid receptors. These receptors are located in many areas of the brain and body, especially areas involved in the perception of pain and pleasure, as well as a part of the brain that regulates breathing.

Short-term effects of heroin include a rush of good feelings and clouded thinking. These effects can last for a few hours, and during this time people feel drowsy, and their heart rate and breathing slow down. When the drug wears off, people experience a depressed mood and often crave the drug to regain the good feelings.

Regular heroin use changes the functioning of the brain and can result in the following:

- *tolerance*: more of the drug is needed to achieve the same "high"

- *dependence*: the need to continue use of the drug to avoid withdrawal symptoms
- *addiction (i.e. substance use disorder):* a devastating brain disease where, without proper treatment, people have trouble stopping using drugs even when they really want to and even after it causes terrible consequences to their health and other parts of their lives.

Adverse Effects of Heroin

Opioid receptors are located in the brain, the brain stem, down the spinal cord, and in the lungs and intestines. Thus, using heroin can result in a wide variety of physical problems related to breathing and other basic life functions, some of which may be very serious. A sample of these effects are given below.

Short-Term Effects

- dry mouth
- warm flushing skin
- feeling sick to the stomach and throwing up
- severe itching
- clouded thinking
- going "on the nod," switching back and forth between being conscious and semi-conscious
- increased risk of HIV and hepatitis (a liver disease) through shared needles and poor judgment while “high” leading to other risky behaviors.

When mixed with alcohol, short-term effects can include:

- coma—a deep state of unconsciousness
- dangerously slowed (or even stopped) breathing that can lead to overdose death

Long-Term Effects

- problems sleeping
- damage to the tissues inside the nose for people who sniff or snort it
- infection of the heart
- constipation and stomach cramping
- liver and kidney disease
- lung problems
- mental health problems, such as depression
- sexual problems for men & changes in menstrual cycles for women

In addition to the effects of the drug itself, heroin bought on the street often contains a mix of substances, including the dangerous opioid called **fentanyl** (see section below). Drug dealers add fentanyl because it is cheap, and they can save money. Some of these substances can be toxic and can clog the blood vessels leading to the lungs, liver, kidney, or brain. This can cause permanent damage to those organs.

Fentanyl

Fentanyl is a powerful synthetic opioid that is similar to morphine but is 50 to 100 times more potent. It is a prescription drug that is also made and used illegally. Like morphine, it is a medicine that is typically used to treat patients with severe pain, especially after surgery. It is also sometimes used to treat patients with chronic pain who are physically tolerant to other opioids. Tolerance occurs when you need a higher and/or more frequent amount of a drug to get the desired effects.

Synthetic opioids, including fentanyl, are now the most common drugs involved in drug overdose deaths in the United States. In 2017, 59 percent of opioid-related deaths involved fentanyl compared to 14.3 percent in 2010.

When prescribed by a doctor, fentanyl can be given as a shot, a patch that is put on a person’s skin, or as lozenges that are sucked like cough drops. The illegally used fentanyl most often associated with recent overdoses is made in labs. This synthetic fentanyl is sold illegally as a powder, dropped onto blotter paper, put in eye droppers and nasal sprays, or made into pills that look like other prescription opioids.

Some drug dealers are mixing fentanyl with other drugs, such as heroin, cocaine, methamphetamine, and MDMA (Ectasy). This is because it takes very little to produce a high with fentanyl, making it a cheaper option. This is especially risky when people taking drugs don't realize they might contain fentanyl as a cheap but dangerous additive. They might be taking stronger opioids than their bodies are used to and can be more likely to overdose.

Fentanyl Effects on the Brain and Behavior

Like heroin, morphine, and other opioid drugs, fentanyl works by binding to the body's opioid receptors, which are found in areas of the brain that control pain and emotions. After taking opioids many times, the brain adapts to the drug, diminishing its sensitivity, making it hard to feel pleasure from anything besides the drug.

Fentanyl's effects include

- extreme happiness
- drowsiness
- nausea
- confusion
- constipation
- sedation
- problems breathing
- unconsciousness

Fentanyl is addictive because of its potency. A person taking prescription fentanyl as instructed by a doctor can experience dependence, which is characterized by withdrawal symptoms when the drug is stopped. A person can be dependent on a substance without being addicted, but dependence can sometimes lead to addiction.

People addicted to fentanyl who stop using it can have severe withdrawal symptoms that begin as early as a few hours after the drug was last taken. These symptoms include:

- muscle and bone pain
- sleep problems
- diarrhea and vomiting
- cold flashes with goose bumps
- uncontrollable leg movements
- severe cravings

These symptoms can be extremely uncomfortable and are the reason many people find it so difficult to stop taking fentanyl. There are medicines being developed to help with the withdrawal process for fentanyl and other opioids. The FDA has approved lofexidine, a non-opioid medicine designed to reduce opioid withdrawal symptoms. Also, the NSS-2 Bridge device is a small electrical nerve stimulator placed behind the person's ear, that can be used to try to ease symptoms for up to five days during the acute withdrawal phase. In December 2018, the FDA cleared a mobile medical application, reSET®, to help treat opioid use disorders. This application is a prescription cognitive behavioral therapy and should be used in conjunction with treatment that includes buprenorphine and contingency management.

Overdose Risk

The rise of fentanyl misuse has coincided with an unprecedented rise in opioid-related overdose deaths. An overdose occurs when a drug produces serious adverse effects and life-threatening symptoms. When people overdose on fentanyl or other drugs mixed with fentanyl, their breathing can slow or stop. This can decrease the amount of oxygen that reaches the brain, a condition called *hypoxia*. Hypoxia can lead to a coma and permanent brain damage, and even death.

5.6: Psychotherapeutics

Learning Objectives

- Differentiate the various classifications of Psychotherapeutic drugs based on their therapeutic action, effects on steps of neurotransmission, and neurotransmitter specificity
- Compare and contrast the effectiveness and side effects of Psychotherapeutics

Overview

Psychotherapeutic medications can play a role in treating several mental disorders and conditions. Treatment may also include psychotherapy (also called “talk therapy”) and a variety of other medical and non-medical interventions. In some cases, psychotherapy alone may be the best treatment option. Choosing the right treatment plan should be based on a person's individual needs and medical situation, and under a mental health professional’s care.

The National Institute of Mental Health (NIMH) also does not endorse or recommend any particular drug, herb, or supplement. Results from NIMH-supported clinical trials that examine the effectiveness of treatments, including medications, are reported in the medical literature. This section is intended to provide basic information about mental health medications. It is not a complete source for all medications available and should not be used as a guide for making medical decisions.

Information about medications changes frequently. Check the U.S. Food and Drug Administration (FDA) website for the latest warnings, patient medication guides, or newly approved medications. Brand names are not referenced on this page, but you can search by brand name on MedlinePlus Drugs, Herbs and Supplements Drugs website. The MedlinePlus website also provides additional information about each medication, including side effects and FDA warnings.

Psychotherapeutic Classification

Much like the general classification of psychoactive drugs, there are multiple schemes of categorization that can be used. The most clear and useful system is based on the therapeutic purpose of the drugs rather than their synaptic mechanism of action or physiological effects (i.e. stimulant, depressant, etc.). Comprehensive information on various psychotherapeutic medications is available from the National Institute of Mental Health.

Antidepressants

Antidepressants are medications commonly used to treat depression. Antidepressants are also used for other health conditions, such as anxiety, pain and insomnia. Although antidepressants are not FDA-approved specifically to treat ADHD, antidepressants are sometimes used to treat ADHD in adults.

The most popular types of antidepressants are called selective serotonin reuptake inhibitors (**SSRIs**). Examples of SSRIs include, Fluoxetine (Prozac), Citalopram (Celexa), and Escitalopram (Lexapro). Other types of antidepressants are serotonin and norepinephrine reuptake inhibitors (SNRIs). SNRIs are similar to SSRIs and include venlafaxine (Effexor) and duloxetine (Cymbalta). By inhibiting the reuptake of either serotonin or norepinephrine, these drugs enhance the activity of these systems by allowing these transmitters to stay in the synapse longer.

Another antidepressant that is commonly used is bupropion. **Bupropion** is a third type of antidepressant which **inhibits the reuptake** of **both norepinephrine and dopamine**. Bupropion is also used to treat seasonal affective disorder and to help people stop smoking.

SSRIs, SNRIs, and bupropion are popular because they do not cause as many side effects as older classes of antidepressants, and seem to help a broader group of depressive and anxiety disorders. Older antidepressant medications include tricyclics, tetracyclics, and monoamine oxidase inhibitors (MAOIs). For some people, these may be the best medications.

How do people respond to antidepressants?

According to a research review by the Agency for Healthcare Research and Quality, all antidepressant medications work about as well as each other to improve symptoms of depression and to keep depression symptoms from coming back. For reasons not yet well understood, some people respond better to some antidepressant medications than to others.

Therefore, it is important to know that some people may not feel better with the first medicine they try and may need to try several medicines to find the one that works for them. Others may find that a medicine helped for a while, but their symptoms came back. It is important to carefully follow your doctor's directions for taking your medicine at an adequate dose and over an extended period of time (often 4 to 6 weeks) for it to work.

Once a person begins taking antidepressants, it is important to not stop taking them without the help of a doctor. Sometimes people taking antidepressants feel better and stop taking the medication too soon, and the depression may return. When it is time to stop the medication, the doctor will help the person slowly and safely decrease the dose. It's important to give the body time to adjust to the change. People don't get addicted (or "hooked") on these medications, but stopping them abruptly may also cause withdrawal symptoms

Side Effects of Antidepressants

Some antidepressants may cause more side effects than others. You may need to try several different antidepressant medications before finding the one that improves your symptoms and that causes side effects that you can manage.

The most common side effects listed by the FDA include:

- Nausea and vomiting
- Weight gain
- Diarrhea
- Sleepiness
- Sexual problems

Combining the newer SSRI or SNRI antidepressants with one of the commonly-used "triptan" medications used to treat migraine headaches could cause a life-threatening illness called "serotonin syndrome." A person with serotonin syndrome may be agitated, have hallucinations (see or hear things that are not real), have a high temperature, or have unusual blood pressure changes. Serotonin syndrome is usually associated with the older antidepressants called MAOIs, but it can happen with the newer antidepressants as well, if they are mixed with the wrong medications.

Anti-Anxiety Medications

Anti-anxiety medications help reduce the symptoms of anxiety, such as panic attacks, or extreme fear and worry. The most common anti-anxiety medications are called **benzodiazepines** which act to increase GABA function. Benzodiazepines can be effective in treating generalized anxiety disorder, but in the case of panic disorder or social phobia (social anxiety disorder), benzodiazepines are usually second-line treatments, behind SSRIs or other antidepressants.

Benzodiazepines used to treat anxiety disorders include, Clonazepam (Klonopin), Alprazolam (Xanax), and Lorazepam (Ativan).

Short half-life (or short-acting) benzodiazepines (such as Lorazepam) and beta-blockers (adrenaline inhibitors) are used to treat the short-term symptoms of anxiety. Beta-blockers help manage physical symptoms of anxiety, such as trembling, rapid heartbeat, and sweating that people with phobias (an overwhelming and unreasonable fear of an object or situation, such as public speaking) experience in difficult situations. Taking these medications for a short period of time can help the person keep physical symptoms under control and can be used “as needed” to reduce acute anxiety.

Buspirone (which is unrelated to the benzodiazepines) is sometimes used for the long-term treatment of chronic anxiety. In contrast to the benzodiazepines, buspirone has both agonist and antagonist properties and effects serotonin and dopamine systems in complex ways. This drug must be taken every day for a few weeks to reach its full effect, thus, it is not useful for immediate treatment of anxiety symptoms.

MDMA is an empathogen with both stimulant and hallucinogenic properties. As mentioned in Section 6.4, it was first used in

the 1970s as an aid in psychotherapy but faced many legal and regulatory challenges in subsequent years that stalled both the research and clinical tests of its effectiveness. However, some researchers remained interested in its value in psychotherapy when given to patients under carefully controlled conditions. MDMA is currently in clinical trials as a possible treatment aid for post-traumatic stress disorder (PTSD); for anxiety in terminally ill patients; and for social anxiety in autistic adults. Recently, the FDA gave MDMA-assisted psychotherapy for PTSD a "Breakthrough Therapy" designation.

How do people respond to anti-anxiety medications?

Anti-anxiety medications such as benzodiazepines are effective in relieving anxiety and take effect more quickly than the antidepressant medications (or buspirone) often prescribed for anxiety. However, people can build up a tolerance to benzodiazepines if they are taken over a long period of time and may need higher and higher doses to get the same effect. Some people may even become dependent on them. To avoid these problems, doctors usually prescribe benzodiazepines for short periods, a practice that is especially helpful for older adults, people who have substance abuse problems and people who become dependent on medication easily. If people suddenly stop taking benzodiazepines, they may have withdrawal symptoms or their anxiety may return. Therefore, benzodiazepines should be tapered off slowly.

*Side Effects of A*nti-Anxiety Medications

Like other medications, anti-anxiety medications may cause side effects. Some of these side effects and risks are serious. The most common side effects for benzodiazepines are drowsiness and dizziness. For beta-blockers the common side effects include, fatigue, cold hands, dizziness or light-headedness, and weakness. Beta-blockers generally are not recommended for people with asthma or diabetes because they may worsen symptoms related to both. Possible side effects from buspirone include, dizziness, headaches, nausea, nervousness, lightheadedness, excitement, and trouble sleeping

Stimulants

As the name suggests, stimulants increase alertness, attention, and energy, as well as elevate blood pressure, heart rate, and respiration (National Institute on Drug Abuse, 2014). Stimulant medications are often prescribed to treat children, adolescents, or adults diagnosed with Attention Deficit, Hyperactivity Disorder (ADHD).

Two of the most common stimulants used to treat ADHD are Methylphenidate (Ritalin), and Amphetamine/Dextroamphetamine (Adderall)

Stimulants are also prescribed to treat other health conditions, including narcolepsy, and occasionally depression (especially in older or chronically medically ill people and in those who have not responded to other treatments).

How do people respond to stimulants?

Stimulants have the potential to cause excessive activity and physiological activation, however, for individuals with ADHD the opposite is true in that it can have a calming and “focusing” effect. Stimulant medications are safe when given under a doctor's supervision. Some children taking them may feel slightly different or "funny."

Some parents worry that stimulant medications may lead to drug abuse or dependence, but there is little evidence of this when they are used properly as prescribed. Additionally, research shows that teens with ADHD who took stimulant medications were less likely to abuse drugs than those who did not take stimulant medications. Despite the findings noted above, there is also research indicating the risk of "diversion" of prescribed stimulants for nonmedical uses between students at educational institutions. This diversion could put individuals at a higher risk for stimulant abuse.

Side Effects of Stimulants

Most side effects are minor and disappear when dosage levels are lowered. The most common side effects include:

- Difficulty falling asleep or staying asleep
- Loss of appetite
- Stomach pain
- Headache

Less common side effects include:

- Motor tics or verbal tics (sudden, repetitive movements or sounds)
- Personality changes, such as appearing “flat” or without emotion

Antipsychotics

Antipsychotic medicines are primarily used to manage psychosis. The word “psychosis” is used to describe conditions that affect the mind, and in which there has been some loss of contact with reality, often including delusions (false, fixed beliefs) or hallucinations (hearing or seeing things that are not really there). It can be a symptom of a physical condition such as drug abuse or a mental disorder such as schizophrenia, bipolar disorder, or very severe depression (also known as “psychotic depression”).

Antipsychotic medicines do not cure these conditions. They are used to help relieve symptoms and improve quality of life.

Older or first-generation antipsychotic medications are also called conventional "typical" antipsychotics or “neuroleptics”. Most of the drugs in this class act as potent dopamine antagonists primarily effecting the dopamine D2 receptor. This antagonistic effect reduces the dopamine overactivity found in psychotic disorders, such as Schizophrenia. Some of the common first-generation antipsychotics include:

- Chlorpromazine
- Haloperidol
- Fluphenazine

Newer or second generation medications are also called "atypical" antipsychotics. These drugs act on various neurotransmitters systems in addition to dopamine and, as such are not as potent in their dopamine antagonism. Some of the common atypical antipsychotics include:

- Risperidone
- Olanzapine
- Quetiapine

Both typical and atypical antipsychotics have been shown to work to treat symptoms of schizophrenia and the manic phase of bipolar disorder. In addtion, several atypical antipsychotics have a “broader spectrum” of action than the older medications, and are used for treating bipolar depression or depression that has not responded to an antidepressant medication alone.

How do people respond to antipsychotics?

Certain symptoms, such as feeling agitated and having hallucinations, usually go away within days of starting an antipsychotic medication. Symptoms like delusions usually go away within a few weeks, but the full effects of the medication may not be seen for up to six weeks. Every patient responds differently, so it may take several trials of different antipsychotic medications to find the one that works best.

Some people may have a relapse—meaning their symptoms come back or get worse. Usually relapses happen when people stop taking their medication, or when they only take it sometimes. Some people stop taking the medication because they feel better or they may feel that they don't need it anymore, but no one should stop taking an antipsychotic medication without talking to his or her doctor.When a doctor says it is okay to stop taking a medication, it should be gradually tapered off— never stopped suddenly. Many people must stay on an antipsychotic continuously for months or years in order to stay well; treatment should be personalized for each individual.

Side Effects of Antipsychotics?

Antipsychotics have many side effects (or adverse events) and risks. The FDA lists the following side effects of antipsychotic medicines:

- Drowsiness
- Dizziness
- Restlessness

- Weight gain (the risk is higher with some atypical antipsychotic medicines)
- Dry mouth
- Constipation
- Nausea
- Vomiting
- Blurred vision
- Low blood pressure
- Uncontrollable movements, such as tics and tremors (the risk is higher with typical antipsychotic medicines)
- Seizures
- A low number of white blood cells, which fight infections

The older, typical antipsychotic medications can also cause additional side effects related to physical movement, such as:

- Rigidity
- Persistent muscle spasms
- Tremors
- Restlessness

Long-term use of typical antipsychotic medications may lead to a condition called tardive dyskinesia (TD). TD causes muscle movements, commonly around the mouth, that a person can't control. TD can range from mild to severe, and in some people, the problem cannot be cured. Sometimes people with TD recover partially or fully after they stop taking typical antipsychotic medication. People who think that they might have TD should check with their doctor before stopping their medication. TD rarely occurs while taking atypical antipsychotics.

Mood Stabilizers

Mood stabilizers are used primarily to treat bipolar disorder, mood swings associated with other mental disorders, and in some cases, to augment the effect of other medications used to treat depression. **Lithium**, which is an effective mood stabilizer, has a broad spectrum of action including the inhibition of dopamine and glutamate systems and increased GABA action (Malhi, et al., 2013). Lithium is approved for the treatment of mania and the maintenance treatment of bipolar disorder. Additionally, a number of cohort studies describe anti-suicide benefits of lithium for individuals on long-term maintenance. Because mood stabilizers work primarily by decreasing abnormal activity in the brain they are also sometimes used to treat:

- Depression (usually along with an antidepressant)
- Schizoaffective Disorder
- Disorders of impulse control
- Certain mental illnesses in children

Anticonvulsant medications that primarily act as agonists to GABA neurotransmitter systems are also used as mood stabilizers. They were originally developed to treat seizures, but they were found to help control unstable moods as well. One anticonvulsant commonly used as a mood stabilizer is valproic acid (also called divalproex sodium). For some people, especially those with “mixed” symptoms of mania and depression or those with rapid-cycling bipolar disorder, valproic acid may work better than lithium. Other anticonvulsants used as mood stabilizers include:

- Carbamazepine
- Lamotrigine
- Oxcarbazepine

*Side Effects of M*ood Stabilizers

Mood stabilizers can cause several side effects, and some of them may become serious, especially at excessively high blood levels. These side effects include:

- Itching, rash
- Excessive thirst
- Frequent urination
- Tremor (shakiness) of the hands

- Nausea and vomiting
- Slurred speech
- Fast, slow, irregular, or pounding heartbeat
- Blackouts
- Changes in vision
- Seizures
- Hallucinations (seeing things or hearing voices that do not exist)
- Loss of coordination
- Swelling of the eyes, face, lips, tongue, throat, hands, feet, ankles, or lower legs.

Some possible side effects linked to anticonvulsants (such as valproic acid) include:

- Drowsiness
- Dizziness
- Headache
- Diarrhea
- Constipation
- Changes in appetite and/or weight
- Agitation
- Mood swings
- Abnormal thinking
- Uncontrollable shaking or movement of a part of the body
- Loss of coordination
- Blurred or double vision
- Ringing in the ears
- Hair loss

Summary

It should be clear that psychotherapeutic medications have been proven effective at treating a wide variety of psychological disorders, with only a few major types reviewed here. The drugs that treat depression, anxiety, psychosis, and various other disorders of mood and cognition do so by a variety of means. Each category of psychotherapeutic drug can include various different drugs with different actions at the synaptic and neurotransmitter levels. Many other drugs not referenced here, such as hallucinogens and marijuana have also been studied for their potential effectiveness in treating disorders, such as Post Traumatic Stress Disorder, Anxiety, and depression. Some positive outcomes have been found, but more definitive research is needed in order to validate these findings.

5.8.1: Biological Factors in Psychological Disorders- An Introduction

Learning Objectives

- Identify 3 biological areas that contribute to psychological disorders.
- Describe the role of neural structures in psychological disorders.
- Identify 2 systems of chemical communication used by the brain.
- Describe how genetics and epigenetics contribute to psychological disorders.

Chapter Overview

This chapter discusses the biological perspective on psychological disorders, exploring how our brain structures, neural systems, and genetics contribute to the etiology of such disorders as schizophrenia, depression, bipolar, anxiety, and obsessive/compulsion.

Introduction

by Amy E. Coren, Ph.D., Pasadena City College

Although the term mental illness is often used when referring to disorders such as depression or anxiety, are these disorders really illnesses in the way that diabetes is an illness – that is a purely biological malfunction? Or are psychological disorders the product of something more intangible than a neurochemical imbalance or malfunctioning amygdala, something such as a conditioned response to stress learned in childhood? The answer is both.

Within the field of psychology, it is generally acknowledged that psychological disorders develop out of a complex interaction of biological, social, and environmental factors. However, exactly how these factors interact with one another to produce a particular psychological disorder is still unclear. This is because diagnosing a psychological disorder is not like diagnosing other illnesses, such as diabetes or pneumonia.

When making a diagnosis of diabetes, a doctor may use a blood test to determine blood glucose levels. Similarly, to diagnose pneumonia, a doctor may order a chest x-ray to look for evidence of the infection. However, when it comes to diagnosing psychological disorders, there is currently no x-ray for depression or blood test for anxiety. Diagnosing psychological disorders is a more subjective process, based on the current symptoms an individual is experiencing.

The Diagnostic and Statistical Manual of Mental Disorders, 5th edition, (American Psychiatric Association, 2013) is the most widely accepted system used by clinicians and researchers for the classification of mental disorders, and outlines the diagnostic criteria for a specific mental disorder based on the symptoms an individual is experiencing. However, individuals suffering from the same disorder often display different symptoms while individuals suffering from different disorders may display many of the same symptoms, making the diagnosis of psychological disorders from outward symptoms alone, difficult.

Note

The American Psychological Association periodically updates the Diagnostic and Statistical Manual of Mental Disorders - also called the **DSM** - so that it will accurately reflect our current understanding of the symptoms, etiology, and treatment of psychological disorders. The revisions to the DSM-5 were released in early 2022, in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Text Revision (DSM-5-TR).

The remainder of this chapter focuses on the contributions of biological factors - such as brain structure abnormalities - to the development of psychological disorders.

Biology of Psychological Disorders

Research into the underlying biology of psychological disorders has primarily focused on the following three areas: (1) the structures of the brain, (2) the biochemistry of the brain, and (3) genetics and epigenetics.

Structures of the Brain

Research has shown that some psychological disorders appear to involve specific structures within the brain. For example, overactivity in an area of the brain known as Brodmann Area 25 (BA25), shown in Figure 17.1.1, is often present in individuals with clinical depression (also known as Major Depressive Disorder) (Mayberg et al., 2005). BA25 acts as a "junction box" that interacts, through the use of neurotransmitters such as dopamine, with other areas of the brain involved in mood, emotion and thinking. When the BA25 region is overactive, a person can experience an increased negative affect (e.g. sadness, anxiety) and decreased positive affect (e.g. happiness, joy) (Jumah & Dossani, 2021). We will explore the role of brain structures in more detail as we discuss specific disorders later in this chapter.

Biochemistry of the Brain

In addition to the individual structures of the brain, researchers are also interested in what role our chemical communication systems – hormones and neurotransmitters –play in the development of psychological disorders.

The primary communication in the brain occurs between neurons (neurotransmission) using chemicals known as neurotransmitters. When the levels of these neurotransmitters are out of balance, the communication between neurons can be altered or disrupted, resulting in a display of symptoms associated with various psychological disorders.

For example, researchers believe that disruptions in the neurotransmitters, particularly dopamine, play an important role in schizophrenia (NIH, 2007). This link between dopamine and schizophrenia arose out of observations that individuals addicted to cocaine sometimes showed symptoms very similar to those seen in cases of schizophrenia. Cocaine works by reducing the amount of monoamine neurotransmitters (dopamine, norepinephrine, epinephrine, and serotonin) that are taken back into the

presynaptic neuron (Richards & Laurin, 2021), as shown in Figure 2. When this happens, more monoamine neurotransmitters, crucially dopamine, are available in the synapse for binding to the receptors on the postsynaptic neuron. We will discuss the dopamine theory of schizophrenia in more detail later in this chapter.

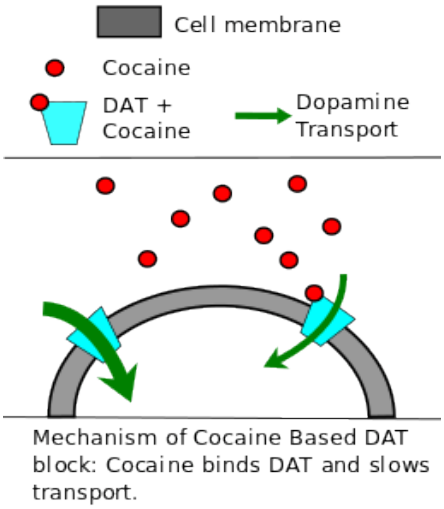

Figure 5.8.1.2: **How cocaine increases the amount of dopamine in the synapse by reducing the activity of the dopamine reuptake transporter (DAT)**; (CC BY-SA 3.0; Hard-59 via Wikimedia Commons.)

In addition to neurotransmitters, the brain also communicates via hormones, which are released by the endocrine system, and activate behaviors such as alertness or sleepiness, concentration, and reactions to stress. Elevated or depleted levels of certain hormones may be responsible for some of the symptoms seen in psychological disorders. For example, elevated levels of cortisol, a stress hormone, interfere with learning and memory as well as increase the risk of depression. High levels of cortisol have been shown to alter the function of serotonin receptors in the brain, leading to symptoms of depression (Qin et al., 2018).

Genetics and Epigenetics

Researchers have long recognized that many psychological disorders tend to run in families, suggesting a potential genetic factor. In family and twin studies, schizophrenia is significantly more likely to be present in an identical twin than a fraternal twin (Coon & Miller, 2007) and in individuals with a first-degree relative (e.g. mother or father) with schizophrenia.

Researchers have also linked several genetic variations, or mutations, to psychological disorders, including variations in two genes which code for the cellular machinery that helps regulate the flow of calcium into neurons (NIH, 2013). One of these calcium channel genes, CACNA1C, is known to affect the brain circuitry involved in emotion, thinking, attention and memory. Variations in this gene have been linked to disorders such as bipolar disorder, schizophrenia, and major depression.

Figure 5.8.1.3: **Dr. Bruce Cuthbert, Ph.D., director of NIMH's Division of Adult Translational Research, explains the significance of genetic findings for diagnosis and treatment of mental illnesses.**

Although individual genes, such as CACNA1C, have been linked to psychological disorders, most disorders are believed to be polygenic; that is linked to abnormalities in many genes, rather than just one. It is the complex interaction between multiple genes

which may trigger a psychological disorder.

Furthermore, while researchers currently believe that genetic factors are implicated in all psychological disorders, they are not believed to be the sole cause. There are important gene-environment interactions, also known as epigenetic factors, unique to each individual (even identical twins) which may explain why some individuals with a genetic predisposition toward a certain disorder develop that disorder while others do not (e.g., why one identical twin develops schizophrenia, but the other does not).

5.8.2: Biological Basis of Mood Disorders- Major Depressive and Bipolar Disorders

Learning Objectives

- Describe what is meant by the term “mood disorder”.
- Describe the differences between depressive and bipolar disorders.
- Identify the biology thought to underlie the etiology of Major Depressive Disorder.
- Identify the biology thought to underlie the etiology of Bipolar Disorder (I & II).

Chapter Overview

Mood disorders are a broad category of psychological disorders characterized by severe disturbances in mood and emotion. While these disorders share common features of extreme mood alteration, most research suggests that they have different biological origins (Cuellar et al., 2005).

An Introduction to Mood Disorders

The classification, **mood disorders,** is used by mental health professionals to describe a broad group of psychological disorders characterized by severe disturbances in mood and emotion. Also known as **affective disorders**, disorders in this category are typically classified into two distinct groups: depressive disorders and bipolar disorders (Figure 17.2.1.).

Depressive disorders typically include major depressive disorder, also known as clinical depression, which is characterized by episodes of profound sadness and loss of interest or pleasure in usual activities, among other features, and persistent depressive disorder (formerly **dysthymia**), a milder but long-term, chronic form of depression. Bipolar disorders are characterized by mood states that vacillate between sadness and euphoria and include bipolar disorder types I and II, as well as cyclothymic disorder (APA, 2013).

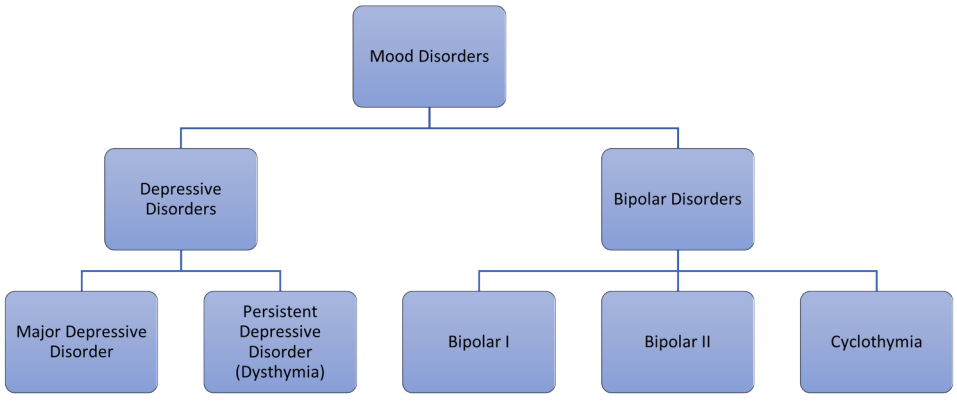

Figure 5.8.2.1: **Mood disorders are typically grouped in two categories: (1) Depressive disorders, which include Major Depressive Disorder and Persistent Depressive Disorder (Dysthymia) and (2) Bipolar disorders which includes Bipolar I & II and Cyclothymia.** (CC BY-NC-SA 4.0; by Amy E. Coren, Ph.D.)

Depressive Disorders

Depressive disorders are a group of disorders whose main features include a depressed mood for most of the day and/or feelings of **anhedonia** (the inability to feel pleasure from activities usual found enjoyable) (Post & Warden, 2018).

The DSM-5 describes the main features of depressive disorders as "the presence of sad, empty, or irritable mood, accompanied by somatic and cognitive changes that significantly affect the individual's capacity to function." (APA, 2013) Depressed people often report feeling sad, discouraged, and hopeless (Figure 17.2.2) These individuals lose interest in activities they once enjoyed, and often experience a decrease in drives such as hunger and sex, and frequently doubt their personal worth. When these features are triggered by a traumatic or negative experience (e.g. death of close loved one), it is called **reactive depression**. When there is no apparent reason or cause, it is known as **endogenous depression.**

Figure 5.8.2.2: **Individuals suffering from a depressive disorder often feel sad, discouraged, and alone.** (Public Domain; Jack Lucas Smith via Unsplash)

Depressive disorders are often highly **comorbid** (meaning more than one health condition is present in the same person at the same time) with other psychological disorders. Depressive disorders are often seen occurring alongside anxiety disorders, bipolar disorders, and OCD and related disorders (Groen, et al., 2020).

Perhaps the most well-known example of a depressive disorder is **Major Depressive Disorder (MDD)**, also known as **clinical depression**. Major depressive disorder is believed to affect about 2-5% of the global population each year (Han, et al., 2019). According to the DSM-5, the defining symptoms of **major depressive disorder** include "depressed mood most of the day, nearly every day" (feeling sad, empty, hopeless, or appearing tearful to others) and loss of interest and pleasure in usual activities (APA, 2013). When these symptoms last for longer than 2 weeks, and significantly impair an individual's ability to function, that individual is said to be suffering from MDD.

Researchers and mental health professionals both agree that there is no single cause responsible for any of the depressive disorders. Rather it is thought that depressive disorders arise from the interaction between multiple biological and environmental factors. However, this interaction is thought to be extremely complex and is still not well understood. As such, the biology underlying depressive disorders continues to be a major subject of ongoing research and is explored in more detail below.

The Genetics and Epigenetics of Depressive Disorders

Historically, evidence from family, twin, and adoption studies has seemed to support the idea that genetic factors play an important role in the development of depressive disorders, although which genes are involved and the how these genes interact to contribute to the development of depressive disorders is still not understood (Lohoff, 2010).

In 2015, several genome-wide association studies (GWASs), which involve scanning the genomes of large groups of people to find genetic variations associated with a disorder, identified over 100 possible genes which may play a role in increasing an

individual's risk for developing a depressive disorder (Ormel, et al., 2019, Shadrina, et al., 2018).

As a result of these studies, and others, it is now believed that an individual's genetic predisposition to a depressive disorder is determined by (1) the coordinated action of many genes, (2) the genes' interactions with each other, and (3) their interactions with environmental factors through epigenetic mechanisms (Shardina, et al., 2018).

Current research is now focusing on the role of epigenetics - how behaviors and environment can cause changes that affect the way our genes work, in the development of depressive disorders such as MDD (Barbu, et al., 2020).

The Role of Neurotransmitters in Depressive Disorders

Until relatively recently, low levels of neurotransmitters in the brain were believed to be the main culprits behind depressive disorders. However, current research now suggests that, while neurotransmitters do play an important role, the reality is much more complicated than previously thought.

Monoamine Theory of Depression

It has historically been believed that low activity levels of monoamine neurotransmitters (norepinephrine, serotonin, and dopamine) contribute to the symptoms associated with depressive disorders (Nutt, 2008). The discovery that certain drugs which increased levels of serotonin and norepinephrine in the brain, alleviated depressive symptoms, lead to formulation of the monoamine theory of depression by Joseph Schildkraut in the 1960s. According to the monoamine theory, low levels of serotonin, norepinephrine, and/or dopamine in the central nervous system are primarily the basis for the development of depressive disorders (Hirschfeld, 2000). This theory prevailed for more than 50 years before being challenged by an increasing number of research studies and clinical observations.

Today, most current research acknowledges that while monoamine neurotransmitters are important, they are by far not the *only* neurotransmitters involved in depressive disorders. The following video from Yale Medicine explains why the monoamine theory of depression is no longer believed to be correct and what alternative theories researchers are currently exploring. For example, other neurotransmitters, such as glutamate and GABA, are increasingly being investigated for their role in the development of depression.

YouTube Video

This interactive element is not available in this format. Visit the link or scan the QR code to access it online.

View this YouTube Video online

Furthermore, research is increasingly focused not only on individual neurotransmitters, but also on the *interactions* between the various neurotransmitters themselves as well as how they interact with other biological systems such as the endocrine system

(Ding et al., 2014). For example, serotonin production and activity are affected by the hormones secreted by the endocrine system, such as cortisol, in response to threat or stress.

The role of neural structures in MDD

Research into the neural basis of MDD has focused on examining the neural architecture of individuals with MDD by using a variety of both structural and functional neuroimaging techniques. Structural techniques, such as CT scans and magnetic resonance imaging (MRI), take static pictures of the brain to determine whether any specific neural structures are different in subjects with MDD than control subjects.

By using these static neuroimaging techniques, researchers have discovered several areas of the brain where the volume of **grey matter** is significantly decreased in those individuals with MDD (Filatova, et al., 2021). These areas include the prefrontal cortex (PFC), hippocampus, amygdala, and cingulate cortex (Ancelin, et al. 2019).

Importantly, these areas comprise most of the major structures in the brain's **corticolimbic system**, a system responsible for regulating multiple behavioral and cognitive functions, including decision making, motivation, emotional processing, and our response to stress and pain (Vachon-Presseau, 2018) (Figure 16.2.3.).

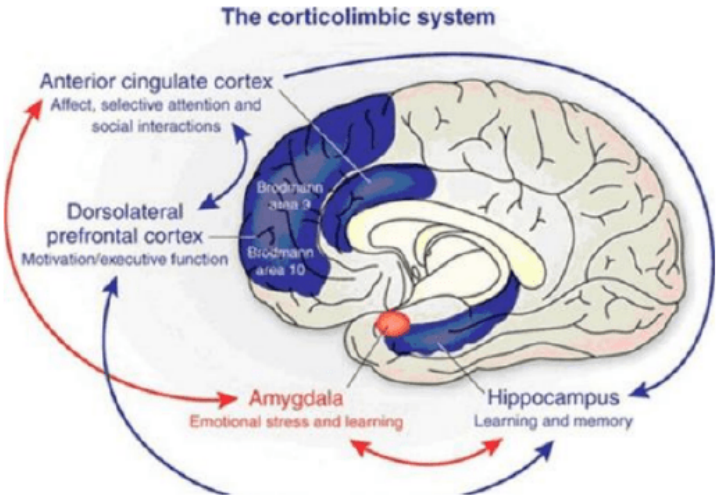

Figure 5.8.2.3: **The corticolimbic system in the brain regulates several important behavioral and cognitive functions, including our reactions to stress and pain.** (CC BY-SA 4.0; Benes 2010 via Wikimedia Commons)

In addition to looking at the overall structure of the brain, researchers also use functional neuroimaging techniques, such as positron emission tomography (PET) scans and functional magnetic resonance imaging (fMRI), to examine the brain in action, looking for any areas of atypical activation.

For example, a meta-analysis of neuroimaging studies showed that when viewing negative stimuli (e.g., picture of an angry face, picture of a car accident), participants with MDD have *greater* activation in brain regions involved in stress response, such as the amygdala and anterior cingulate cortex, and *reduced* activation in brain regions involved in positively motivated behaviors, such as the prefrontal cortex, compared with healthy control participants. (Hamilton, et al., 2012).

Other functional imaging studies have examined alterations in the **functional connectivity** - the strength of the connections between regions of the brain. These connections allow multiple brain regions to properly "talk" to one another; that is to perceive, generate, and encode information in concert. By examining these neural connections, researchers can see if there are problems in the way the brain processes specific types of information in individuals with MDD, and where these "faulty" connections may occur (Goldstein-Peikarski, et al. 2018).

Several studies have noted differences in the neural networks of individuals with MDD, compared to those without. For example, abnormally low activity in brain regions related to stopping thoughts and shifting to new ones, referred to in the research as "cognitive control," and hyperactivity in other brain regions that "process emotional thoughts and feelings" has consistently been

found in individuals with MDD (Janiri, et al., 2019).

Bipolar Disorders

Some people who suffer from clinical depression may also experience what are known as **manic** or **hypomanic** episodes. When this occurs, the individual is usually diagnosed with **bipolar disorder**.

Hypomanic episodes are fairly short– around 4 days in duration, and are characterized by a positive mood, reduced need for sleep, and high energy. Individuals experiencing a hypomanic episode are often talkative, impulsive, energetic, and very confident. It is important to note that by definition, hypomanic episodes cannot cause impairment, distress, or the need for hospitalization. If any of these three features are present the episode is considered to be manic, rather than hypomanic.

Manic episodes are longer, at least 1 week in duration, and have features similar to hypomania but taken to an extreme. In addition, manic episodes are often characterized by delusions of grandeur, psychosis, and distractibility. Additionally, for an episode to be considered manic, it must cause impairment in functioning, significant distress, or require the individual to be hospitalized.

Bipolar I disorder, previously known as manic-depressive disorder, is diagnosed when there is at least one manic episode. This manic episode may be preceded by or followed by a major depressive episode but that is not required for the Bipolar I diagnosis. In contrast, a diagnosis of **bipolar II disorder** is made when the individual has experienced *both* a hypomanic episode and a depressive episode, but no manic episodes. Alternatively, an individual may suffer from **cyclothymic disorder**, which characterized by multiple, alternating periods of hypomania and depression, lasting at least two years. To qualify for cyclothymic disorder, the person must experience symptoms at least half the time with no more than two consecutive symptom-free months; and the symptoms must cause significant distress or impairment (APA, 2013).

The Genetics and Epigenetics of Bipolar Disorders

Numerous twin and family studies have shown that there is a strong genetic component to bipolar disorders, especially Bipolar I (Edvardsen et al., 2008, Escamilla & Zavala, 2008). However, the exact nature of this genetic component remains elusive – numerous studies, include a genome-wide association study (GWAS) of more than 40,000 bipolar disorder cases, have identified hundreds to thousands of genes associated with bipolar disorder (Gandal, et al. 2018).

Given the complicated genetic component, recent research has focused on the identifying epigenetic mechanisms which may play role in the risk and development of bipolar disorders (Duffy, et al. 2019).

Dig Deeper

Genome-wide association studies, or GWAS, have become an increasingly popular tool for exploring the genetic and epigenetic factors involved in psychological disorders, such as Biopolar Disorders. To learn more about GWAS and their use in Bipolar disorder research, check out the following video:

The Role of Neurotransmitters and Neural Structures in Bipolar Disorders

As depression was often a characteristic of bipolar disorders, researchers initially believed that norepinephrine, serotonin, and dopamine were all implicated in the development of bipolar disorder. It was thought that manic episodes were the result of drastic increases in serotonin. Unfortunately, research did not support this hypothesis. It is now believed that manic episodes may, in fact, be explained by low levels of serotonin and high levels of norepinephrine (Soreff & McInnes, 2014).

In addition, consistent decreases in gray matter volume in both the prefrontal cortex and areas of the limbic system, such as the hippocampus, have been reported, as have enlargement of the ventricles (Jiang, et al. 2020).

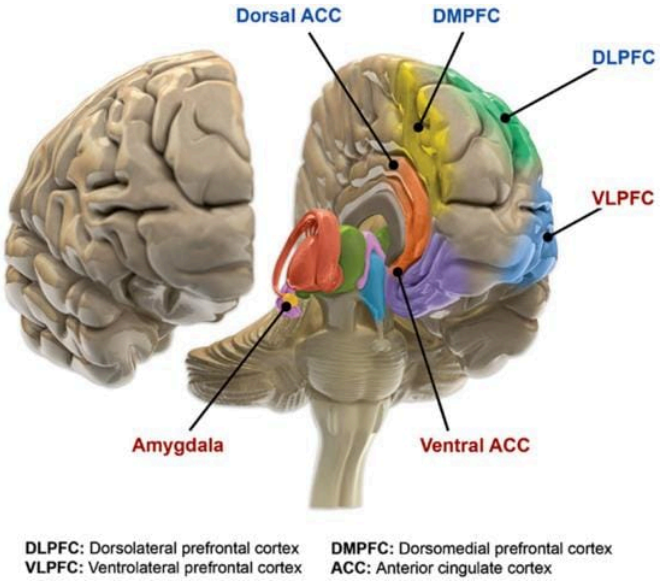

Figure 5.8.2.4: **Regions of the brain implicated in Bipolar disorders.** (CC BY 4.0; Maletic V, Raison C via Wikimedia Commons)

Studies of brain activity have led to the view that bipolar disorder may be a suite of related neurological issues with interconnected functional abnormalities that often appear early in life and worsen over time. In support of this hypothesis, fMRI techniques have noted atypical activation of the frontal cortex and basil ganglia, as well as disruption in the connectivity between these structures (Maletic & Rasion, 2014). The issues in connectivity seem to cluster around those networks in the brain associated with emotional processing.

5.8.3: Biological Basis of Anxiety Disorders

Learning Objectives

- Describe the principal features of anxiety disorders.
- Describe the difference between fear and anxiety.
- Identify the major biological systems involved in anxiety and fear.
- Identify the biology thought to underlie the etiology of anxiety disorders.

Overview

Anxiety disorders are the most prevalent of all psychological disorders. Large scale surveys estimate that around 33% of the population is likely to suffer from an anxiety disorder at some point in their lives (Bandelow & Michaelis, 2015). The category of anxiety disorders encompasses a broad range of disorders marked by severe levels of fear and anxiety. Similar to the other disorders discussed in this chapter, the etiology of anxiety disorders is thought to be a complex combination of biological and environmental factors.

Introduction to Anxiety Disorders

The main feature common to all individuals suffering from an anxiety disorder is the experience of excessive **anxiety**. Similar to the emotion, fear, anxiety acts as a signal of danger, threat, or motivational conflict, and prepares the body for action. While *fear* is a physical and emotional response to a real or external imminent threat, *anxiety* is a generalized response to an unknown threat or internal conflict, often accompanied by bodily symptoms such as increased heart rate, muscle tension, a sense of unease, and apprehension about the future (APA, 2013). The category of anxiety disorders includes generalized anxiety disorder, panic disorder, specific phobia, and social anxiety disorder (social phobia) (APA, 2013).

Figure 5.8.3.1: **Anxiety is generalized, unfocused fear that may be triggered by a variety of sources, both internal and external.** (Public Domain; Mohammad_Hassan via Pixabay)

Like many psychological disorders, anxiety disorders are believed to arise from a complex blend of factors, both biological and environmental, that when combined with stress, lead to the development of a particular anxiety disorder.

Although all the anxiety disorders share the feeling of anxiety as a symptom, there are many different ways in which this anxiety may manifest in an individual, leading to the diversity seen among the disorders in this category.

Genetic and epigenetic factors in anxiety disorders

Anxiety disorders are believed to be highly complex and polygenic (Meier & Decker, 2019). While genetics have been known to contribute to the presentation of anxiety symptoms, the interaction between genetics and stressful environmental influences accounts for more anxiety disorders than genetics alone (Bienvenu, et al., 2011). Nevertheless, several genes have been identified that may contribute to the increased risk of the development of anxiety disorders.

One of the first promising genes to be identified was a serotonin transporter or SERT gene. The serotonin transporter is of major importance in regulating levels of serotonin in the synapse. Serotonin synapses play a central role in the neural circuitry controlling mood and temperament (Houwing, et al., 2017). Disturbances in the serotonin system are known to contribute to many psychological disorders (Andrews et al., 2015). Mutation of the SERT gene have been found to be related to a reduction in serotonin activity and an increase in anxiety-related personality traits (Munafo, et al, 2008).

In 2020, a large research study of over 200,000 participants identified a gene known as SATB1 (Levey, et al. 2020). This gene is believed to influence the activity ("expression") of multiple other genes involved in neuronal development, including a gene known as CRH1. The CRH1 gene codes for the protein, Corticotropin Releasing Hormone (*CRH*), which is a hormone that plays an essential role in our body's hypothalamic-pituitary-adrenal (HPA) axis, the pathway that modulates our stress and fear/anxiety responses.

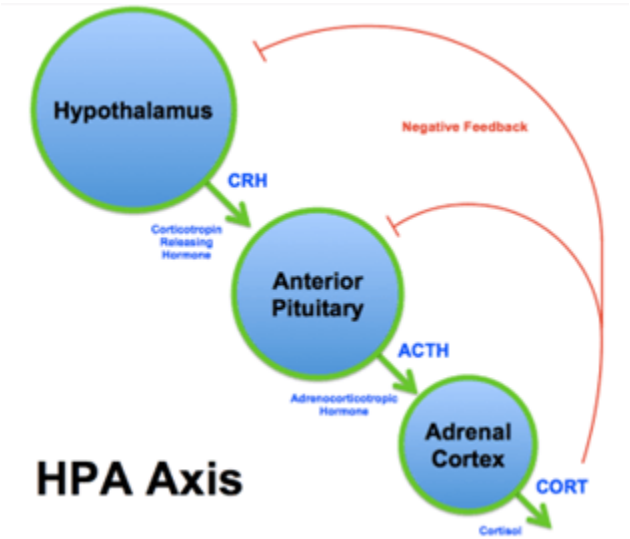

Figure 5.8.3.2: **The body's HPA axis regulates stress responses. Genes which help maintain this system, may play a role in the risk of developing an anxiety disorder.** (CC BY-SA 3.0; BrianMSweis via Wikimedia Commons)

Neural structures and neurotransmitters involved anxiety disorders

Researchers have identified several brain structures and pathways that are may be responsible for the excessive anxiety responses often seen in anxiety disorders. In particular, the atypical activation in the prefrontal cortex, hippocampus, and amygdala has been implicated in anxiety disorders (Shin & Liberzon, 2010, Maron & Nutt, 2017).

A region of the brain called the locus coeruleus has been of particular interest to researchers studying panic disorder. Located in the brainstem, the locus coeruleus is the brain's major source of norepinephrine, a neurotransmitter that triggers the body's fight-or-flight response (Figure 16.3.4.1). Research with nonhuman primates has shown that stimulating the locus coeruleus either electrically or through drugs produces panic-like symptoms (Charney et al., 1990). Such findings have led to the theory that individuals with panic disorder may have a hyperactive locus coeruleus, leaving them an increased likelihood of experiencing more intense and frequent physiological arousal than the general public (Gorman, et al., 2000). This theory is supported by studies in which individuals experienced increased panic symptoms following injection of norepinephrine (Bourin, et al., 1995).

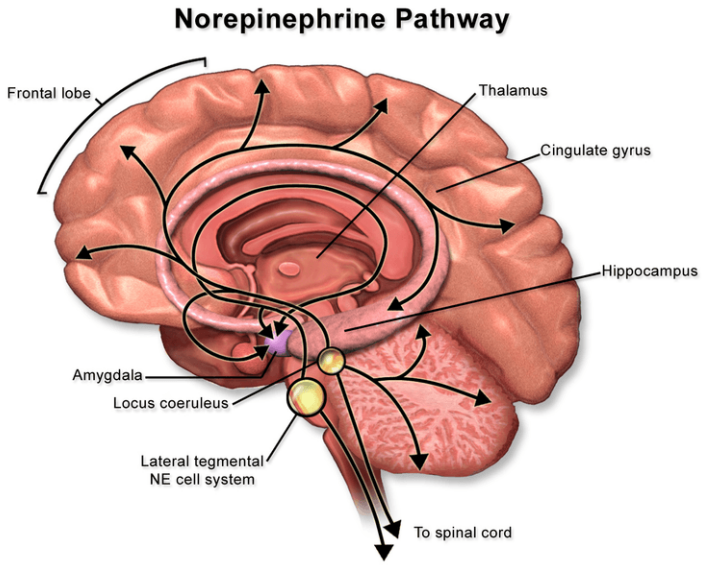

Figure 5.8.3.3: **The locus coeruleus and the norepinephrine pathway.** (CC BY-SA 4.0; BruceBlaus via Wikimedia Commons)

Unfortunately, norepinephrine and the locus coeruleus fail to fully explain the development of panic disorder, and a more complex neuropathway is likely implicated in the development of panic disorder. More specifically, the corticostriatal-thalamocortical (CSTC) circuit, also known as the fear-specific circuit, is theorized as a major contributor to panic symptoms (Gutman, et al., 2004). When an individual is presented with a frightening object or situation, the amygdala is activated, sending a fear response to the anterior cingulate cortex and the orbitofrontal cortex. Additional projections from the amygdala to the hypothalamus activate endocrinologic responses to fear- releasing adrenaline and cortisol to help prepare the body to fight or flight (Gutman, et al. 2004).

5.8.4: Biological Basis of Schizophrenia Spectrum Disorder

Learning Objectives

- Describe the principal features of schizophrenia spectrum disorders.
- Identify the difference between positive and negative symptoms in schizophrenia.
- Identify the biology thought to underlie the etiology of schizophrenia.
- Describe the dopamine hypothesis of schizophrenia.

Section Overview

Schizophrenia spectrum and other psychotic disorders are a category of psychological disorders encompassing an incredibly diverse range of characteristics, including distortions in perception, impairments in cognition, and abnormal motor activity. In addition, the symptoms vary greatly among individuals, as there are rarely two cases similar in presentation, course, or responsiveness to treatment (APA, 2013).

This category also includes schizophreniform disorder (a briefer version of schizophrenia), schizoaffective disorder (a mixture of psychosis and depression/mania symptoms), delusional disorder (the experience of only delusions), and brief psychotic disorder (psychotic symptoms that last only a few days or weeks). However, as many of the symptoms of these disorders overlap with schizophrenia, this disorder is the primary focus of this section.

Introduction to Schizophrenia

Originally termed *dementia praecox* (Latin for premature dementia), schizophrenia involves a diverse and complex set of symptoms, such as delusions, hallucinations, disorganized speech and behavior, abnormal motor behavior (including catatonia), anhedonia/amotivation and blunted affect/reduced speech (APA, 2013). Given this diversity of symptoms, and the fact that the presentation of symptoms can vary widely from case to case, it has been difficult for researchers and clinicians to precisely define schizophrenia as a disorder (Tandor, 2013). Growing evidence suggests that schizophrenia represents a broad and heterogenous syndrome, rather than a specific disorder, and is better classified along a psychosis spectrum (APA, 2013, Cuthbert & Morris, 2021).

When considering the symptoms of schizophrenia, it is common practice to divide the symptoms into **positive symptoms** (symptoms that demonstrate an excess of function) and **negative symptoms** (symptoms that represent a loss or reduction in function) (see Figure 17.4.2.1).

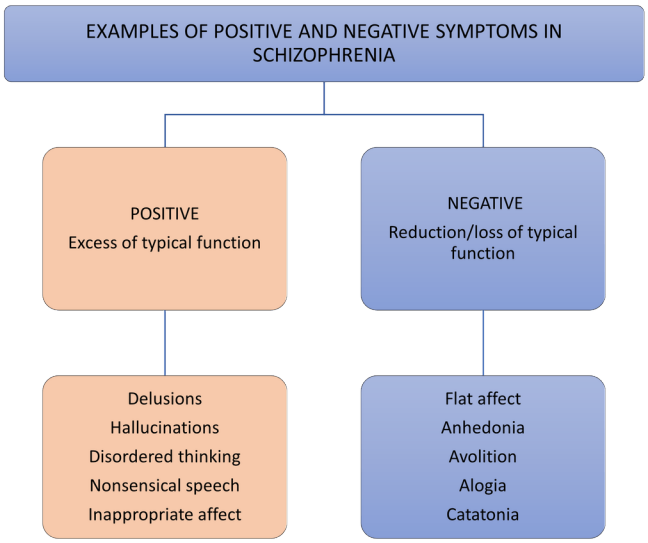

Figure 5.8.4.1: **Schizophrenia symptoms are often classified as positive (an excess of typical function) or negative (a loss/reduction in typical function).** (CC BY-SA 4.0; Amy E. Coren, Ph.D.)

The most common positive symptoms are **delusions** and **hallucinations**. Delusions are "fixed beliefs that are not amenable to change in light of conflicting evidence" (APA, 2013, pp. 87). An individual suffering from delusions remains convinced in their belief, even when presented with clear, contradicting evidence. Researchers believe that delusions primarily relate to the social, emotional, educational, and cultural background of the individual (Arango & Carpenter, 2010). For example, an individual with schizophrenia who comes from a highly religious family is more likely to experience religious delusions (delusions of grandeur) than another type of delusion.

Hallucinations are perceptual experiences with no external stimulus (such as hearing voices when no one else is present). Hallucinations can occur in any sensory modality: auditory, visual, olfactory (smell), gustatory (taste), or somatic (touch), however the most common type are auditory hallucinations (APA, 2013). The content of these auditory hallucinations is frequently negative, making critical comments ("you're worthless") or telling the person what to do.

Negative symptoms typically involve an impairment in functions – cognitive, physical, and/or emotional. For example, anhedonia reflects a lack of apparent drive to engage in social or recreational activities. Importantly, this does not seem to reflect a lack of enjoyment in pleasurable activities or events (as is often seen in Depressive Disorders) (Llerena, et al., 2012) but rather a reduced drive or ability to take the steps necessary to obtain the potentially positive outcomes (Barch & Dowd, 2010). Flat affect and reduced speech (alogia) reflect a lack of showing emotions through facial expressions, gestures, and speech intonation, as well as a reduced amount of speech and increased pause frequency and duration.

Genetics and Epigenetics in Schizophrenia

Numerous family and twin studies have provided evidence that genetics play a significant role in an individual's risk of developing schizophrenia (Henriksen, et al., 2017). However, as is the case with many psychological disorders, the genetics underlying schizophrenia have proven to be highly complex, heterogeneous, and polygenic. Furthermore, the wide variations in symptoms among cases (i.e., one individual may demonstrate only negative symptoms, while another may present only positive symptoms) makes it even more challenging to identify specific genes associated with risk for schizophrenia.

Genome-wide studies have identified more than 70 genes suspected of playing a role in producing schizophrenia (Flint & Munafò, 2014), and it is believed that the development of schizophrenia involves the cumulative effects of multiple genes, with most of these having only a small effect by themselves.

While our understanding of the genetic basis underlying schizophrenia is still developing, recent research has noted several genes associated with various aspects of brain development, including myelination and synaptic transmission (Smigielski, et al. 2020), that are also associated with an increased susceptibility to schizophrenia (Gürel, et al. 2020). It is now believed that this genetic susceptibility may be triggered by early environmental factors, through epigenetic mechanisms, and alter the course of neural development, leading to the later development of schizophrenia. (Gürel, et al. 2020.)

The Role of Neurotransmitters in Schizophrenia

Since the 1960s, it has been believed that many of the symptoms of schizophrenia were the result of an overactivity of dopamine. As with many of the psychological disorders, it is now understood that the biochemistry underlying schizophrenia is complex and involves multiple biological systems.

The Dopamine Hypothesis

Although the first **antipsychotic** drugs appeared in the 1950s, it was not well understood how these drugs were alleviating some of the symptoms of schizophrenia, nor why they also produced side effects, similar to those seen in patients with Parkinson's disease (muscular rigidity, tremors, decrease in voluntary movement). It wasn't until the late 1960s when further research made the notable discovery that the striatums of individuals with Parkinson's disease were completely depleted of dopamine (Goetz, 2011). This discovery led researchers to further speculate that antipsychotic drugs might be producing their rigidity and tremor side effects by reducing dopamine activity, which then implied that many of the psychotic symptoms alleviated by these drugs were being caused by the overactivity of dopamine in the brain. These speculations developed into what eventually became known as the dopamine theory of schizophrenia (see Brisch, et al., 2014).

As researchers came to better understand the biological complexities of schizophrenia, the original version of the dopamine hypothesis no longer fit with our understanding of the disorder. This has led to the "revised dopamine hypothesis" (Brisch, et al., 2014). This revised hypothesis proposes that the increased dopamine transmission in the mesocorticolimbic areas (see Figure 17.4.2.2) and decreased dopamine transmission in the prefrontal cortex seen in individuals with schizophrenia account for many of their symptoms. (Pogarell, et al. 2012).

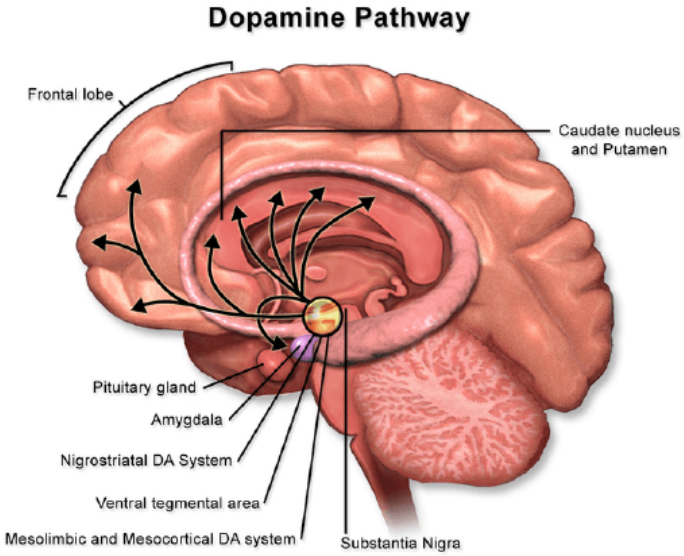

Figure 5.8.4.2: **The mesocorticolimbic dopamine pathway. The revised dopamine hypothesis proposes that many of the symptoms of schizophrenia arise from dopamine dysfunction in this pathway.** (CC BY-SA 4.0; BruceBlaus via Wikimedia Commons)

In addition to the mesolimbic brain areas, dopamine dysregulation has also been observed in the amygdala and prefrontal cortex, which are important for emotional processing, and differences in dopamine contents in the prefrontal cortex, cingulate cortex, and hippocampus between schizophrenia patients and healthy control subjects (Patel, et al., 2010). In particular, the dopamine system in the hippocampus is overactive in schizophrenia patients (Grace, 2012).

Neural Structures in Schizophrenia

There is a long and reliable history of research into the neural basis of schizophrenia. Neuroimaging studies have found a significant reduction in overall and specific brain region volumes, as well as tissue density of individuals with schizophrenia compared to healthy controls (Brugger & Howes, 2017). Additionally, there has been evidence of ventricle enlargement as well as volume reductions in the medial temporal lobe, which contains such structures as the amygdala (involved in emotion regulation), the hippocampus (involved in memory), as well as the neocortical surface of the temporal lobes (processing of

auditory information) (Kurtz, 2015). Additional studies also indicate a reduction in the orbitofrontal regions of the brain, a part of the frontal lobe that is responsible for response inhibition (Kurtz, 2015).

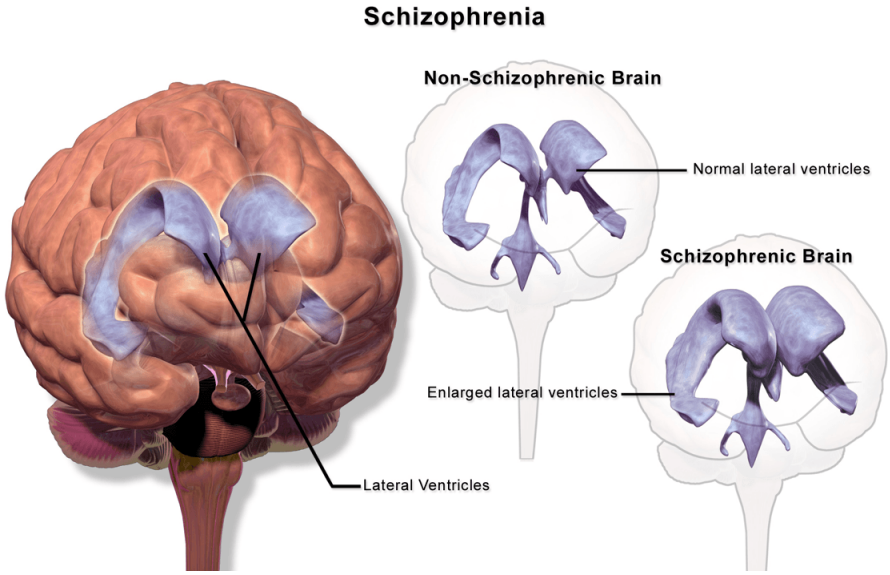

Figure 5.8.4.3: **The enlarged ventricles are often seen in the brains of individuals diagnosed with Schizophrenia.** (CC BY-SA 4.0; BruceBlaus via Wikimedia Commons)

6.20.1: Chapter 3- Population Evolution (and the Modern Synthesis)

Learning Objectives

1. Define population genetics and describe how population genetics is used in the study of the evolution of populations.
2. Explain what is meant by "the modern synthesis."
3. Define phenotypic change and genotypic change.
4. Discuss the importance of allele frequency in modern conceptions of evolution.
5. Define genetic drift.
6. Explain Hardy-Weinberg equilibrium and the significance of deviations from it.

Overview

Natural selection is the most dominant of evolutionary forces. Natural selection acts to promote traits and behaviors that increase an organism's chances of survival and reproduction, while eliminating those traits and behaviors that are to the organism's detriment. But natural selection can only, as its name implies, select—it cannot create. The introduction of novel traits and behaviors falls on the shoulders of another evolutionary force—mutation. Mutation and other sources of variation among individuals, as well as the evolutionary forces that act upon them, alter populations and species. This combination of processes has led to the world of life we see today.

1. Introduction. All life on Earth is related. Evolutionary theory states that humans, beetles, plants, and bacteria all share a common ancestor, but that millions of years of evolution have shaped each of these organisms into the forms seen today. Scientists consider evolution a key concept to understanding life. Natural selection is one of the most dominant evolutionary forces.
2. Population Evolution. Initially, the newly discovered particulate nature of genes made it difficult for biologists to understand how gradual evolution could occur. But over the next few decades, genetics and evolution were integrated in what became known as the modern synthesis—the coherent understanding of the relationship between natural selection and genetics that took shape by the 1940s and is generally accepted today.
3. Population Genetics. Individuals of a population often display different phenotypes, or express different alleles of a particular gene, referred to as polymorphisms. Populations with two or more variations of particular characteristics are called polymorphic. The distribution of phenotypes among individuals, known as the population variation, is influenced by a number of factors, including the population's genetic structure and the environment.
4. Adaptive Evolution. Fitness is often quantifiable and is measured by scientists in the field. However, it is not the absolute fitness of an individual that counts, but rather how it compares to the other organisms in the population. This concept, called relative fitness, allows researchers to determine which individuals are contributing additional offspring to the next generation, and thus, how the population might evolve.

Introduction

Figure 6.20.1.1: Living things may be single-celled or complex, multicellular organisms. They may be plants, animals, fungi, bacteria, or archaea. This diversity results from evolution. (credit "wolf": modification of work by Gary Kramer; credit "coral": modification of work by William Harrigan, NOAA; credit "river": modification of work by Vojtěch Dostál; credit "fish" modification of work by Christian Mehlführer; credit "mushroom": modification of work by Cory Zanker; credit "tree": modification of work by Joseph Kranak; credit "bee": modification of work by Cory Zanker)

All life on Earth is related. Evolutionary theory states that humans, beetles, plants, and bacteria all share a common ancestor, but that millions of years of evolution have shaped each of these organisms into the forms seen today. Scientists consider evolution a key concept to understanding life. Natural selection is one of the most dominant evolutionary forces. Natural selection acts to promote traits and behaviors that increase an organism's chances of survival and reproduction, while eliminating those traits and behaviors that are to the organism's detriment. But natural selection can only, as its name implies, select—it cannot create. The introduction of novel traits and behaviors falls on the shoulders of another evolutionary force—mutation. Mutation and other sources of variation among individuals, as well as the evolutionary forces that act upon them, alter populations and species. This combination of processes has led to the world of life we see today--the physical and psychological traits of each species.

Population Evolution

The mechanisms of inheritance, or genetics, were not understood at the time Charles Darwin and Alfred Russel Wallace were developing their idea of natural selection. This lack of understanding was a stumbling block to understanding many aspects of evolution. In fact, the predominant (and incorrect) genetic theory of the time, blending inheritance, made it difficult to understand how natural selection might operate. Darwin and Wallace were unaware of the genetics work by Austrian monk Gregor Mendel, which was published in 1866, not long after publication of Darwin's book, *On the Origin of Species* (1859). Mendel's work was rediscovered in the early twentieth century at which time geneticists were rapidly coming to an understanding of the basics of inheritance. Initially, the newly discovered particulate nature of genes made it difficult for biologists to understand how gradual evolution could occur. But over the next few decades, genetics and evolution were integrated in what became known as **the modern synthesis**—the coherent understanding of the relationship between natural selection and genetics that took shape by the 1940s and is generally accepted today. In sum, the modern synthesis describes how evolutionary processes, such as natural selection, can affect a population's genetic makeup, and, in turn, how this can result in the gradual evolution of populations and species. The theory also connects this change of a population over time, called microevolution, with the processes that gave rise to new species and higher taxonomic groups with widely divergent characters, called macroevolution.

Everyday Connection: Evolution and Flu Vaccines

Every fall, the media starts reporting on flu vaccinations and potential outbreaks. Scientists, health experts, and institutions determine recommendations for different parts of the population, predict optimal production and inoculation schedules, create vaccines, and set up clinics to provide inoculations. You may think of the annual flu shot as a lot of media hype, an important health protection, or just a briefly uncomfortable prick in your arm. But do you think of it in terms of evolution?

The media hype of annual flu shots is scientifically grounded in our understanding of evolution. Each year, scientists across the globe strive to predict the flu strains that they anticipate being most widespread and harmful in the coming year. This knowledge is based in how flu strains have evolved over time and over the past few flu seasons. Scientists then work to create the most effective vaccine to combat those selected strains. Hundreds of millions of doses are produced in a short period in order to provide vaccinations to key populations at the optimal time.

Because viruses, like the flu, evolve very quickly (especially in evolutionary time), this poses quite a challenge. Viruses mutate and replicate at a fast rate, so the vaccine developed to protect against last year's flu strain may not provide the protection needed against the coming year's strain. Evolution of these viruses means continued adaptions to ensure survival, including adaptations to survive previous vaccines.

Population Genetics

Recall that a gene for a particular character may have several alleles, or variants, that code for different traits associated with that character. For example, in the ABO blood type system in humans, three alleles determine the particular blood-type protein on the surface of red blood cells. Each individual in a population of diploid organisms (organisms that reproduce sexually and have paired chromosomes, unlike haploid organisms that reproduce asexually and have a single set of chromosomes) can only carry two alleles for a particular gene, but more than two may be present in the individuals that make up the population. Mendel followed alleles as they were inherited from parent to offspring. In the early twentieth century, biologists in a field of study known as population genetics began to study how selective forces change a population through changes in allele and genotypic frequencies.

The allele frequency (or gene frequency) is the rate at which a specific allele appears within a population. Until now, we have discussed evolution as a change in the characteristics of a population of organisms, but behind that phenotypic change is genetic change. In population genetics, the term evolution is defined as a change in the frequency of an allele in a population. Using the ABO blood type system as an example, the frequency of one of the alleles, A, is the number of copies of that allele divided by all the copies of the ABO gene in the population. For example, a study by Sahar et al. (2007) found a frequency of A to be 26.1 percent. The B and 0 alleles made up 13.4 percent and 60.5 percent of the alleles respectively, and all of the frequencies added up to 100 percent. A change in this frequency over time would constitute evolution in the population.

The allele frequency within a given population can change depending on environmental factors; therefore, certain alleles become more widespread than others during the process of natural selection. Natural selection can alter the population's genetic makeup; for example, if a given allele confers a phenotype that allows an individual to better survive or have more offspring. Because many of those offspring will also carry the beneficial allele, and often the corresponding phenotype, they will have more offspring of their own that also carry the allele, thus, perpetuating the cycle. Over time, the allele will spread throughout the population. Some alleles will quickly become fixed in this way, meaning that every individual of the population will carry the allele, while detrimental mutations may be swiftly eliminated if derived from a dominant allele from the gene pool. The gene pool is the sum of all the alleles in a population.

Sometimes, allele frequencies within a population change randomly with no advantage to the population over existing allele frequencies. This phenomenon is called **genetic drift**. Natural selection and genetic drift usually occur simultaneously in populations and are not isolated events. It is hard to determine which process dominates because it is often nearly impossible to determine the cause of change in allele frequencies at each occurrence. An event that initiates an allele frequency change in an isolated part of the population, which is not typical of the original population, is called the **founder effect**. Natural selection, random genetic drift, and founder effects can lead to significant changes in the genome of a population.

Hardy-Weinberg Principle of Equilibrium

In the early twentieth century, English mathematician Godfrey Hardy and German physician Wilhelm Weinberg stated the principle of equilibrium to describe the genetic makeup of a population. The theory, which later became known as the Hardy-Weinberg principle of equilibrium, states that a population's allele and genotype frequencies are inherently stable—neither the allele nor the genotypic frequencies would change, unless some kind of evolutionary force is acting upon the population. The Hardy-Weinberg principle assumes conditions with no mutations, migration, emigration, or selective pressure for or against any genotype, plus an infinite population; while no population can satisfy those conditions, the principle offers a useful model against which to compare real population changes.

In theory, if a population is at equilibrium—that is, there are no evolutionary forces acting upon it—generation after generation would have the same gene pool and genetic structure, and the equilibrium equations of Hardy-Weinberg would all hold true all of the time. Of course, even Hardy and Weinberg recognized that no natural population is immune to evolution. Populations in nature are constantly changing in genetic makeup due to drift, mutation, possibly migration, natural selection, and in social species, kin selection. As a result, the only way to determine the exact distribution of phenotypes in a population is to go out and count them. But the Hardy-Weinberg principle gives scientists a mathematical baseline of a non-evolving population to which they can compare evolving populations and thereby infer what evolutionary forces might be at play. If the frequencies of alleles or genotypes deviate from the value expected from the Hardy-Weinberg equilibrium equation, then the population is evolving.

Additional Concepts in Evolutionary Science

Species

Although all life on earth shares various genetic similarities, only certain organisms combine genetic information by sexual reproduction and have offspring that can then successfully reproduce. Scientists call such organisms members of the same biological species.

A **species** is a group of individual organisms that interbreed and produce fertile, viable offspring. According to this definition, one species is distinguished from another when, in nature, it is not possible for matings between individuals from each species to produce fertile offspring. The biological definition of species, which works for sexually reproducing organisms, is a group of actually or potentially interbreeding individuals.

Members of the same species share both external and internal characteristics, which develop from their DNA. The closer relationship two organisms share, the more DNA they have in common, just like people and their families. Organisms of the same species have the highest level of DNA alignment and therefore share characteristics and behaviors that lead to successful reproduction.

Populations of species share a **gene pool**: a collection of all the variants of genes in the species. Remember that any evolutionary changes in a population of organisms must be genetic because genes are the only way to share and pass on heritable traits. Only heritable traits can evolve. Therefore, reproduction plays a paramount role for genetic change to take root in a population or species. Differential rates of reproduction among the genetic variants in a population drive evolutionary change.

Speciation

Given the extraordinary diversity of life on the planet, there must be mechanisms for speciation: the formation of two species from one original species. Darwin envisioned this process as a branching event.

Biologists think of speciation events as the splitting of one ancestral species into two descendant species.

For speciation to occur, two new populations must be formed from one original population and they must evolve in such a way that it becomes impossible for individuals from the two new populations to interbreed. Biologists have proposed mechanisms by which this could occur that fall into two broad categories. Allopatric speciation (allo- = "other"; -patric = "homeland") involves geographic separation of populations from a parent species and subsequent evolution. Sympatric speciation (sym- = "same"; -patric = "homeland") involves speciation occurring within a parent species remaining in one location. Isolation of populations leading to allopatric speciation can occur in a variety of ways: a river forming a new branch, erosion forming a new valley, a group of organisms traveling to a new location without the ability to return, or seeds floating over the ocean to an island. Additionally,

scientists have found that the further the distance between two groups that once were the same species, the more likely it is that speciation will occur.

In some cases, a population of one species disperses throughout an area, and each finds a distinct niche or isolated habitat. Over time, the varied demands of their new lifestyles lead to multiple speciation events originating from a single species. This is called adaptive radiation because many adaptations evolve from a single point of origin; thus, causing the species to radiate into several new ones. Island archipelagos like the Hawaiian Islands provide an ideal context for adaptive radiation events because water surrounds each island which leads to geographical isolation for many organisms.

Rates of Speciation

Speciation occurs over a span of evolutionary time, so when a new species arises, there is a transition period during which the closely related species continue to interact.

In terms of how quickly speciation occurs, two patterns are currently observed: gradual speciation model and punctuated equilibrium model.

In the gradual speciation model, species diverge gradually over time in small steps. In the punctuated equilibrium model, a new species undergoes changes quickly from the parent species, and then remains largely unchanged for long periods of time afterward (Figure 18.3.218.3.2). This early change model is called punctuated equilibrium, because it begins with a punctuated or periodic change and then remains in balance afterward. While punctuated equilibrium suggests a faster tempo, it does not necessarily exclude gradualism.

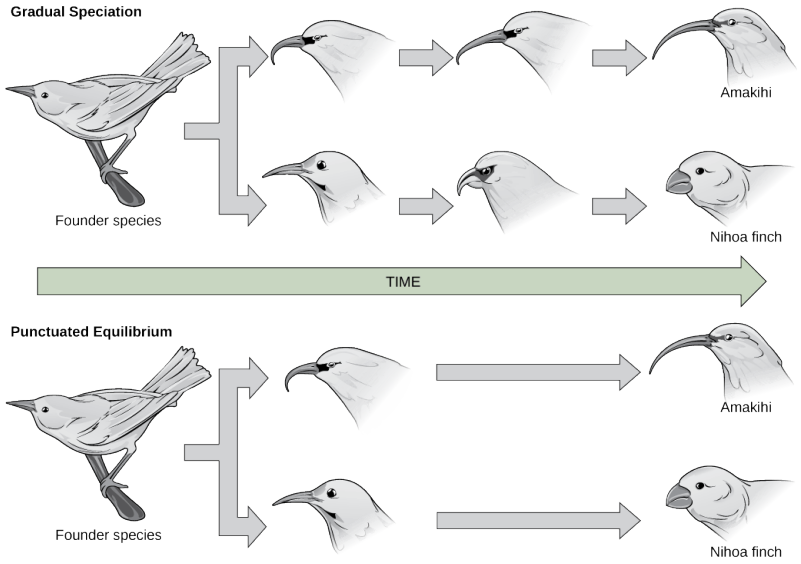

Figure 6.20.1.2: In (a) gradual speciation, species diverge at a slow, steady pace as traits change incrementally. In (b) punctuated equilibrium, species diverge quickly and then remain unchanged for long periods of time.

The primary influencing factor on changes in speciation rate is environmental conditions. Under some conditions, selection occurs quickly or radically. Consider a species of snails that had been living with the same basic form for many thousands of years. Layers of their fossils would appear similar for a long time. When a change in the environment takes place—such as a drop in the water level—a small number of organisms are separated from the rest in a brief period of time, essentially forming one large and one tiny population. The tiny population faces new environmental conditions. Because its gene pool quickly became so small, any variation that surfaces and that aids in surviving the new conditions becomes the predominant form.

Which of the following statements is false? (Answer at end of this module).

1. Punctuated equilibrium is most likely to occur in a small population that experiences a rapid change in its environment.
2. Punctuated equilibrium is most likely to occur in a large population that lives in a stable climate.
3. Gradual speciation is most likely to occur in species that live in a stable climate.
4. Gradual speciation and punctuated equilibrium both result in the divergence of species.

Summary

The modern synthesis of evolutionary theory grew out of the combination of Darwin's and Wallace's formulations of evolution with Mendel's analysis of heredity, along with the more modern study of population genetics. The modern synthesis describes the evolution of populations and species, from small-scale changes among individuals to large-scale changes over paleontological time periods. To understand how organisms evolve, scientists can track populations' allele frequencies over time. If they differ from generation to generation, scientists can conclude that the population is not in Hardy-Weinberg equilibrium, and is thus evolving.

Speciation is not a precise division: overlap between closely related species can occur in areas called hybrid zones. Organisms reproduce with other similar organisms. The fitness of these hybrid offspring can affect the evolutionary path of the two species. Scientists propose two models for the rate of speciation: one model illustrates how a species can change slowly over time; the other model demonstrates how change can occur quickly from a parent generation to a new species. Both models continue to follow the patterns of natural selection.

(Answer to review question above: 2 is false. "Punctuated equilibrium is most likely to occur in a large population that lives in a stable climate").

6.20.2: Chapter 3- Phenotypic Variation and Population Genetics

Learning Objectives

1. Describe the different types of variation in a population.
2. Explain why only heritable variation can be acted upon by natural selection.
3. Describe genetic drift and the bottleneck effect.
4. Explain how each evolutionary force can influence the allele frequencies of a population.

Overview

Individuals of a population often display different phenotypes, or express different alleles of a particular gene, referred to as polymorphisms. Populations with two or more variations of particular characteristics are called polymorphic. The distribution of phenotypes among individuals, known as the population variation, is influenced by a number of factors, including the population's genetic structure and the environment. Understanding the sources of a phenotypic variation in a population is important for determining how a population will evolve in response to different evolutionary pressures.

Figure 6.20.2.1: The distribution of phenotypes in this litter of kittens illustrates population variation. (credit: Pieter Lanser)

Genetic Variance

Natural selection and some of the other evolutionary forces can only act on heritable traits, namely an organism's genetic code. Because alleles are passed from parent to offspring, those that confer beneficial traits or behaviors may be selected for, while deleterious alleles may be selected against. Acquired traits, for the most part, are not heritable. For example, if an athlete works out in the gym every day, building up muscle strength, the athlete's offspring will not necessarily grow up to be a body builder. If there is a genetic basis for the ability to run fast, on the other hand, this may be passed to a child.

Heritability is the fraction of phenotype variation that can be attributed to genetic differences, or genetic variance, among individuals in a population. The greater the hereditability of a population's phenotypic variation, the more susceptible it is to the

evolutionary forces that act on heritable variation.

The diversity of alleles and genotypes within a population is called **genetic variance**. When scientists are involved in the breeding of a species, such as with animals in zoos and nature preserves, they try to increase a population's genetic variance to preserve as much of the phenotypic diversity as they can. This also helps reduce the risks associated with inbreeding, the mating of closely related individuals, which can have the undesirable effect of bringing together deleterious recessive mutations that can cause abnormalities and susceptibility to disease.

Changes in allele frequencies that are identified in a population can shed light on how it is evolving. In addition to natural selection, there are other evolutionary forces that could be in play: genetic drift, gene flow, mutation, nonrandom mating, and environmental variances.

Genetic Drift

The theory of natural selection stems from the observation that some individuals in a population are more likely to survive longer and have more offspring than others; thus, they will pass on more of their genes to the next generation. A big, powerful male gorilla, for example, is much more likely than a smaller, weaker one to become the population's silverback, the pack's leader who mates far more than the other males of the group. The pack leader will father more offspring, who share half of his genes, and are likely to also grow bigger and stronger like their father. Over time, the genes for bigger size will increase in frequency in the population, and the population will, as a result, grow larger on average. That is, this would occur if this particular selection pressure, or driving selective force, were the only one acting on the population. In other examples, better camouflage or a stronger resistance to drought might provide a selection pressure.

Another way a population's allele and genotype frequencies can change is **genetic drift**, which is simply the effect of chance. By chance, some individuals will have more offspring than others—not due to an advantage conferred by some genetically-encoded trait, but just because one male happened to be in the right place at the right time (when the receptive female walked by) or because others happened to be in the wrong place at the wrong time (when a predator was hunting).

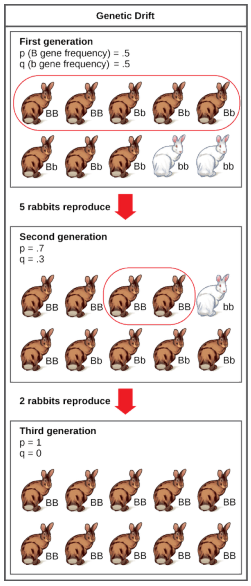

Figure 6.20.2.2: Genetic drift in a population can lead to the elimination of an allele from a population by chance. In this example, rabbits with the brown coat color allele (B) are dominant over rabbits with the white coat color allele (b). In the first generation, the two alleles occur with equal frequency in the population, resulting in p and q values of 0.5. Only half of the individuals reproduce, resulting in a second generation with p and q values of .7 and .3, respectively. Only two individuals in the second generation reproduce, and by chance these individuals are homozygous dominant for brown coat color. As a result, in the third generation the recessive b allele is lost.

Do you think genetic drift would happen more quickly on an island or on the mainland?

Small populations are more susceptible to the forces of genetic drift. Large populations, on the other hand, are buffered against the effects of chance. If one individual of a population of 10 individuals happens to die at a young age before it leaves any offspring to the next generation, all of its genes—1/10 of the population's gene pool—will be suddenly lost. In a population of 100,

that's only 1 percent of the overall gene pool; therefore, it is much less impactful on the population's genetic structure.

Genetic drift can also be magnified by natural events, such as a natural disaster that kills—at random—a large portion of the population. Known as the bottleneck effect, it results in a large portion of the genome suddenly being wiped out. In one fell swoop, the genetic structure of the survivors becomes the genetic structure of the entire population, which may be very different from the pre-disaster population.

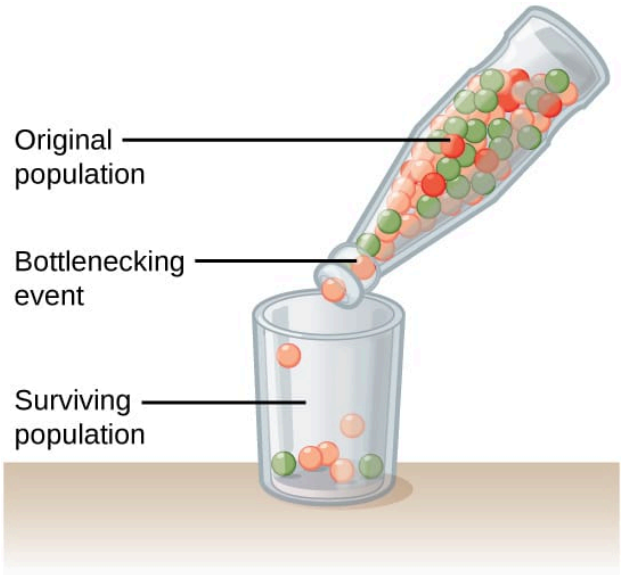

Figure 6.20.2.3: A chance event or catastrophe can reduce the genetic variability within a population.

Another scenario in which populations might experience a strong influence of genetic drift is if some portion of the population leaves to start a new population in a new location or if a population gets divided by a physical barrier of some kind. In this situation, those individuals are unlikely to be representative of the entire population, which results in the founder effect. The founder effect occurs when the genetic structure changes to match that of the new population's founding fathers and mothers. The founder effect is believed to have been a key factor in the genetic history of the Afrikaner population of Dutch settlers in South Africa, as evidenced by mutations that are common in Afrikaners but rare in most other populations. This is likely due to the fact that a higher-than-normal proportion of the founding colonists carried these mutations. As a result, the population expresses unusually high incidences of Huntington's disease (HD) and Fanconi anemia (FA), a genetic disorder known to cause blood marrow and congenital abnormalities—even cancer.

Scientific Method Connection: Testing the Bottleneck Effect

- **Question**: How do natural disasters affect the genetic structure of a population?
- **Background**: When much of a population is suddenly wiped out by an earthquake or hurricane, the individuals that survive the event are usually a random sampling of the original group. As a result, the genetic makeup of the population can change dramatically. This phenomenon is known as the bottleneck effect.
- **Hypothesis**: Repeated natural disasters will yield different population genetic structures; therefore, each time this experiment is run, the results will vary.
- **Test the hypothesis**: Count out the original population using different colored beads. For example, red, blue, and yellow beads might represent red, blue, and yellow individuals. After recording the number of each individual in the original population, place them all in a bottle with a narrow neck that will only allow a few beads out at a time. Then, pour 1/3 of the bottle's contents into a bowl. This represents the surviving individuals after a natural disaster kills a majority of the population. Count the number of the different colored beads in the bowl, and record it. Then, place all of the beads back in the bottle and repeat the experiment four more times.
- **Analyze the data**: Compare the five populations that resulted from the experiment. Do the populations all contain the same number of different colored beads, or do they vary? Remember, these populations all came from the same exact parent population.

- **Form a conclusion**: Most likely, the five resulting populations will differ quite dramatically. This is because natural disasters are not selective—they kill and spare individuals at random. Now think about how this might affect a real population. What happens when a hurricane hits the Mississippi Gulf Coast? How do the seabirds that live on the beach fare?

Gene Flow

Another important evolutionary force is **gene flow**: the flow of alleles in and out of a population due to the migration of individuals or gametes. While some populations are fairly stable, others experience more flux. Many plants, for example, send their pollen far and wide, by wind or by bird, to pollinate other populations of the same species some distance away. Even a population that may initially appear to be stable, such as a pride of lions, can experience its fair share of immigration and emigration as developing males leave their mothers to seek out a new pride with genetically unrelated females. This variable flow of individuals in and out of the group not only changes the gene structure of the population, but it can also introduce new genetic variation to populations in different geological locations and habitats.

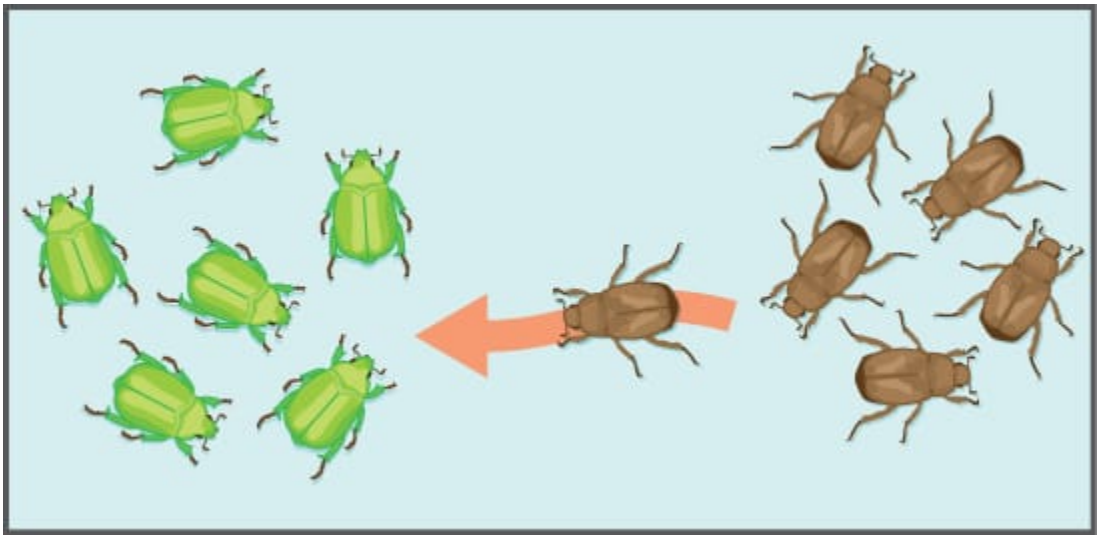

Figure 6.20.2.4: Gene flow can occur when an individual travels from one geographic location to another.

Mutation

Mutations are changes to an organism's DNA and are an important driver of diversity in populations. Species evolve because of the accumulation of mutations that occur over time. The appearance of new mutations is the most common way to introduce novel genotypic and phenotypic variance. Some mutations are unfavorable or harmful and are quickly eliminated from the population by natural selection. Others are beneficial and will spread through the population. Whether or not a mutation is beneficial or harmful is determined by whether it helps an organism survive to sexual maturity and reproduce. Some mutations do not do anything and can linger, unaffected by natural selection, in the genome. Some can have a dramatic effect on a gene and the resulting phenotype.

Nonrandom Mating

If individuals nonrandomly mate with their peers, the result can be a changing population. There are many reasons nonrandom mating occurs. One reason is simple mate choice (sexual selection); for example, female peahens may prefer peacocks with bigger, brighter tails. Sexual attractiveness, hypothesized by some evolutionary psychologists to be a phenotypic indicator of health and reproductive potential, increases mating opportunities. Traits that lead to more matings for an individual become selected for by natural selection. One common form of mate choice, called assortative mating, is an individual's preference to mate with partners who are phenotypically similar to themselves. On the other hand, you may have heard of the saying, opposites attract.

Humans frequently engage in behaviors to enhance their attractiveness to potential mates. For example, women in many modern

cultures shape their eyebrows making them thinner and more arched above the eyes. Why this works to increase attractiveness is a matter for speculation, but one possibility is that traits that exaggerate differences between the sexes can enhance attractiveness. In this case, thinner arched eyebrows contrast more sharply with the human male "brow ridge," a ridge of bone above the eye sockets in human adult males that gives their brows a heavier and lower profile on the human male face. When women thin out and arch their eyebrows they are exaggerating the difference between female facial bone structure and male facial bone structure. This enhances a sexual cue on the human face which identifies it as female. Evolution may have selected for male brain circuitry that stimulates sexual feeling in males more readily in the presence of a face with this identifying feature of femaleness (Koenigshofer, 2011). In addition, there are many examples of humans using various adornments on the body and face and other strategies to enhance their attractiveness (think of makeup and jewelry; men working out to get more muscular or buying expensive cars to signal high status). Human mate choice is the result of complex interacting factors, but it is clearly nonrandom.

Another cause of nonrandom mating is physical location. This is especially true in large populations spread over large geographic distances where not all individuals will have equal access to one another. Some might be miles apart through woods or over rough terrain, while others might live immediately nearby.

Environmental Variance

Genes are not the only players involved in determining population variation. Phenotypes are also influenced by other factors, such as the environment. A beachgoer is likely to have darker skin than a city dweller, for example, due to regular exposure to the sun, an environmental factor. Some major characteristics, such as gender, are determined by the environment for some species. For example, some turtles and other reptiles have temperature-dependent sex determination (TSD). TSD means that individuals develop into males if their eggs are incubated within a certain temperature range, or females at a different temperature range.

Figure 6.20.2.5: The sex of the American alligator (Alligator mississippiensis) is determined by the temperature at which the eggs are incubated. Eggs incubated at 30°C produce females, and eggs incubated at 33°C produce males. (credit: Steve Hillebrand, USFWS)

Geographic separation between populations can lead to differences in the phenotypic variation between those populations. Such geographical variation is seen between most populations and can be significant. One type of geographic variation, called a cline, can be seen as populations of a given species vary gradually across an ecological gradient. Species of warm-blooded animals, for example, tend to have larger bodies in the cooler climates closer to the earth's poles, allowing them to better conserve heat. This is considered a latitudinal cline. Alternatively, flowering plants tend to bloom at different times depending on where they are along the slope of a mountain, known as an altitudinal cline.

If there is gene flow between the populations, the individuals will likely show gradual differences in phenotype along the cline. Restricted gene flow, on the other hand, can lead to abrupt differences, even speciation.

Summary

Both genetic and environmental factors can cause phenotypic variation in a population. Different alleles can confer different phenotypes, and different environments can also cause individuals to look or act differently. Only those differences encoded in an individual's genes, however, can be passed to its offspring genetically and, thus, be a target of natural selection. Natural selection works by selecting for alleles that confer beneficial traits or behaviors, while selecting against those for deleterious qualities. Genetic drift stems from the chance occurrence that some individuals in the germ line have more offspring than others. When individuals leave or join the population, allele frequencies can change as a result of gene flow. Mutations to an individual's DNA may introduce new variation into a population. Allele frequencies can also be altered when individuals do not randomly mate with others in the group (sexual selection, some mates are more desirable than others and therefore mate more frequently and consequently tend to leave more offspring).

6.20.3: Chapter 3- Adaptive Evolution

Learning Objectives

1. Explain the different ways natural selection can shape populations
2. Describe how these different forces can lead to different outcomes in terms of the population variation

Overview

In this module we examine the ways in which natural selection, and its action under different conditions, leads to adaptive evolution under a variety of conditions. Different types of selection include stabilizing, directional, diversifying, and frequency-dependent selection. Sexual selection, resulting from competition for mating opportunities among individuals in sexually dimorphic species, can lead to evolution of traits which increase chances for mating but actually reduce chances of survival (e.g. male peacock's tail feathers). Evolutionary fitness refers to the genetic contribution that individuals make to the next generation (i.e. reproductive success). Natural selection does not create a perfect organism. It can generate populations of organism that are better adapted to survive and reproduce in their environments. Natural selection can only select on existing variation in the population; it does not create anything from scratch. Thus, it is limited by a population's existing genetic variance and whatever new alleles arise through mutation and gene flow.

Natural Selection and Adaptive Evolution

Natural selection drives adaptive evolution by selecting for and increasing the occurrence of beneficial traits (traits which increase survival and reproduction) in a population and by selecting against non-beneficial traits.

Key Points

- Natural selection increases or decreases biological traits within a population, thereby selecting for individuals with greater evolutionary fitness.
- An individual with a high evolutionary fitness will provide more beneficial contributions to the gene pool of the next generation.
- Relative fitness, which compares an organism's fitness to the others in the population, allows researchers to establish how a population may evolve by determining which individuals are contributing additional offspring to the next generation.
- Stabilizing selection, directional selection, diversifying selection, frequency-dependent selection, and sexual selection all contribute to the way natural selection can affect variation within a population.

Key Terms

- **natural selection**: a process in which individual organisms or phenotypes that possess favorable traits are more likely to survive and reproduce
- **fecundity**: number, rate, or capacity of offspring production
- **Darwinian fitness**: the average contribution to the gene pool of the next generation that is made by an average individual of the specified genotype or phenotype

Introduction: Natural Selection and Adaptive Evolution

Natural selection only acts on the population's heritable traits: selecting for beneficial alleles and thus increasing their frequency in the population, while selecting against deleterious alleles and thereby decreasing their frequency—a process known as **adaptive evolution**. Natural selection does not act on individual alleles, however, but on entire organisms. An individual may carry a very beneficial genotype with a resulting phenotype that, for example, increases the ability to reproduce (fecundity), but if that same individual also carries an allele that results in a fatal childhood disease, that fecundity phenotype will not be passed on to the next generation because the individual will not live to reach reproductive age. Natural selection acts at the level of the

individual; it selects for individuals with greater contributions to the gene pool of the next generation, known as an organism's evolutionary (Darwinian) fitness.

Fitness is often quantifiable and is measured by scientists in the field. However, it is not the absolute fitness of an individual that counts, but rather how it compares to the other organisms in the population. This concept, called relative fitness, allows researchers to determine which individuals are contributing additional offspring to the next generation, and thus, how the population might evolve.

There are several ways selection can affect population variation: stabilizing selection, directional selection, diversifying selection, frequency-dependent selection, and sexual selection. As natural selection influences the allele frequencies in a population, individuals can either become more or less genetically similar and the phenotypes displayed can become more similar or more disparate.

Stabilizing Selection

If natural selection favors an average phenotype, selecting against extreme variation, the population will undergo stabilizing selection. In a population of mice that live in the woods, for example, natural selection is likely to favor individuals that best blend in with the forest floor and are less likely to be spotted by predators. Assuming the ground is a fairly consistent shade of brown, those mice whose fur is most closely matched to that color will be most likely to survive and reproduce, passing on their genes for their brown coat. Mice that carry alleles that make them a bit lighter or a bit darker will stand out against the ground and be more likely to fall victim to predation. As a result of this selection, the population's genetic variance will decrease.

Directional Selection

When the environment changes, populations will often undergo directional selection, which selects for phenotypes at one end of the spectrum of existing variation. A classic example of this type of selection is the evolution of the peppered moth in eighteenth- and nineteenth-century England. Prior to the Industrial Revolution, the moths were predominately light in color, which allowed them to blend in with the light-colored trees and lichens in their environment. But as soot began spewing from factories, the trees became darkened, and the light-colored moths became easier for predatory birds to spot. Over time, the frequency of the melanic form of the moth increased because they had a higher survival rate in habitats affected by air pollution because their darker coloration blended with the sooty trees. Similarly, the hypothetical mouse population may evolve to take on a different coloration if something were to cause the forest floor where they live to change color. The result of this type of selection is a shift in the population's genetic variance toward the new, fit phenotype.

Diversifying Selection

Sometimes two or more distinct phenotypes can each have their advantages and be selected for by natural selection, while the intermediate phenotypes are, on average, less fit. Known as diversifying selection, this is seen in many populations of animals that have multiple male forms. Large, dominant alpha males obtain mates by brute force, while small males can sneak in for furtive copulations with the females in an alpha male's territory. In this case, both the alpha males and the "sneaking" males will be selected for, but medium-sized males, which can't overtake the alpha males and are too big to sneak copulations, are selected against. Diversifying selection can also occur when environmental changes favor individuals on either end of the phenotypic spectrum. Imagine a population of mice living at the beach where there is light-colored sand interspersed with patches of tall grass. In this scenario, light-colored mice that blend in with the sand would be favored, as well as dark-colored mice that can hide in the grass. Medium-colored mice, on the other hand, would not blend in with either the grass or the sand, and would thus be more likely to be eaten by predators. The result of this type of selection is increased genetic variance as the population becomes more diverse.

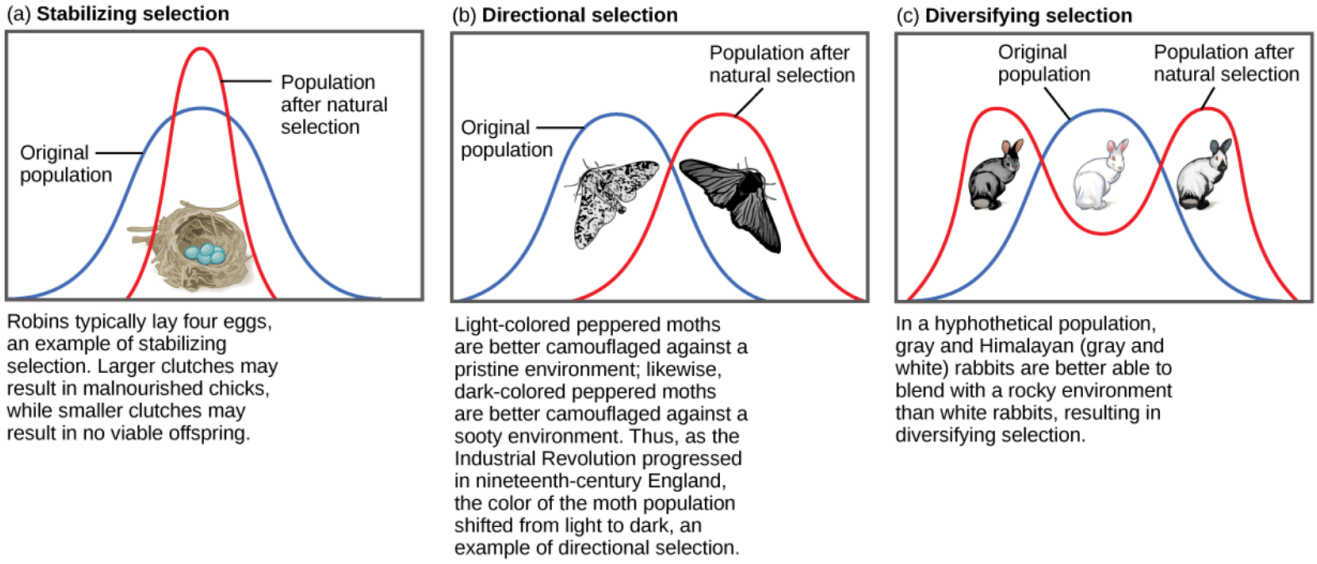

Figure 6.20.3.1: Different types of natural selection can impact the distribution of phenotypes within a population. In (a) stabilizing selection, an average phenotype is favored. In (b) directional selection, a change in the environment shifts the spectrum of phenotypes observed. In (c) diversifying selection, two or more extreme phenotypes are selected for, while the average phenotype is selected against. Part (a) shows a robin clutch size as an example of stabilizing selection. Robins typically lay four eggs. Larger clutches may result in malnourished chicks, while smaller clutches may result in no viable offspring. A wide bell curve indicates that, in the original population, there was a lot of variability in clutch size. Overlaying this wide bell curve is a narrow one that represents the clutch size after natural selection, which is much less variable. Part (b) shows moth color as an example of directional selection. Light-colored pepper moths are better camouflaged against a pristine environment, while dark-colored peppered moths are better camouflaged against a sooty environment. Thus, as the Industrial Revolution progressed in nineteenth-century England, the color of the moth population shifted from light to dark, an example of directional selection. A bell curve representing the original population and one representing the population after natural selection only slightly overlap. Part (c) shows rabbit coat color as an example of diversifying selection. In this hypothetical example, gray and Himalayan (gray and white) rabbits are better able to blend into their rocky environment than white ones. The original population is represented by a bell curve in which white is the most common coat color, while gray and Himalayan colors, on the right and left flank of the curve, are less common. After natural selection, the bell curve splits into two peaks, indicating gray and Himalayan coat color have become more common than the intermediate white coat color.

Exercise 6.20.3.1

In recent years, factories have become cleaner, and less soot is released into the environment. What impact do you think this has had on the distribution of moth color in the population?

Answer available at the end of this section.

Frequency-dependent Selection

Another type of selection, called frequency-dependent selection, favors phenotypes that are either common (positive frequency-dependent selection) or rare (negative frequency-dependent selection). An interesting example of this type of selection is seen in a unique group of lizards of the Pacific Northwest. Male common side-blotched lizards come in three throat-color patterns: orange, blue, and yellow. Each of these forms has a different reproductive strategy: orange males are the strongest and can fight other males for access to their females; blue males are medium-sized and form strong pair bonds with their mates; and yellow males are the smallest, and look a bit like females, which allows them to sneak copulations. Like a game of rock-paper-scissors, orange beats blue, blue beats yellow, and yellow beats orange in the competition for females. That is, the big, strong orange males can fight off the blue males to mate with the blue's pair-bonded females, the blue males are successful at guarding their mates against yellow sneaker males, and the yellow males can sneak copulations from the potential mates of the large, polygynous orange males.

Figure 6.20.3.2: A yellow-throated side-blotched lizard is smaller than either the blue-throated or orange-throated males and appears a bit like the females of the species, allowing it to sneak copulations. (credit: “tinyfroglet”/Flickr)

In this scenario, orange males will be favored by natural selection when the population is dominated by blue males, blue males will thrive when the population is mostly yellow males, and yellow males will be selected for when orange males are the most populous. As a result, populations of side-blotched lizards cycle in the distribution of these phenotypes—in one generation, orange might be predominant, and then yellow males will begin to rise in frequency. Once yellow males make up a majority of the population, blue males will be selected for. Finally, when blue males become common, orange males will once again be favored.

Negative frequency-dependent selection serves to increase the population’s genetic variance by selecting for rare phenotypes, whereas positive frequency-dependent selection usually decreases genetic variance by selecting for common phenotypes.

Sexual Selection

Males and females of certain species are often quite different from one another in ways beyond the reproductive organs. Males are often larger, for example, and display many elaborate colors and adornments, like the peacock’s tail, while females tend to be smaller and duller in decoration. Such differences are known as sexual dimorphisms, which arise from the fact that in many populations, particularly animal populations, there is more variance in the reproductive success of the males than there is of the females. That is, some males—often the bigger, stronger, or more decorated males—get the vast majority of the total matings, while others receive none. This can occur because the males are better at fighting off other males, or because females will choose to mate with the bigger or more decorated males. In either case, this variation in reproductive success generates a strong selection pressure among males to get those matings, resulting in the evolution of bigger body size and elaborate ornaments to get the females’ attention. Females, on the other hand, tend to get a handful of selected matings; therefore, they are more likely to select more desirable males.

Sexual dimorphism varies widely among species, of course, and some species are even sex-role reversed. In such cases, females tend to have a greater variance in their reproductive success than males and are correspondingly selected for the bigger body size and elaborate traits usually characteristic of males.

Figure 6.20.3.3: Sexual dimorphism is observed in (a) peacocks and peahens, (b) Argiope appensa spiders (the female spider is the large one), and in (c) wood ducks; males are much more colorful than females. At left, a peacock with a bright blue body and flared tail feathers standing next to a brown, drab peahen. The middle photo shows a large female spider sitting on a web next to its male counterpart. The photo on the right shows a brightly colored male wood duck swimming next to a drab brown female.(credit "spiders": modification of work by "Sanba38"/Wikimedia Commons; credit "duck": modification of work by Kevin Cole)

The selection pressures on males and females to obtain matings is known as sexual selection; it can result in the development of secondary sexual characteristics that do not benefit the individual's likelihood of survival but help to maximize its reproductive success. Sexual selection can be so strong that it selects for traits that are actually detrimental to the individual's survival. Think, once again, about the peacock's tail. While it is beautiful and the male with the largest, most colorful tail is more likely to win the female, it is not the most practical appendage. In addition to being more visible to predators, it makes the males slower in their attempted escapes. There is some evidence that this risk, in fact, is why females like the big tails in the first place. The speculation is that large tails carry risk, and only the best males survive that risk: the bigger the tail, the more fit the male. This idea is known as the handicap principle.

The good genes hypothesis states that males develop these impressive ornaments to show off their efficient metabolism or their ability to fight disease. Females then choose males with the most impressive traits because it signals their genetic superiority, which they will then pass on to their offspring. Though it might be argued that females should not be picky because it will likely reduce their number of offspring, if better males father more fit offspring, it may be beneficial. Fewer, healthier offspring may increase the chances of survival more than many, weaker offspring.

In both the handicap principle and the good genes hypothesis, the trait is said to be an honest signal of the males' quality, thus giving females a way to find the fittest mates— males that will pass the best genes to their offspring.

No Perfect Organism

Natural selection is a driving force in evolution and can generate populations that are better adapted to survive and successfully reproduce in their environments. But natural selection cannot produce the perfect organism. Natural selection can only select on existing variation in the population; it does not create anything from scratch. Thus, it is limited by a population's existing genetic variance and whatever new alleles arise through mutation and gene flow.

Natural selection is also limited because it works at the level of individuals, not alleles, and some alleles are linked due to their physical proximity in the genome, making them more likely to be passed on together (linkage disequilibrium). Any given individual may carry some beneficial alleles and some unfavorable alleles. It is the net effect of these alleles, or the organism's fitness, upon which natural selection can act. As a result, good alleles can be lost if they are carried by individuals that also have several overwhelmingly bad alleles; likewise, bad alleles can be kept if they are carried by individuals that have enough good alleles to result in an overall fitness benefit.

Furthermore, natural selection can be constrained by the relationships between different polymorphisms. One morph may confer a higher fitness than another, but may not increase in frequency due to the fact that going from the less beneficial to the more beneficial trait would require going through a less beneficial phenotype. Think back to the mice that live at the beach. Some are light-colored and blend in with the sand, while others are dark and blend in with the patches of grass. The dark-colored mice may be, overall, more fit than the light-colored mice, and at first glance, one might expect the light-colored mice be selected for a

darker coloration. But remember that the intermediate phenotype, a medium-colored coat, is very bad for the mice—they cannot blend in with either the sand or the grass and are more likely to be eaten by predators. As a result, the light-colored mice would not be selected for a dark coloration because those individuals that began moving in that direction (began being selected for a darker coat) would be less fit than those that stayed light.

Finally, it is important to understand that not all evolution is adaptive. While natural selection selects the fittest individuals and often results in a more fit population overall, other forces of evolution, including genetic drift and gene flow, often do the opposite: introducing deleterious alleles to the population's gene pool. Evolution has no purpose—it is not changing a population into a preconceived ideal. It is simply the sum of the various forces described in this chapter and how they influence the genetic and phenotypic variance of a population.

Summary

Because natural selection acts to increase the frequency of beneficial alleles and traits while decreasing the frequency of deleterious qualities, it results in adaptive evolution. Natural selection acts at the level of the individual, selecting for those that have a higher overall fitness compared to the rest of the population. If the fit phenotypes are those that are similar, natural selection will result in stabilizing selection, and an overall decrease in the population's variation. Directional selection works to shift a population's variance toward a new, fit phenotype, as environmental conditions change. In contrast, diversifying selection results in increased genetic variance by selecting for two or more distinct phenotypes.

Other types of selection include frequency-dependent selection, in which individuals with either common (positive frequency-dependent selection) or rare (negative frequency-dependent selection) are selected for. Finally, sexual selection results from the fact that one sex has more variance in the reproductive success than the other. As a result, males and females experience different selective pressures, which can often lead to the evolution of phenotypic differences, or sexual dimorphisms, between the two. Sexual selection can result in the evolution of traits that attract the opposite sex, but at the same time might reduce chances of survival--one example is the peacock's large tail feather display which may attract females but also make escape from predators more difficult.

6.20.4: Chapter 3- Modern Primates and Their Evolution

Learning Objectives

1. Describe the distinguishing features of mammals and of primates
2. Discuss the range of physical and behavioral traits in several different species of primate
3. Describe general principles of brain evolution as proposed by Striedter (2006) and discuss one short coming of his principles
4. List major steps in primate evolution
5. Describe the taxonomic classification of our species, Homo sapiens

Overview

Humans are primates. We belong to the taxonomic order Primates. This order encompasses humans as well as non-human primates. Non-human primates are our closest biological and evolutionary relatives. So, we study them in order to learn more about ourselves. All primates are mammals.

Figure 6.20.4.1: Golden Lion Tamarin, a primate found in Brazil. Woodland Park Zoo, Seattle, WA 9/30/2011

General Mammalian Characteristics

The earliest evidence of mammals is from the Mesozoic era (see table of geological time below), however, there is limited fossil evidence and the fossils that have been found are mouse-like forms with quadrupedal locomotion. Primates evolved from an ancestral mammal during the Cenozoic era and share many characteristics with other mammals. The Cenozoic is the era of the adaptive radiation of mammals with thirty different mammalian orders evolving.

Some of the general characteristics of mammals includes:

- mammary glands: females produce milk to feed young during their immediate post-natal growth period
- mammals have hair (sometimes called fur) that covers all or parts of their body
- the lower jaw is a single bone
- the middle ear contains three bones: stapes (stirrup), incus (anvil), and malleus (hammer)
- four-chambered heart
- main artery leaving the heart curves to the left to form the aortic arch

- mammals have a diaphragm
- mammals regulate their body temperature to maintain homeostais (a constant body temperature)
- teeth are replaced only once during lifetime

Primate Evolution in Summary

The first fifty million years of primate evolution was a series of adaptive radiations (diversification of a group of organisms into forms filling different ecological niches) leading to the diversification of the earliest lemurs, monkeys, and apes. The primate story begins in the forest canopy (overlapping branches and leaves high above ground) and understory of conifer-dominated forests, with our small, furtive ancestors subsisting at night, beneath the notice of day-active dinosaurs. From the archaic primates to the earliest groups of true primates (euprimates), the origin of our own order (the Primates) is characterized by the struggle for new food sources and microhabitats in the arboreal setting. Climate change forced major extinctions as the northern continents became increasingly dry, cold, and seasonal and as tropical rainforests gave way to deciduous forests, woodlands, and eventually grasslands. Lemurs, lorises, and tarsiers—once diverse groups containing many species—became rare, except for lemurs in Madagascar where there were no anthropoid competitors and perhaps few predators. Meanwhile, anthropoids (monkeys and apes) emerged in the Old World (Africa, Europe, and Asia), then dispersed across parts of the northern hemisphere, Africa, and ultimately South America. Meanwhile, the movement of continents, shifting sea levels, and changing patterns of rainfall and vegetation contributed to the developing landscape of primate biogeography, morphology, and behavior. Today's primates provide a few reminders of the past diversity and remarkable adaptations of their extinct relatives.

A Simplified Classification of Living Primates

File:Primate Hand Mnemonic.png

Drawing of two hands showing prosimians on left palm, apes on the right palm, and name of a primate or group on each finger.

Figure 6.20.4.2: This image is a hand mnemonic used to help students learn a categorization of primates. The right hand (held palm upward) correlates to the apes, including the great apes and lesser apes. Humans are distinct from that group as the thumb is distinct from the other four digits of the hand. All apes evolved to be tailless, whereas species grouped onto the left hand are characterized as having tails (with certain exceptions, such as the Barbary macaque). Old world monkeys have a family name that means "tailed ape" and are indicated on the left thumb that points toward the right hand of apes. Old world monkeys are grouped with all of the apes in the parvorder called Catarrhini. New world monkeys on the left index finger form their own parvorder called Platyrrhini (meaning "flat nosed"). These are the only monkeys with prehensile tails. The group of simians (higher primates) are all apes and monkeys, so includes all of the above (Catarrhini and Platyrrhini). The three remaining digits on the left hand form the group of prosimians (lower primates).

The hand phalanges are not to be mistaken for a phylogeny as the branching geometry is not accurate. And the ten hand digits do not correspond to any single particular level of taxonomy. The specific correspondence of digits is:

- right thumb = genus *Homo* => 1 species: humans,
- right index = genus *Pan* => 2 species: common chimpanzees (4 subspecies) and bonobos,
- right middle = subfamily Gorillinae => genus *Gorilla* => 2 species: western gorillas (2 subspecies) and eastern gorillas (2 subspecies),
- right ring = subfamily Ponginae => genus *Pongo* => 2 species: Bornean orangutans (3 subspecies) and Sumatran orangutans,
- right pinky = family Hylobatidae => 4 genera of gibbons => nearly twenty species in total, including siamangs, lar gibbons and hoolock gibbons,

- left thumb = superfamily Cercopithecoidea (old world monkeys) => well over one hundred species including baboons and macaques,
- left index = parvorder Platyrrhini => superfamily Ceboidea (new world monkeys) => well over one hundred species including marmosets, tamarins, titis, howlers and squirrel monkeys,
- left middle = infraorder of tarsiers,
- left ring = superfamily of lemurs,
- left pinky = superfamily of lorisoids.

Categorization of humans has not been without controversy. One position is that homo sapiens are above apes and that it is improper to categorize the species as one of the great apes. The opposite extreme is the view that humans are "the third

chimpanzee", based upon the very high percentage of genetic commonality between the species. This image follows a convention found between these two positions.

General Primate Characteristics

While primates share traits with other mammals, such as mammary glands and regulation of body temperature, there are a number of traits that all primates share. Because humans and non-human primates share a common evolutionary history (we have a common primate ancestor), human and non-human primates have a number of similar biological and behavioral traits.

Body

Primates have a **flexible** and **generalized** limb structure that's able to move readily in many directions. Compare the flexibility of the spider monkeys on the left with the horse on the right.

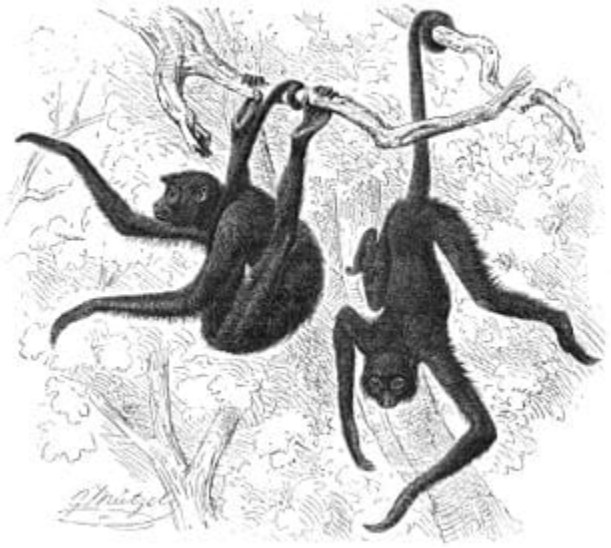

Figure 6.20.4.3: Spider monkeys.

Figure 6.20.4.4: Horse.

Hands

Primates have **prehensile** hands (and most of them have prehensile feet also). This means that they have the ability to grasp and manipulate objects. Primates have 5 digits on their hands and feet. Note that a few primates, like spider monkeys, have what are called **vestigial** thumbs. This means that they have either a very small or non-existent external thumb (but in that case, they will still have a small internal thumb bone).

Figure 6.20.4.5: Primate hands and feet.

Teeth

Primates have different teeth that perform different tasks when processing food via biting or chewing. Thus, they have the ability for a more generalized diet (compared to a specialist diet), meaning that they have more dietary flexibility. Why would this be a good thing to have?

Compare the teeth of the cayman (a relative of crocodiles and alligators) with the human teeth on the right. While the cayman's teeth do vary in size, they don't vary in structure. However, the human has incisors, canines, premolars, and molars -- all of which perform different food processing tasks.

Figure 6.20.4.6: Cayman.

Figure 6.20.4.7: Human jawbone.

Senses

Compared to most other mammals, primates have an increased reliance on vision and a decreased reliance on their senses of smell and hearing. Associated with this are their smaller, flattened noses, loss of whiskers, and relatively small, hairless ears. Also associated with this are their forward-facing eyes with accompanying binocular or stereoscopic vision. This type of vision means that both eyes have nearly the same field of vision with a lot of overlap between them. This arrangement provides good depth perception (but a loss of peripheral vision)--very useful for moving through tree branches.

Note first how the eyes of the monkey on the left are more front-facing than the eyes of the cow on the right. Also note how flat the monkey's nose is and how small its ears are, when compared to those of the cow.

Figure 6.20.4.8: Monkey.

Figure 6.20.4.9: Cow. Note placement of the eyes compared to the monkey.

Brain Evolution

In relation to other mammals, primates have a more expanded and elaborate brain, including expansion of the cerebral cortex. Compare the complexity of the human brain on the left to the cat brain on the right.

Figure 6.20.4.10: Human Brain.

Figure 6.20.4.11: Cat Brain.

Clearly, significant anatomical changes have taken place during the evolution of the brain in primates, in other mammals, and in animals in general. Are there generalizations that can be made about the evolution of animal brains?

Striedter (2006) has identified a number of general principles of brain evolution applicable across a wide range of species (i.e. not just primates or mammals).

1) Embryonic brains across species are more similar than adult brains, because brains tend to diversify more as they grow toward adult form;

2) relative brain size to body size in the vertebrates (animals with backbones) has tended to increase more often than decrease over evolutionary time;

3) it appears that increases in relative brain size were generally accompanied by increases in social or food foraging complexity;

4) most increases in relative brain size were accompanied by increases in absolute body size;

5) increases in absolute brain size require changes in the brain's internal connections which imply greater modularity (specialized processing modules increasing the "division of labor") of brain anatomy and functioning;

6) evolution generally enlarges brains by extending the period of brain development while conserving (keeping the same) the "birth order" of different brain regions, so that big-brained animals tend to have disproportionately larger late-"born" (late-developing) regions ("late equals large"), such as cerebral cortex, leading to disproportionately more cerebral cortex (increased corticalization) in big-brained mammals (non-mammals don't have cerebral cortex); however there are exceptions to this rule, for example, at any given absolute brain size, there is more cerebral cortex in simians than in prosimians, and in parrots there is an unusually large telencephalon which is not accounted for by the rule;

7) changes in size proportions of brain areas, although "automatic" within the scaling (allometric) rules above, can still be adaptive and undergo natural selection;

8) as brain regions increase in absolute or proportional size, they tend to become laminated--organized into sheets of neurons--allowing point for point corresponding connections between sensory and motor maps with minimal axonal and dendritic wiring, saving space and metabolic energy;

9) as brain size increases, more regional subdivisions occur from ancestral parts subdividing into new parts, as in the dorsal thalamus, or, as in the case of neocortex, a new part was added to an ancestral set of conserved parts;

10) Deacon's rule is that "large equals well connected," meaning that as the relative size of a brain structure increases it tends to receive more connections and to project more outputs to other structures.

Striedter (2006) adds a number of additional generalizations about the mammal and primate brains, including human:

11) six-layered mammalian neocortex probably evolved from a 3-layered reptilian precursor (something like that in turtles) called dorsal cortex by adding several layers;

12) aside from neocortex, the mammalian brain is similar to the reptilian brain (which also has hippocampus, for example) but even with a "fundamental scheme" of brain regions and circuitry, many minor changes in wiring can drastically change how information flows through a brain and thus how it functions--thus, the mammal brain is not just an upscale version of the reptilian brain;

13) increasing corticalization in mammals cannot be explained in terms of the above scaling (allometric) rules and involved highly specialized changes in brain anatomy presumably due to natural selection which expanded precursor sensory and motor cortical regions;

14) bird forebrains evolved along a very different path with expansion of their dorsal ventricular ridge (DVR), the major sensorimotor region of the avian telencephalon, highly similar in function to mammalian neocortex, making "many birds at least as intelligent as most mammals."

Striedter adds a number of points about the human brain in an attempt to identify features that make it special compared to the brains of other mammals.

15) In the six million years since bipedal apes (hominins) diverged from other apes, absolute brain size increased radically (about fourfold), not gradually, but in bursts--from when genus *Homo* first evolved, absolute brain size doubled from 400 to 800 cubic centimeters, then remained relatively steady in *Homo erectus* during the next 1.5 million years, but then exploded again in the transition to *Homo sapien* until about 100,000 years ago, at which time absolute brain size reached its current value of about 1,200 to 1,800 cubic centimeters. The first jump in Homo brain size was likely related to change in diet involving transition to meat and later the cooking of meat. The second leap was perhaps stimulated by competition among humans for mates and other resources;

16) the principle of "late equals large" predicts large neocortex in humans (the human neocortex to medulla ratio is twice that of

chimpanzees);

17) the principle of "large equals well connected" is consistent with known expanded numbers of projections from human neocortex to motor neurons in medulla and spinal cord permitting greater precision of control over muscles serving hands, lips, tongue, face, jaw, respiratory muscles, and vocal folds, required for the development of human language about 50,000 to 100,000 years ago;

18) once human language appeared, dramatic changes in human behavior became possible without further increases in brain size;

19) increase in brain size has some disadvantages: including increased metabolic costs because the brain utilizes so much metabolic energy (20% of human metabolic energy even though it is only 2% of human body weight; being so metabolically expensive increases in brain size must be paid for by improved diet or reduction of other metabolic energy demands); decreased connectivity perhaps making the two hemispheres more independent of one another, and perhaps explaining why the two cerebral hemispheres became functionally specialized; and size limits of neonatal brain due to constraints imposed by size of the human mother's pelvis and birth canal. According to Striedter, these costs may explain why human brain size plateaued about 100,000 years ago;

20) within neocortex, the lateral prefrontal cortex has become relatively enlarged in the human brain, likely increasing its role in behavior (see Chapter 14 for discussion of the the lateral prefrontal cortex and higher cognitive functions);

21) some key evolutionary changes in brain structure were not caused by increases in absolute or relative brain size, such as evolution of the neocortex of mammals, but require additional explanation; comparing distantly related species on absolute brain size alone misses important factors, for example, brains of some large whales weight 5 times as much as the human brain but whale brains have poorly laminated and thin neocortex; in cases of distantly related species, comparisons of relative brain size are more useful, for example, human and some toothed whales have relative brain sizes significantly larger than average mammals of similar body size;

22) two general hypotheses about brain evolution are that individual brain systems evolve independently by natural selection (the mosaic hypothesis) or alternatively that components of such systems evolve together because of functional constraints (the concerted or constraint hypothesis), with a third view being that all brain evolution is simultaneously both mosaic and concerted.

One problem with Striedter's approach is that it doesn't explicate the forces of natural selection that may account for more specific features of brain evolution in specific species, including our own. He admits that evolution of the neocortex cannot be explained by evolution of bigger brains and that neocortex evolved independently of absolute brain size. However, aside from restating the theory that complex social life in ancestral humans, along with competition among humans for resources, stimulated the evolution of increases in the size and complexity of the neocortex, he offers little about what role natural selection played in the evolution of neocortex, or in brain evolution in general. As Adkins-Regan (2006, p.12-13) states in her critique of Striedter's work, "There is relatively little discussion of tests of hypotheses about the selective pressures responsible for the origin and maintenance of traits . . . The author would seem to be experiencing symptoms of discomfort with the concept of adaptation. . ..Given that brain mechanisms are products of natural selection, a central strategy in neuroscience should be to use the methods of evolutionary biology, which have been so successful in helping us to understand the mechanisms and design of organisms generally." In Chapter 14 of this text, on Intelligence, Cognition, and Language, consistent with this advice, you will find an extensive discussion of the role of natural selection in evolution of brain systems involved in intelligence and thinking.

Primate Life History

Life history refers to the pattern that an organism takes from conception to death. When compared to other mammals, primates have:

- longer gestation (pregnancy) periods
- reduced number of offspring (usually one, but some species commonly have twins)
- delayed maturation, with a long infancy and juvenile learning period, reflecting substantial brain development after birth
- longer lifespan

Figure 6.20.4.12: Chimpanzee mother and baby.

Primate Ecology

Primate ecology refers to the relationship between primates and their environment. Their environment includes not only the physical environment (e.g., trees, water, weather) but also the other animals in the environment, including other non-human primates and even humans. Why should we care about primates and their ecology? Remember that evolution is always environmentally dependent. Also, keep in mind that primates are not only affected by their environments, they affect their environments as well (by eating plants and insects, dispersing seeds, etc.).

Figure 6.20.4.13: Monkey feeding.

There are two primary environmental factors to consider: Food and Predators.

1) **Food**

- Primate researchers examine the quality, quantity, and distribution of food in a primate's environment.
- Why? Because food = babies. This means that those individuals who acquire more high-quality food more efficiently are likely to have more offspring and therefore will be more evolutionarily successful.
- There is greater pressure for females than for males, because of the higher biological costs of reproduction for primate females (**reproductive asymmetry**)--remember that primates spend a very long time as dependent nursing infants, so primate mothers have a heavy burden when caring for them (the only exceptions are some New World monkeys: the father cares for the infants, but the mother still nurses them).

2) **Predators**

- the types and distribution of potential predators in a primate's ecosystem is important.
- Why? Because no one wants to get eaten, right? Those who can most efficiently and effectively avoid predation are likely to have more offspring and therefore will be more evolutionarily successful.

Figure 6.20.4.14: Jaguar, a primate predator.

Other important environmental factors are:

- weather
- the distribution of water
- the distribution of sleeping sites, and
- the primate's relationships with other individuals within their social group, other groups of their own species, and other species (including humans).

Food

Figure 6.20.4.15: Baboon examining a leaf.

Most primates are **herbivores** (they eat plant foods) and are dietary generalists. Some primates are **omnivores** and eat lots of things (plant and animal). However, some primates are more specialized.

- **Folivores**: eat mainly leaves.
- **Frugivores**: eat mainly fruit.
- **Insectivores**: eat mainly insects.
- **Gummivores**: eat mainly tree sap.

Figure 6.20.4.16: Lemur eating fruit.

One of the challenges that primates face in their day-to-day life is a type of **evolutionary arms race** they have with their food. Some food items, like fruit, "want" to be eaten. In other words, it's evolutionarily advantageous for a fruit to be eaten by a primate, who then carries the fruit's seeds far away from the parent plant in its stomach, to deposit them elsewhere. The fruit benefits from this **seed dispersal**, thereby limiting competition between the parent plant and its offspring. This is one of the hypothesized reasons that fruits have high sugar or fat contents, to make them attractive to seed dispersers, such as primates and birds.

However, some food items, like leaves, don't "want" to be eaten. It's not evolutionarily advantageous for a plant to be stripped of its leaves. A leafless tree would not be able to perform photosynthesis and would promptly die. This is why plants have developed certain chemicals in their leaves that make the leaves unpalatable or indigestible to primates. In these cases, most leaf-eating monkeys prefer to eat young leaves, which are visually identifiable (either lighter in color or a different color) and higher in nutrients than mature leaves.

Some primates have evolved color vision in order to more successfully forage for food and other primates have developed specialized digestive systems to deal with low-quality (high-fiber) foods.

Figure 6.20.4.17: Black and white colobus monkey resting.

Activity budgets

How a primate spends its time is called its **activity budget**. These are comprised of the major categories of:

- foraging/feeding
- mating
- social behavior
- locomotion/traveling, and
- resting/sleeping

Why should we care about activity budgets?

Examining a primate's activity budget gives a good idea of how that particular primate (or primate group) "makes a living". For example, time spent foraging, gives clues about how much food in its area and how much time it has to spend searching for food. Eating meat provides a concentrated source of calories; meat eating after a successful hunt in meat-eating primates such as chimpanzees and humans leaves more time and calories for activities other than food gathering.

Remember also that if a primate has to spend more time eating or moving around in order to find something to eat, then it has less time for either resting or socializing. Primates only have a finite amount of time in their day, so they have to maximize the use of it the best they can within their environmental parameters.

Activity budgets denote **when** a primate is "making a living":

- **Diurnal**: active during the day, generally inactive at night. Most primates are diurnal.
- **Nocturnal**: active during the night, generally inactive during the day.
- **Crepuscular**: active during dawn and dusk. Ring-tailed lemurs (pictured below left) have this activity pattern.
- **Cathemeral**: active during irregular periods during day and night. Black lemurs (pictured below right) are one of the few primate species who have this activity pattern.

Figure 6.20.4.18: Ringtailed lemur.

Figure 6.20.4.19: Black lemurs.

Note that these activity patterns are not hard and fast rules. As with diet, there is a lot of variation in how flexible a particular species (or group within a species) is when it comes to their activity patterns. For example, although traditionally thought of as strictly nocturnal, the activity patterns of owl monkeys have been found to be highly sensitive to environmental factors such as

temperature and amount of moonlight.

Food and Feeding Competition

One of the main factors that affects a primate "making a living" is **feeding competition** (competing with others for food).

There are two groups that a primate competes with;

- other primates in its social group (**within-group competition**)
- primates (of the same species) in other groups (**between-group competition**)

Figure 6.20.4.20: Macaques fighting.

There are also two types of competition. The type of competition prevalent in a situation depends on the quality and quantity of food available in the environment.

- **Scramble competition**: happens when there is a lot of low quality food. This is more common for leaf-eating primates, because trees tend to have large quantities of edible leaves (although some types, such as young leaves, may be preferable to others). It's an **indirect competition** in which whoever finds food faster or eats faster gets more food than do other individuals.
- **Contest competition**: happens when there is a small amount of high quality food. This is more common for fruit-eating primates, because a fruiting tree has a limited amount of high-quality fruit. It's a **direct competition**, where certain individuals (stronger, higher social status) get more food than do other individuals via squabbling or fighting.

In total, one can have:

- within-group scramble competition
- within-group contest competition
- between-group scramble competition, and
- between-group contest competition.

Feeding competition can be severe and have serious effects on the health, well-being, and reproductive capacities of primates. In other words, it has a direct effect on their evolutionary fitness. As expected, primates demonstrate a lot of **behavioral strategies** to deal with the feeding competition they face. For example, a group with **high scramble competition** may **spread out** more when feeding so as to access more resources OR in a group with **high contest competition**, some individuals may form **coalitions** in order to "gang up on" other primates to take their food.

Spatial use: home ranges and territories

The area that a primate uses is its **home range**. The part of the home range that's used most often is the **core area**. Some species, such as snub-nosed monkeys, have very large home ranges (32 sq. km) and other species, such as the pygmy marmoset, have very small ones (0.003 sq. km). A primate's home range has to contain all of the resources it needs in order to survive (food, water, sleeping sites, etc.). The home ranges of different primate groups often overlap, sometimes only a little, but sometimes a

lot. If the home range is physically defended, it's a **territory**. Chimpanzees are famous for their territorial conflicts, which are so organized and violent that scientists have begun calling it "warfare".

Primate Behavior

The behavioral traits we share with other primates include:

- a greater dependence on flexible, learned behavior, reflecting neuroplasticity of the brain and corticalization (increased development of cerebral cortex)
- a tendency to live in social groups

Figure 6.20.4.21: Baboons crossing the road. Baboons live in complex social groups.

Primate Social Behavior

One of the fundamental traits that primates share is that we are **social** creatures. All primates share some form of social structure with others of their own species, whether that be in a large permanent social group or as an individual who has repeated short-term interactions with others. The social relationships that primates have with other members of their own species have a huge impact on the individuals involved and are incredibly important to their health, well-being, and reproductive success. This makes the study of primate social behavior very important.

Figure 6.20.4.22: Chimpanzees, our closest living relative, in captivity.

Primate behavior studies come in three formats:

- **Captive**: The animals are in captivity. Variables are easy to control in these situations (for example, the number of individuals

in a group or food availability) and the primates are easier to observe at close-range. However, because of the artificiality of the situation, the primates may not be exhibiting normal behavior.
- **Semi-captive (semi-free-ranging)**: The animals are captive, but in a very large area like an island or a fenced-in compound. Variables are still relatively easy to control and the primates are easier to observe (than in the wild). The primates tend to exhibit more natural behavior patterns in this type of setting than when compared to a completely captive situation.
- **Free-ranging**: The animals are living in the wild, in their natural environment. This is the most logistically difficult type of primate study. The animals are more difficult to observe (often requiring a **habituation** period to get them accustomed to the presence of observers). However, the primates are most likely to perform their normal array of behaviors in this type of study.

Social structure: the "whys" and the "hows"

The basic premise of why primates have certain social behaviors is due to **reproductive asymmetry**. Females are under a lot more pressure than males to forage effectively because of the biological pressures they're under (due to the burden of reproduction). It is precisely this inequality that causes the sexes to have different evolutionary priorities:

- For **females**, their priority is **food**. Females can only reproduce at a certain rate, due to the length of time it takes to be pregnant, raise an infant to independence, and have their bodies recover to do it all over again. Access to lots of good quality food through little effort is the key to accomplishing this task.
- For **males**, their priority is finding **mates**. Males can reproduce at a much faster rate than can females. The only real constraint on their reproductive rate is how frequently they can get fertile females to mate with them.

So, **primate social structure** works like this:

- male distribution follows how the females distribute themselves, and
- the females distribute themselves depending on how the food is laid out in their environment.

Social groups have two **immigration/emigration** patterns:

Figure 6.20.4.23: Baboon social group.

Female philopatry:

- Females do not emigrate (depart) from their birth group at sexual maturity.
- Males usually do emigrate from their birth group at sexual maturity.
- Females form the core of the group, are biologically related, and have tight social bonds (often exhibited through social cooperation and grooming: seen in these baboons, pictured right). Males have few positive social relationships.
- This is the most common form of social system in primates.

Male philopatry:

- Males do not emigrate from their birth group at sexual maturity.
- Females usually do emigrate from their birth group at sexual maturity.
- Males form the core of the group, are related and have tight social bonds. Females have few positive social relationships.
- This type of social system tends to occur when resources are widely dispersed, so females are widespread and difficult for males to consistently access.

Social strategies

In order to achieve their priorities, male and females must utilize certain social strategies.

Dominance

- As with chickens, primates have a "pecking order" or **dominance hierarchy** in their social groups.
- One's position in the dominance hierarchy often gives them access to preferred resources, including not only food and mates, but other resources such as sleeping sites and water.
- Sometimes dominance hierarchies are determined through fighting, but more often they are sorted out through a series of aggressive/submissive non-contact interactions, such as approach/avoidance, facial expressions, and body postures. Primates try to avoid direct aggressive contact in an effort to avoid risk of bodily harm.

Figure 6.20.4.24: Macaques grooming.

Cooperation

- Dominance hierarchies aren't completely linear. One's rank in the hierarchy often depends on who they can get to cooperate with them during conflicts. For example, Monkey 2 may be submissive to Monkey 1 when alone, but when her buddy Monkey 3 is around, the two of them cooperate and chase Monkey 1 away from food together. Therefore, Monkey 2's position in the dominance hierarchy is situationally dependent.
- These cooperative relationships are usually between relatives. In male philopatric groups, they're usually brothers. In female philopatric groups, it's often mother-offspring or siblings.
- The relationships are cultivated through **affiliative behaviors**, such as play, grooming, and other forms of body contact (e.g., hugging). So, primates practice *You scratch my back, I'll scratch yours* both literally and figuratively.

Why be in a social group?

Figure 6.20.4.25: Harpy Eagle. Predator of smaller primates. (Copyright; author via source).

So, why be in a social group if it is just one big mess of food competition, mate competition, and political posturing? Well, because there are benefits, of course!

Living in a social group:

- provides access to **mates**. While there is, of course, competition for mates within the group, a social group ensures that there are at least mates available to fight over.
- provides more eyes looking for **food** and more brains remembering where food is in the ecosystem
- provides **anti-predator defense**
- There are more eyes on the lookout for predators.
- An additional anti-predator benefit is known as "The Selfish Herd" (safety in numbers). It basically comes down to "you don't have to run faster than the predator, just faster than the other guy".
- Some social groups will "mob" predators and drive them away. This only works on smaller predators, especially those who rely on surprise attacks (such as the Harpy Eagle, pictured above).

Types of primate social groups

Solitary:

Figure 6.20.4.26: Galago. These small nocturnal primates are also called "bush babies" and are native to sub-Saharan Africa. Social groups consist of closely related females and their young. Males leave the group at puberty.

- Males are alone most of the time, except when seeking out mates. Females live with their dependent offspring.

- One male will have territorial overlap with several females.
- Some prosimians have this social system, like the galago, pictured above.

Monogamy:

Figure 6.20.4.27: Titi monkey.

- A social group is comprised of a male, a female, and their dependent offspring.
- This is also called "pair bonded".
- This is common in New World monkeys (for example, titi monkeys, pictured above) and the "lesser apes" (siamangs and gibbons).

Single-male multi-female:

Figure 6.20.4.28: Diana monkey.

- A social group is comprised of one adult male, several (to many) adult females, and their dependent offspring.
- Males that don't belong to a social group may either live alone or in multimale (bachelor) groups that have no females.
- It's a difficult life for the resident male in these social groups, because not only did he have to fight his way into the group (either driving the previous resident male out or stealing females from another male), he has to continually fight to keep other males out of his group, while keeping the females in the group.
- When males take over groups, some may commit infanticide (killing the previous resident male's infants).
- This is a common social group in Old World monkeys (like the Diana monkey, pictured above)

Multi-male multi-female

Figure 6.20.4.29: Hanuman langur.

- A social group is comprised of more than one adult male, more than one adult female, and their dependent offspring
- In these groups, in order to have preferential access to females, males will form dominance hierarchies or develop biological characteristics that the females find attractive. For example, during the mating season, squirrel monkey males begin storing large amounts of water and fat on their bodies.
- Some species (such as Hanuman langurs - pictured above) have both single-male and multimale-multifemale social groups in the same population.

Fission-fusion

Figure 6.20.4.30: Bonobo. Chimps and bonobos are our closest living relatives. Humans, chimps and bonobos descended from a single ancestor species that lived six or seven million years ago.

- In this situation, individuals belong to a large group called a community. Each community has a home range and consistent community membership. Within the community, individuals form temporary foraging groups called parties. Parties have an unpredictable membership. So, on any given day (or even part of a day), one cannot predict who will be foraging with whom.
- Females always travel with their dependent offspring.
- Sometimes males form partnerships and forage together.
- This type of social group is thought to have been an adaptation to environments with patchy, unpredictable fruit availability.
- It's found in chimpanzees, bonobos (pictured above), and spider monkeys.

Single-female multi-male

Figure 6.20.4.31: Tamarins.

- A social group is comprised of one adult female, more than one adult male, and their dependent offspring.
- This is rare in primates.
- Found in marmosets and tamarins (pictured right), this type of social system is thought to be an adaptation to the twinning (giving birth to twins) that it common to these small primates. The males carry the dependent infants.

Primate Evolution

Now that you have an understanding of living primates' morphology and behavior, it is time to learn about the origins of primates. the study of primate evolution is multidisciplinary in nature and incorporates data and methods from paleontology, geology, anthropology, and archaeology to study the fossil record of primates.

Fossils

Figure 6.20.4.32: Permineralized wood.

Fossils are at the center of the study of ancestral primates. Animal fossils provide insight into morphology and behavior of ancient organisms while plant fossils help to determine what the landscape may have looked like during the time that a particular organism, including primates, lived there (remember, evolution is environmentally dependent!).

When a fossil is found, it can be dated using a variety of methods. Some methods date the fossil itself; other methods use the surrounding indicators There are relative dating techniques that provide an order of occurrence, but no absolute dates, and there

are absolute, or chronometric, dating techniques that provide dates (usually a range of dates) for an object.

Geologic time

From geology we have an understanding of the time involved in the development of earth. In this section we are specifically focused on the late Mesozoic/early Cenozoic eras in relation to primate evolution (see chart below).

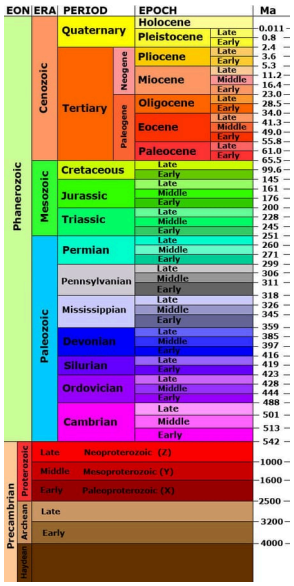

Figure 6.20.4.33: Geologic time scale (Ma = millions of years ago).

Tracking Primate Evolution

The Mesozoic: the origin of mammals

The Mesozoic era is known as "the age of the dinosaurs" due to their ecological dominance at the time; however, it is during this era that the first mammals evolved, including a primate-like mammalian ancestor. Research using DNA analysis and fossils suggests that by 75 mya (million years ago) all of the mammalian orders had diverged.

The Cenozoic era

The Paleocene epoch

Proto-primates, primate-like mammals, evolved in the Paleocene epoch, about 65 mya. The proto-primates from this epoch are controversial; some argue that they are related to primates but are not actually primates (hence, "proto-primates").

The Eocene epoch

The Eocene epoch (56-33 mya), with its warmer and wetter climate and diversification of rainforests and flowering plants, sees the emergence of the first true primates.

Eocene primates were (Jurmain et al. 2013: 189):

- about the same size as modern squirrels, with prehensile hands and feet and more forward-facing eyes that gave them stereoscopic vision.
- widely distributed
- mostly extinct by the end of the Eocene

- most are not ancestral to later primates

The Oligocene epoch: the monkey/ape divergence (34 to 23 mya)

The global climate shifted again, cooling and drying, during the Oligocene epoch (33-23 mya). There is a reduction in the amount of rainforests, which retreated toward the equator, but an expansion of grasslands. So, there was an increase in terrestrial (ground) niches and a decrease in arboreal (tree) niches. While most of the fossils from this time are Old World monkeys, some are ancestors of New World monkeys; at this point the American continents had separated from Africa and Eurasia.

The Miocene epoch: the Old World monkey/ape divergence (23 to 5 mya)

There were two climate shifts during this period, first there was a warm period with heavy forestation, followed by drier and cooler climates with decreasing forest and increased grasslands.

At this point, the Old World monkeys and apes split. The fossils are from east Africa.

The ape ancestors had the following traits:

- no tail
- arboreal quadrupeds (limb structure was still monkey-like)

The Old World monkey ancestors at this point in time had the following traits:

- A tail
- Had macaque-like faces
- Were medium sized 7-11 lbs

Where did primates come from?

There are three primary hypotheses about the origins of primates. The earliest hypothesis, the arboreal hypothesis, claims that the first primates evolved a suite of traits for living in trees, e.g., grasping hands and feet and stereoscopic vision. This hypothesis held sway from the early 1900s until the 1970s when the visual predation hypothesis was proposed. This hypothesis suggests that primates evolved because they provided an advantage for hunting small insects, e.g., orbital convergence that allowed for 3d-vision. Shortly thereafter, the angiosperm hypothesis was proposed, which claims that primate evolution is related to the adaptive radiation (diversification into different ecological niches) of angiosperms or flowering plants. Each of these hypotheses have been challenged over time, and it may be that each may play a part in explaining primate evolution.

The Taxonomy of Humans

At this point, it is useful to review taxonomy, the biological classification of organisms, using the human species to illustrate the taxonomic classifications.

Biological classification of Humans illustrating taxonomic categories of kingdom, phylum, class, order, family, genus, species.

Figure 6.20.4.34: Taxonomic classification of humans illustrating taxonomic categories used for all living things. (Image from Wikimedia Commons; File:Biological classification of Humans Britfix.png; https://commons.wikimedia.org/wiki/F...ns_Britfix.png; by L Pengo PD-User, Modified by Britfix; made available under the Creative Commons CC0 1.0 Universal Public Domain Dedication).

Summary

Humans are primates and primates are mammals. Both mammals and primates have distinguishing features, anatomical, physiological, and behavioral. One distinguishing feature of mammals with direct relevance for behavior is that only mammals have six-layered neocortex (cerebral cortex), while non-mammals lack six-layered cortex. Larger brains tend to be found in larger animals. Cerebral cortex developed as a result of natural selection, perhaps related to the increased information processing

demands of living in complex social groups, although this is only one theory of the evolutionary origins of cerebral cortex. Brains are metabolically expensive organs--they require a lot of metabolic energy (in humans, the brain is only 2% of body weight, but it consumes 20% of the body's metabolic energy). Larger brains in human ancestors requiring more metabolic energy may have come about after ancestral humans began to eat meat, a concentrated source of calories and nutrients, and later to cook the meat making it easier to digest, leaving more metabolic energy from the meat to support energy requirements of bigger brains. In subsequent modules, we consider more details of hominin and human evolution.

6.20.5: Chapter 3- Material Culture

Learning Objectives

1. Briefly explain why material culture is important to biological psychologists as well as anthropologists
2. Briefly list the types of tool industries, the date ranges associated with each, and the species of hominin or human associated with each if known

Overview

The earliest evidence of material culture is in the form of stone tools found on sites dated to 2.4 millions years ago (mya). This does not mean that early hominins did not use tools. New finds from Ethiopia indicate that *A. afarensis* used stone tools to extract marrow from bones 3.4 million years ago. What is not known is whether *A. afarensis* was making tools or simply using found rocks as tools. From material culture, biological psychologists and anthropologists can make inferences about cognitive capacities of hominins and early humans.

Material Culture

Harmand et al. (2015) reported that they had found 3.3 million-year-old (myo) stone tools at West Turkana, Kenya, which they proposed calling Lomekwian as the tools predate Oldowan tools (see below) by 700,000 years. What is particularly interesting is that the oldest *Homo* fossils found in West Turkana are 2.34 myo, although *Au. afarensis* is known from 3.39 mya. Questions remain as to which hominin left behind the assemblage (an assemblage is a group of artifacts found together at a specific site) of 149 artifacts, including flake fragments, worked cobbles, and cores, and how it compares with Oldowan tools. Material culture can give clues about cognitive capacities in hominins based on the assumption that more sophisticated tools would require more advanced cognitive abilities.

Oldowan Tool Industry

The oldest stone tool assemblage is the Oldowan tool industry (at least it is the oldest until the field comes to a consensus about Lomekwian tools). First identified at Olduvai Gorge, Tanzania by Louis and Mary Leakey, Oldowan tools are stone pebble tools manufactured using a hard percussion technique. This technique involves striking two stones together to knock off a flake or create an edge on a piece of stone. While this seems like a simple technique, to make one of these tools, the individual needs to be able to understand how the stone will break when struck. The presence of Oldowan tools is an indication of changing cognitive abilities.

Figure 6.20.5.1: Olduwan flake tool.

Oldowan tools were used for cutting, chopping and scraping.

Figure 6.20.5.2: Olduwan chopper.

*Homo habili*s was not reliant primarily on hunting but instead scavenging. Researchers used Oldowan tools to scavenge a carcass and found that in about 10 minutes, it was possible to extract enough meat and bone to meet about 60% of the estimated daily caloric intake (approximately 1500 calories). Furthermore, researchers found that it was easy to scare off other scavengers and even some predators in order to gain access to the carcass. As a subsistence strategy, scavenging does have some advantages:

- it is less dangerous as the scavenger does not have to risk themselves for the kill
- it is quicker as the scavenger can simply follow the roar of the lion or look for vultures circling overhead
- there is less energy expenditure for the reasons listed above and the short amount of time it would take to butcher the remaining carcass using stone tools

The first definitive evidence of hunting is from Schöningen, Germany in the form of wooden spears dated to 400,000 years. The artifacts were identified as spears because they have similar morphology to modern javelins, e.g., the balance point is 1/3 the way from the spear point. The spears are about 7 feet long with sharpened points and were found with the remains of butchered horses.

All researchers agree that *Homo* was making and using tools. Recently reported finds of stone tools 3.3 myo at West Turkana, Kenya may end up demonstrating that an early australopith was the first tool maker.

Acheulean Tool Industry

One thing we see with tool technologies is that as time passes the tools become more and more sophisticated. About 1.9 million years ago, *Homo erectus* invented a new sophisticated technology for making stone tools, which started with the hard percussion technique, but then employed a soft hammer technique to get more refined and sharper edges. This new tool industry is called the Acheulean.

The Acheulean tool industry, first found at St. Acheul, France, is characterized by bifacial tools. This means that the stone is worked on both sides. This tool industry is a marked step in the cognitive abilities of hominins because the tool has to be conceptualized prior to manufacturing. Dozens of flakes have to be removed precisely in order to maintain the symmetry of the tool and keep the edges straight. The signature tool of the Acheulean tool industry is the tear-drop shaped handaxe. Often referred to as the Swiss Army knife of the Pleistocene, the handaxe was an all-purpose tool used for a multitude of activities including digging, sawing, and cutting.

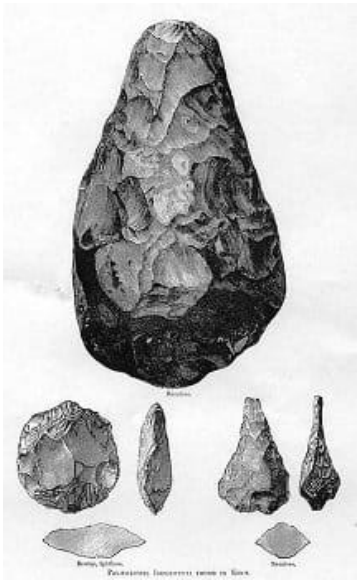

Figure 6.20.5.3: Acheulean Handaxes.

Mousterian Tool Industry

Neanderthals took the next step in the evolution of stone tools by making tools for specialized tasks. These flake tools found in a cave in France developed out of a manufacturing technique characterized by preparing the core of raw material from which flakes can be struck and then worked. Sharper tools with a finer edge are produced using this technique. Neanderthals shaped these flakes into tools like scrapers, blades, and projectile points, specifically spear points. In fact, at Neanderthal caves sites in the Middle East, there are a higher percentage of spear points found than at neighboring Homo sapiens sites. Mousterian tools are a technological advance, taking a high degree of conceptualization and knowledge of the properties of the stone.

Figure 6.20.5.4: Mousterian Tool Industry.

Upper Paleolithic Tool Industries

The Upper Paleolithic of Europe begins 45,000 years ago and ushers in further advances in tool technology. Not only are there a wider variety of tools made, but new materials are used, including bone and antler. Blade tools emerge. A blade tool is a tool that is at least twice as long as it is wide. The benefit of blade tool technology is that blades can be easily knocked off a prepared core and then made into a wide range of tools, e.g., projectile points, drills, needles, scrapers, burins. By 31,000 years ago, these tools are widespread throughout Europe, allowing archaeologists to trace the movement of modern *Homo sapiens*.

Figure 6.20.5.5: Aurignacian Backed Knives (Wellcome M0011849).

This tool industry disappears from the archeological record by 29,000 years ago. It is replaced by another tool industry, which is found at European sites until around 21,000 years ago. This tool industry is characterized by small blades and serrated knives, as well as projectile points that can be hafted onto a shaft. The small size of some of the projectile points leads some archeologists to surmise that the bow and arrow was invented during this period, although the first definitive evidence of arrows comes from Stellmoor, Germany (10,500 years ago). It does appear that the spearthrower was invented during this time frame. This is an important advance as it allowed a hunter to throw farther and with more force, making hunting the large animals of the period a little safer.

Figure 6.20.5.6: Gravettian tools (Fleche Font Robert 231.4 (2)).

Figure 6.20.5.7: Solutrean Point.

Solutrean points are some of the best made points of the Upper Paleolithic. The technology flourished from around 21,000 to 16,000 years ago, but then disappears for thousands of years until a similar manufacturing process appears in North America during the Clovis period. To explain this, some archeologists propose that there was a migration of peoples from the Iberian Peninsula to North America in the late Pleistocene who carried the technology with them; however, there is little other evidence to support this contention. It is probable that the manufacturing techniques were rediscovered by North America's early inhabitants.

One of the reasons that Solutrean points were finely made was because the stone was heat treated before it was worked. Heat treatment means that the stone was placed in a fire for a period of time, making it possible to make pressure flaking more precise. Heat treating was also a hallmark of the Magdelenian tool industry, 16,000-11,000 years ago. Bone and antler tools flourish during the Magdelenian. Harpoons appear in the archeological record, with true barbed harpoons showing up around 13,000 years ago.

Figure 6.20.5.8: Magdalenian Barbed Harpoons.

Why Material Culture is Important to Biological Psychology

For biological psychology some familiarity with the development of tool making is important for what it suggests about the cognitive abilities of various hominin species and early humans. Some of the tools pictured above and the uses that they were put to show sophisticated cognitive abilities to imagine stone tools, how to shape them, and the purposes that they could serve once completed. Evolutionary psychologists such as Cosmides and Tooby from the University of California at Santa Barbara suggest that early humans filled what they refer to as "the cognitive niche," the use of reasoning including use of methods of adaptation such as weapons, traps, coordinated driving of game, and ability to use abstract concepts and metaphors to enhance reasoning about the world (Pinker, 2010). These abilities depend upon the properties of an evolving brain, specifically on the mechanisms involved in an emerging intelligence in early humans. Brain mechanisms involved are discussed in the chapter in this text on Intelligence, Cognition and Language.

Summary

The development of stone tools undergoes several stages and early stages preceded emergence of *Homo sapiens*. The discovery of stone tools gives clues about the cognitive abilities of hominins including Neanderthal and early humans. Creation of sophisticated stone tools required conceptualization of the tool before its manufacture and suggests emerging abilities to imagine and to plan (see Chapter 14 on Intelligence, Coginition, and Language).

6.20.6: Chapter 10- Computer Models and Learning in Artificial Neural Networks

Learning Objectives

1. Explain Hebb's rule and how it is applied in connectionist networks
2. Describe connection weights and how their modification by inputs to them create "learning" in a connectionist network
3. Describe the structure of a simple three-layer network
4. Explain what is meant by "coarse coding" and give an example
5. Explain Hebb's concept of "cell assemblies"
6. Discuss how the graded potentials (EPSPs and IPSPs) in biological neurons undergo a nonlinear transformation during neural communication permitting emergent properties

Overview

Artificial neural networks, or connectionist networks, are computer generated models using principles of computing based loosely on how biological neurons and biological neuron networks operate. Processing units in connectionist networks are frequently arranged in interconnected layers. The connections between processing units in connectionist networks are modifiable and can therefore become stronger or weaker, similar to the way that synapses in the brain are presumed to be modified in strength by learning and experience. Cognitive processes can be studied using artificial neural networks providing insights into how biological brains may code and process information.

Hebbian Synapses, Modification of Connection Weights, and Learning in Artificial Neural Networks

Hebbian Learning, also known as Hebb's Rule or Cell Assembly Theory, attempts to connect the psychological and neurological underpinnings of learning. As discussed in an earlier section of this chapter, the basis of **Hebb's theory** is when our brains learn something new, neurons are activated and connected with other neurons, forming a neural network or cell assembly (a group of synaptically connected neurons) which can represent cognitive structures such as perceptions, concepts, thinking, or memories. How large groups of neurons generate such cognitive structures and processes is unknown. However, in recent years, researchers from neuroscience and computer science have made advances in our understanding of how neurons work together by using computer modeling of brain activity. Not only has computer modeling of brain processes provided new insights about brain mechanisms in learning, memory, and other cognitive functions, but artificial intelligence (AI) research also has powerful practical applications in many areas of human endeavor.

The influence of Hebb's book, *The Organization of Behavior* (1949), has spread beyond psychology and neuroscience to the field of artificial intelligence research using artificial neural networks. An **artificial neural network** is a computer simulation of a "brain-like" system of interconnected processing units, similar to neurons. These processing units, sometimes referred to as "neurodes," mimic many of the properties of biological neurons. For example, "neurodes" in artificial neural networks have connections among them similar to the synapses in biological brains. Just like the strengths of conductivity of synapses between biological neurons can be modified by experience (i.e. learning), the **synaptic "weights"** at connections between "neurodes" can also be **modified by inputs** to the system, permitting **artificial neural networks** to **learn**. The basic idea is that changes in "connection weights" by inputs to an artifical network are analogous to the changes in synaptic strengths between neurons in the brain during learning. Recall from a prior section that experience can strengthen the **associative link between neurons when the activity in those neurons occurs together (i.e. Hebb's Rule**). In artificial neural networks, also called **connectionist networks**, when connection weights between processing units are altered by inputs, the output of the network changes--the artificial neural network learns.

Like biological synapses, the **connections** between processing units in an artificial neural network can be inhibitory as well as excitatory. "The synaptic weight in an artificial neural network is a number that defines the nature and strength of the connection. For example, **inhibitory connections have negative weights, and excitatory connections have positive weights**. Strong connections have strong weights. The signal sent by one processor to another is a number that is transmitted through the weighted connection or "synapse." The "synaptic" connection and its corresponding "weight" serves as a communication channel

between processing units (neurodes) that **amplifies or diminishes signals** being sent through it; the "synaptic" connection amplifies or diminishes the signal because these signals are multiplied by the weight (either positive or negative and of varying magnitude) associated with the "synaptic" connection. Strong connections, either positive or negative, have large (in terms of absolute value disregarding sign) weights and large effects on the signal, while weak connections have near-zero weights" (Libretext, Mind, Body, World: Foundations of Cognitive Science (Dawson), 4.2, Nature vs Nurture). **Changes in synaptic "weights" change** the **output of the neural network** constituting **learning** by the network. Notice the clear **similarity to Hebb's conception of learning in biological brains.**

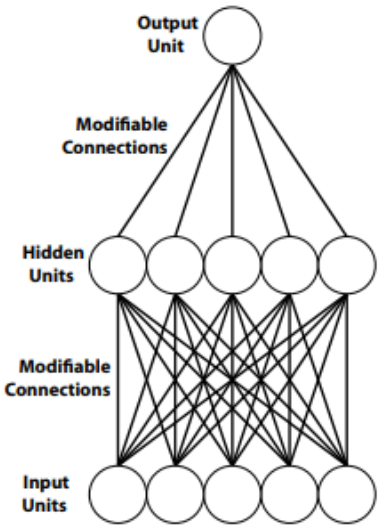

Figure 6.20.6.1: A multilayer neural network with one layer of hidden units between input and output units. (Image from Libretext, Mind, Body, World: Foundations of Cognitive Science (Dawson), 4.5, The Connectionist Sandwich; https://socialsci.libretexts.org/Boo...onist_Sandwich)

Additional hidden layers increase the complexity of the processing that a network can perform. Artificial neural networks with multiple layers have been shown to be capable of quite complex representations and sophisticated learning and problem-solving. This approach to modeling learning, memory, and cognition is known as "connectionism" (see *Matter and Consciousness* by Paul Churchland, MIT Press, 2013, for an excellent and very readable introduction to the field) and is the basis for much of the research in the growing field of artificial intelligence, including voice recognition and machine vision.

Recall that Hebb (1949) proposed that **if two interconnected neurons are both "on" at the same time, then the synaptic weight between them should be increased**. Thus, Hebbian learning is **a form of activity-dependent synaptic plasticity where correlated activation of pre- and postsynaptic neurons leads to the strengthening of the connection between the two neurons**. "The Hebbian learning rule is one of the earliest and the simplest learning rules for neural networks," "and is based in large part on the dynamics of biological systems. A synapse between two neurons is strengthened when the neurons on either side of the synapse (pre- and post-synaptic) have highly correlated outputs (recall the sections of this chapter on LTP). In essence, when an input neuron fires, if it frequently leads to the firing of the output neuron, the synapse is strengthened." Similarly, in an artificial neural network, the "synaptic" weight or strength between units in an artificial neural network "is increased with high correlation between the firing of the pre-synaptic and post-synaptic" units (adapted from Wikibooks, Artificial Neural Networks/Hebbian Learning, https://en.wikibooks.org/wiki/Artifi...bbian_Learning; retrieved 8/13/2021). Artificial neural networks are not hard wired. Instead, they learn from experience to set the values of their connection weights, just as might occur in biological brains when they learn. Changing connection weights within the network, changes the network's output, its "behavior." This is the physical basis of learning in an artificial neural network (a connectionist network) and is analogous to the changes in the brain believed to be the physical basis of learning in animals and humans.

More complex artificial neural networks of several different types using different learning rules or paradigms have been developed, but regardless of the learning rule employed, each uses modification of synaptic weights (synaptic strengths) to modify outputs as learning by the connectionist network proceeds--a fundamentally Hebbian idea.

In some systems, called self-organizing networks, experience shapes connectivity via "unsupervised learning" (Carpenter & Grossberg, 1992). When learning is unsupervised, networks are only provided with input patterns. **Networks whose connection**

weights are modified via unsupervised learning develop sensitivity to statistical regularities in the inputs and organize **their output units** to **reflect these regularities**. In this case, the **connectionist** artificial neural **network can discover new patterns** in data not previously recognized by humans.

In cognitive science, **most networks** reported in the literature are not self-organizing and are not structured via unsupervised learning. Instead, they are networks that are instructed to mediate a desired input-output mapping. This is accomplished via **supervised learning**. In supervised learning, it is assumed that the network has an **external "teacher."** The network is presented with an input pattern and produces a response to it. The teacher compares the response generated by the network to the desired response, usually by calculating the amount of error associated with each output unit. The "teacher" then provides the error as feedback to the network. **A learning rule (such as the delta rule) uses feedback about error to modify connection weights** in the network in such a way that the next time this pattern is presented to the network, the amount of **error** that it produces will be **smaller**. Technically, this learning paradigm is **called "back-propagation of error"** and may be analogous to feedback learning in animals and humans learning to reach a goal (think of operant conditioning, specifically operant shaping).

Representation and Processing of Information in Artifical Networks Gives Clues About Representation and Processing in Biological Brains

One of the assumed advantages of connectionist cognitive science (a branch of psychology, neuroscience, and computer science that attempts to use connectionist systems to model human psychological processes) is that it can inspire alternative notions of representation of information in the brain. How do neurons, populations of neurons, and their operations represent perceptions, mental images, memories, concepts, categories, ideas and other cognitive structures? Coarse coding may be one answer.

A **coarse code** is one in which an individual processing unit is very broadly tuned, sensitive to either a wide range of features or at least to a wide range of values for an individual feature (Churchland & Sejnowski, 1992; Hinton, McClelland, & Rumelhart, 1986). In other words, individual processors are themselves very inaccurate devices for measuring or detecting a feature of the world, such as color. The accurate representation of a feature can become possible, though, by pooling or combining the responses of many such inaccurate detectors, particularly if their perspectives are slightly different (e.g., if they are sensitive to different ranges of features, or if they detect features from different input locations). Here, it is useful to think of auditory receptors, for example, each of which is sensitive to a *range* of frequencies of sound waves. Precision in discrimination of frequency, experienced as pitch, occurs by patterns of activity in auditory receptor cells ("hair cells" on the basilar membrane inside the cochlea of the inner ear) which are sensitive to overlapping ranges of frequencies (auditory receptive fields). Relative firing rates in a group of auditory receptors with overlapping ranges of sensitivity gives a precise neural coding of each particular frequency.

Another familiar example of **coarse coding** is provided by the nineteenth century trichromatic theory of color perception (Helmholtz, 1968; Wasserman, 1978). According to this theory, color perception is mediated by three types of retinal cone receptors. One is maximally sensitive to short (blue) wavelengths of light, another is maximally sensitive to medium (green) wavelengths, and the third is maximally sensitive to long (red) wavelengths. Thus none of these types of receptors are capable of representing, by themselves, the rich rainbow of perceptible hues.

However, these receptors are broadly tuned and have overlapping sensitivities. As a result, most light will activate all three channels simultaneously, but to different degrees. Actual colored light does not produce sensations of absolutely pure color; that red fire engine, for instance, even when completely freed from all admixture of white light, still does not excite those nervous fibers which alone are sensitive to impressions of red, but also, to a very slight degree, those which are sensitive to green, and perhaps to a still smaller extent those which are sensitive to violet rays (Helmholtz, 1968, p. 97).

The study of artificial neural networks has provided biological psychologists and cognitive neuroscientists new insights about how the brain might process information in ways that generate perception, learning and memory, and various forms of cognition including visual recognition and neural representation of spatial maps in the brain (one function of the mammalian hippocampus). Even critics of connectionism admit that “the study of connectionist machines has led to a number of striking and unanticipated findings; it’s surprising how much computing can be done with a uniform network of simple interconnected elements” (Fodor & Pylyshyn, 1988, p. 6). Hillis (1988, p. 176) has noted that artificial neural networks allow “for the possibility of constructing intelligence without first understanding it.” As one researcher put it, “The major lesson of neural network research, I believe, has been to thus expand our vision of the ways a physical system like the brain might encode and exploit information and knowledge” (Clark, 1997, p. 58).

The **key idea in connectionism is association**: different ideas can be linked together, so that if one arises, then the association between them causes the other to arise as well. Note the similarity to Hebb's concept of **cell assemblies**, formed by associations

mediated by changes in synapses, and the association of cell assemblies with one another via the same mechanism. Once again, Hebb's influence is evident in connectionism's artificial neural networks--even the name, connectionism, reflects Hebb's ideas about how cognitive structures and learning and memory are formed in the brain--by changes in connections between neurons. As previously discussed, **long-term potentiation (LTP)** has been extensively studied by biological psychologists and neuroscientists as a biologically plausible mechanism for the synaptic alterations by experience proposed in Hebb's theory of learning and memory in biological brains.

While association is a fundamental notion in connectionist models, other notions are required by modern connectionist cognitive science in the effort to model complex properties of the mind. One of these additional ideas is **nonlinear processing**. If a system is linear, then its whole behavior is exactly equal to the sum of the behaviors of its parts. **Emergent properties**, however, where the properties of a whole (i.e., a complex idea) are more than the sum of the properties of the parts (for example, a set of associated simpler ideas), **require nonlinear processing**. Complex **cognition, perception, learning and memory may be emergent properties** arising from the activities of the **brain's neurons and networks**. This observation suggests that **nonlinear processing** is a key feature of **how information** is **represented and processed in the brain.** We can see the presence of nonlinear processing at the level of individual neurons.

Neurons demonstrate one powerful type of **nonlinear processing involving action potentials**. As discussed in chapter 5, the inputs to a neuron are weak electrical signals, called **graded potentials** (**EPSPs and IPSPs**; see chapter 5 on Communication within the Nervous System), which stimulate and travel through the dendrites of the receiving neuron. If enough of these weak graded potentials arrive at the neuron's soma at roughly the same time, then they summate and if their cumulative effect reaches the neuron's "trigger threshold," a massive depolarization of the membrane of the neuron's axon, the action potential, occurs. The action potential is a signal of constant intensity that travels along the axon to eventually stimulate some other neuron (see chapter 5). A crucial property of the **action potential** is that it is an **all-or-none** phenomenon, representing **a nonlinear transformation of the summed graded potentials**. The neuron converts continuously varying inputs (EPSPs and IPSPs) into a response that is either on (action potential generated) or off (action potential not generated). This has been called the all-or-none law which states that once an action potential is generated it is always full size, minimizing the possibility that information will be lost as the action potential is conducted along the length of axon. The all-or-none output of neurons is a nonlinear transformation of summed, continuously varying input, and it is the reason that the brain can be described as digital in nature (von Neumann, 1958).

Artificial neural networks have been used to model a dizzying variety of phenomena including animal learning (Enquist & Ghirlanda, 2005), cognitive development (Elman et al., 1996), expert systems (Gallant, 1993), language (Mammone, 1993), pattern recognition and visual perception (Ripley, 1996), and musical cognition (Griffith & Todd, 1999). One neural network even discovered a mathematical proof that human mathematicians had been unable to solve (Churchland, 2013).

Researchers at the University of California at San Diego, and elsewhere in labs around the world, are producing "deep learning" using artificial networks with 5 or more layers that can perform tasks such as facial recognition, object categorization, or speech recognition (see https://cseweb.ucsd.edu//groups/guru/). Although psychologists, PDP researchers, and neuroscientists have a long way to go, modeling of learning and memory, perception, and cognition in artificial (PDP) neural networks has contributed to our understanding of how neurons in the brain's networks may represent, encode and process information during the psychological states that we experience daily, including learning and memory. For example, "The simulation of brain processing by artificial networks suggests that multiple memories can be encoded within a single neural network, by different patterns of synaptic connections. Conversely, a single memory may involve simultaneously activating several different groups of neurons in different parts of the brain" (from The Brain from Top to Bottom; https://thebrain.mcgill.ca/flash/a/a...07_cl_tra.html). As we have seen earlier in this chapter, neural activity from different regions of cerebral cortex converges onto the hippocampus where processing may combine memory traces from different modalities into unified multi-modal memories.

6.20.7: Chapter 10- Acetylcholine, Enriched Experience, and Memory

Overview

In this supplementary section, we briefly discuss evidence for the role of the neurotransmitter acetylcholine (ACh) in learning and memory. Some of this evidence involves selective breeding of rats for ability to learn mazes. Rats were tested for their ability to learn mazes. Good maze learners were bred with other good maze learners and poor maze learners were bred with other poor maze learners, generation after generation. After a number of generations of this type of selective breeding, two separate strains of rats were established, one consisting of rats that were good maze learners and a second strain of poor maze learners. Researchers found more whole brain concentrations of ACh, and more ACh metabolism in the cerebral cortex, in rats selectively bred to be good maze learners compared to the rats bred to be poor maze learners. These relationships were interpreted as evidence of an involvement of ACh in learning and memory. Another line of research involved "enriched environments" and their effects on the brain in a variety of species. Small lab animals such as rats and mice are often kept in small wire cages, two animals per cage. In studies using "enriched environments" animals may be kept in large group cages housing together many animals with "toys" such as running wheels, blocks, and other novel or interesting objects. These "enriched environments" not only provide the animals with many things to do, to experience, and to learn about, but these group environments allow much more social interaction than can occur in small cages which house only two animals together. Sometimes, animals are raised in "impoverished environments" in which animals kept by themselves, one animal per cage. Animals raised in "enriched environments" compared to those raised in "impoverished environments" developed thicker and heavier cerebral cortex, greater dendritic branching, more dendritic spines, and other anatomical changes, as well as changes in brain chemistry. Recent research clarifies the mechanisms involved in the effects of ACh on learning and memory. ACh increases the excitability of dendrites of post-synaptic neurons in the CA3 region of the hippocampus involved in memory.

Differences in brain ACh metabolism induced by selective breeding for learning ability

The amnesia and dementia associated with Alzheimer's Disease involve damage to the frontal lobes, the medial temporal lobes, and involve depletion of acetylcholine (ACh) neurotransmitter due to damage in the basal forebrain, located just above the hypothalamus. The basal forebrain is the main source of ACh in the brain (Pinel and Barnes, 2021). Research in animals had long suggested that ACh might be involved in memory.

One way to test for an involvement of ACh in memory is to use selective breeding in animals. If differences in learning ability could be associated with specific differences in brain function, such as ACh activity, these differences might give clues about the physical bases of learning and memory and might contribute to our understanding of some forms of amnesia and dementia.

Rosenzweig and colleagues found chemical differences in the brains of rats selectively bred for maze learning ability (Rosenzweig, 2007). Early experiments focused on the neurotransmitter acetylcholine (ACh). Activity of acetylcholinesterase (AChE), an enzyme which inactivates ACh following its stimulation of cholinergic receptors (post-synaptic receptor sites that receive ACh), was used an indicator of acetylcholine (ACh) metabolism. Comparisons between AChE activity in cerebral cortex in maze-bright and maze-dull rats (rats selectively bred over multiple generations either for superior or inferior maze learning) showed higher cortical AChE activity indicating higher ACh metabolism in the maze-bright strain compared to the maze-dull strain, and within each strain there were significant correlations between behavioral performance and AChE activity in cerebral cortex. In addition, whole brain ACh concentrations were higher in the maze-bright strain than in the maze-dull, suggesting a possible role of ACh synapses in learning and memory. In addition, Rosenzweig and his research group found that AChE activity increases with age in rats up to about 100 days and then declines.

Anatomical and biochemical changes in the brain induced by enriched experience

Additional experiments by Rozensweig and his research group tested the effects of experience on the brain. Rats raised from an early age in an enriched environment, with stimulus objects in a group cage, not only showed differences in AChE activity and increased RNA and protein, but also showed increased weight of cortex and about a 5% increase in thickness of cerebral cortex compared to rats raised by themselves in individual cages in an impoverished environment. This unexpected finding was early

evidence that experience (resulting in learning and memory) can cause anatomical changes in the brain, as well as changes in brain chemistry.

Similar results were found even when older rats were exposed to an enriched environment for as little as 30 days, and several additional studies showed that exposure to enriched environments for as little as 4 days was sufficient to induce cortical weight changes and increased dendritic branching. Later studies in occipital cortex found a 14% increase in glial cells, increased numbers of pyramidal cell bodies, and increased sizes of synaptic junctions, all induced by enriched experience, suggesting possible effects of learning and memory in the brain. These studies also showed increased numbers of dendritic spines in the rats exposed to enriched experience compared to rats in the impoverished environmental condition. As you have already learned, these small spiny structures on dendrites, associated with synapses, undergo transient structural change followed by sustained change in spine volume lasting about 30 minutes or more after stimulation. Renner and Rozensweig (1987) reported that cerebral effects of experience occur in a wide range of species tested, including rats, mice, squirrels, cats, monkeys, fish, and birds. Rosenzweig (2007) reports that Kozorovitskiy, et al. (2005) found that exposure of adult marmosets to an enriched environment in group cages, for just 30 days, "resulted in increases in dendritic spine density, dendritic length, and dendritic complexity of neurons in the hippocampus and the prefrontal cortex, and it raised the expression levels of several synaptic proteins in the same regions."

Acetylcholine Increases Dendritic Excitability in Hippocampus

More recent research is helping to clarify the role of acetylcholine in learning and memory. Humphries, et al. (2022) reported that by inhibiting potassium (K+) ion channels, acetylcholine enhances the excitability of dendrites in the CA3 regions of the hippocampus reducing the number of NMDA receptors that needed to be excited in order to trigger spike activity at NMDA synapses, known to be involved in long-term potentiation (LTP) and long-term memory (see Section 10.4). Thus, these authors propose that "acetylcholine facilitates dendritic integration and NMDA spike generation in selected CA3 dendrites which could strengthen connections between specific CA3 neurons to form memory ensembles" (Humphries, et al., 2022, p. 69).

6.20.8: Chapter 10- Memory Types and Stages

Learning Objectives

1. Summarize main features of the case of Kim Peek and speculate on what might be taking place in his brain to account for his extraordinary memory
2. Compare and contrast explicit and implicit memory, identifying the features that define each.
3. Explain the stages and types of memory and the characteristics of each
4. Summarize the capacities of short-term memory and explain how working memory is used to process information in it
5. Discuss categories, prototypes and schemas, and their relationship to memory
6. Describe counterfactual thinking

Overview

We begin this supplementary section with an example of extraordinary memory in a person with autism. Memory which is so unusual inspires questions about what features of the brain of this individual make his memory so exceptional.

Memory and cognition are the two major interests of cognitive psychologists. The cognitive school was influenced in large part by the development of the electronic computer. Psychologists of this tradition conceptualize memory in terms of types, stages, and processes.

Two types of memory are explicit and implicit. Explicit memory is assessed using measures in which the individual being tested must consciously attempt to remember the information. Explicit memory includes semantic and episodic memory. Explicit memory tests include recall memory tests, recognition memory tests, and measures of relearning (also known as savings).

Implicit memory refers to the influence of experience on behavior, even if the individual is not aware of those influences. Implicit memory is made up of procedural memory, classical conditioning effects, and priming. Priming refers both to the activation of knowledge and to the influence of that activation on behavior. An important characteristic of implicit memories is that they are frequently formed and used automatically, without much effort or awareness on our part.

Stages of memory are sensory, short-term or working memory, and long-term memory. Sensory memory, including iconic and echoic memory, is a memory buffer that lasts only very briefly and then is forgotten, unless it is attended to and passed on for more processing in short-term memory.

Information that we turn our attention to may move into short-term memory (STM). STM is limited in both the length and the amount of information it can hold. Working memory is a set of memory procedures or operations that operates on the information in STM. Working memory's "central executive" directs the strategies used to keep information in STM, such as maintenance rehearsal, visualization, and chunking.

Long-term memory (LTM) is memory storage that can hold information for days, months, and years. The information that we want to remember in LTM must be encoded and stored, and then retrieved. Some strategies for improving LTM include elaborative encoding, relating information to the self, making use of the forgetting curve and the spacing effect, overlearning, and being aware of context- and state-dependent retrieval effects.

Memories that are stored in LTM are not isolated but rather are linked together into categories and schemas. Schemas are important in part because they help us encode and retrieve information by providing an organizational structure for it.

The ability to maintain information in LTM involves a gradual strengthening of the connections among the neurons in the brain, known as long-term potentiation (LTP). The hippocampus is important in explicit memory, the cerebellum is important in implicit memory, and the amygdala is important in emotional memory. A number of neurotransmitters are important in consolidation and memory. Evidence for the role of different brain structures in different types of memories comes in part from case studies of patients who suffer from amnesia.

Extraordinary Memory

Our memories allow us to do relatively simple things, such as remembering where we parked our car or the name of the current president of the United States, but also allow us to form complex memories, such as how to ride a bicycle or to write a computer program. Moreover, our memories define us as individuals—they are our experiences, our relationships, our successes, and our failures. Without our memories, we would not have a life.

At least for some things, our memory is very good (Bahrick, 2000). Once we learn a face, we can recognize that face many years later. We know the lyrics of many songs by heart, and we can give definitions for tens of thousands of words. Mitchell (2006) contacted participants 17 years after they had been briefly exposed to some line drawings in a lab and found that they still could identify the images significantly better than participants who had never seen them.

For some people, memory is truly amazing. Consider, for instance, the case of Kim Peek, who was the inspiration for the film *Rain Man* (Note 10.1 "Video Clip: Kim Peek"). Although Peek's IQ was only 87, significantly below the average of 100, it is estimated that he memorized more than 10,000 books in his lifetime (Wisconsin Medical Society, n.d.; "Kim Peek," 2004).

Figure 6.20.8.1: Kim Peek, the subject of the movie Rain Man, was believed to have memorized the contents of more than 10,000 books. He could read a book in about an hour. (click to see video) *You can view an interview with Kim Peek and see some of his amazing memory abilities at this link.*

In this chapter we will see how psychologists use behavioral responses (such as memory tests and reaction times) to draw inferences about what and how people remember. And we will see that although we have very good memory for some things, our memories are far from perfect (Schacter, 1996). The errors that we make are due to the fact that our memories are not simply recording devices that input, store, and retrieve the world around us. Rather, we actively process and interpret information as we remember and recollect it, and these cognitive processes influence what we remember and how we remember it. Because memories are constructed, not recorded, when we remember events we don't reproduce exact replicas of those events (Bartlett, 1932). People who read the words "*dream*, *sheets*, *rest*, *snore*, *blanket*, *tired*, and *bed*" and then are asked to remember the words often think that they saw the word *sleep* even though that word was not in the list (Roediger & McDermott, 1995). Our cognitive processes influence the accuracy and inaccuracy of our memories and our judgments, and they lead us to be vulnerable to the types of errors that eyewitnesses may make.

In other sections of this chapter we examine the biology of memory including brain areas involved in memory and changes in the brain when a memory is formed. But first we explore the types, processes, and stages of memory.

Memories as Types and Stages

As you can see in Table 10.10.1 "Memory Conceptualized in Terms of Types, Stages, and Processes", psychologists conceptualize memory in terms of *types*, in terms of *stages*, and in terms of *processes*. In this section we will consider the two types of memory,

explicit memory and *implicit memory*, and then the three major memory stages: *sensory*, *short-term*, and *long-term* (Atkinson & Shiffrin, 1968). Then, in the next section, we will consider the nature of long-term memory, with a particular emphasis on the three processes that are central to long-term memory: *encoding*, *storage*, and *retrieval*.

As types	Explicit memory
	Implicit memory
As stages	Sensory memory
	Short-term memory
	Long-term memory
As processes	Encoding
	Storage
	Retrieval

Table 10.10.1 Memory Conceptualized in Terms of Types, Stages, and Processes

Explicit Memory

When we assess memory by asking a person to consciously remember things, we are measuring *explicit memory*. **Explicit memory** refers to *knowledge or experiences that can be consciously remembered*. As you can see in Figure 10.4.2, "Types of Memory," there are two types of explicit memory: *episodic* and *semantic*. **Episodic memory** refers to memories of *the firsthand experiences that we have had* (i.e. memories of episodes in one's life; for example, recollections of our high school graduation day or of the fantastic dinner you had in New York last year). **Semantic memory** refers to *our knowledge of facts and concepts about the world* (e.g., that the absolute value of −90 is greater than the absolute value of 9 and that one definition of the word “affect” is “the experience of feeling or emotion”).

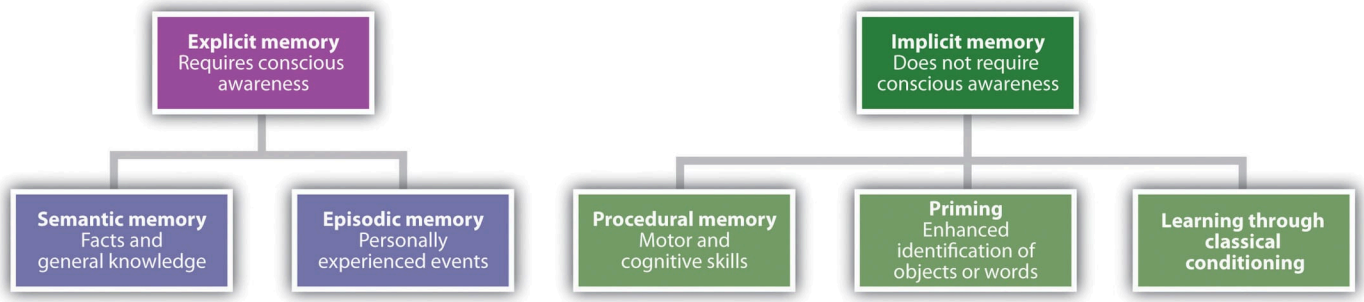

Figure 6.20.8.2: Types of Memory. Explicit memory is divided into semantic and episodic. Implicit memory includes procedural memory for motor and cognitive skills, priming, and classical conditioning.

Explicit memory is assessed using measures in which the individual being tested must consciously attempt to remember the information. A **recall memory test** is *a measure of explicit memory that involves bringing from memory information that has previously been remembered*. We rely on our recall memory when we take an essay test, because the test requires us to generate previously remembered information. A multiple-choice test is an example of a **recognition memory test**, *a measure of explicit memory that involves determining whether information has been seen or learned before*.

Your own experiences taking tests will probably lead you to agree with the scientific research finding that recall is more difficult than recognition. Recall, such as required on essay tests, involves two steps: first generating an answer and then determining whether it seems to be the correct one. Recognition, as on multiple-choice test, only involves determining which item from a list seems most correct (Haist, Shimamura, & Squire, 1992). Although they involve different processes, recall and recognition memory measures tend to be correlated. Students who do better on a multiple-choice exam will also, by and large, do better on an essay exam (Bridgeman & Morgan, 1996).

A third way of measuring memory is known as *relearning* (Nelson, 1985). Measures of **relearning (or savings)** *assess how much more quickly information is processed or learned when it is studied again after it has already been learned but then forgotten*. If you have taken some French courses in the past, for instance, you might have forgotten most of the vocabulary you learned. But if you were to work on your French again, you'd learn the vocabulary much faster the second time around. Relearning can be a more sensitive measure of memory than either recall or recognition because it allows assessing memory in terms of "how much" or "how fast" rather than simply "correct" versus "incorrect" responses. Relearning also allows us to measure memory for procedures like driving a car or playing a piano piece, as well as memory for facts and figures.

Implicit Memory

While explicit memory consists of the things that we can consciously report that we know, implicit memory refers to knowledge that we cannot consciously access. However, implicit memory is nevertheless exceedingly important to us because it has a direct effect on our behavior. **Implicit memory** refers to *the influence of experience on behavior, even if the individual is not aware of those influences*. As you can see in Figure 10.4.2, "Types of Memory," there are three general types of implicit memory: procedural (motor) memory, classical conditioning effects, and priming.

Procedural memory refers to *our often unexplainable knowledge of how to do things*. When we walk from one place to another, speak to another person in English, dial a cell phone, or play a video game, we are using procedural memory. Procedural memory allows us to perform complex tasks, even though we may not be able to explain to others how we do them. There is no way to tell someone how to ride a bicycle; a person has to learn by doing it. The idea of implicit memory helps explain how infants are able to learn. The ability to crawl, walk, and talk are procedures, and these motor skills are easily and efficiently developed while we are children despite the fact that as adults we have no conscious memory of having learned them.

A second type of implicit memory is **classical conditioning** effects, in which we learn, often without effort or awareness, to associate neutral stimuli (such as a sound or a light) with another stimulus (such as food), which creates a naturally occurring response, such as enjoyment or salivation. The memory for the association is demonstrated when the conditioned stimulus (the sound of the bell) begins to create the same response as the unconditioned stimulus (the food) did before the **learning of the predictive relation between bell and food, the CS and US.**

The final type of implicit memory is known as **priming**, or *changes in behavior as a result of experiences that have happened frequently or recently*. Priming refers both to the activation of knowledge (e.g., we can prime the concept of "kindness" by presenting people with words related to kindness) and to the influence of that activation on behavior (people who are primed with the concept of kindness may act more kindly).

One measure of the influence of priming on implicit memory is the *word fragment test*, in which a person is asked to fill in missing letters to make words. You can try this yourself: First, try to complete the following word fragments, but work on each one for only three or four seconds. Do any words pop into mind quickly?

_ i b _ a _ y

_ h _ s _ _ i _ n

_ o _ k

_ h _ i s _

Now read the following sentence carefully:

"He got his materials from the shelves, checked them out, and then left the building."

Then try again to make words out of the word fragments.

I think you might find that it is easier to complete fragments 1 and 3 as "library" and "book," respectively, after you read the sentence than it was before you read it. However, reading the sentence didn't really help you to complete fragments 2 and 4 as "physician" and "chaise." This difference in implicit memory probably occurred because as you read the sentence, the concept of "library" (and perhaps "book") was primed, even though they were never mentioned explicitly. Once a concept is primed it influences our behaviors, for instance, on word fragment tests.

Our everyday behaviors are influenced by priming in a wide variety of situations. Seeing an advertisement for cigarettes may

make us start smoking, seeing the flag of our home country may arouse our patriotism, and seeing a student from a rival school may arouse our competitive spirit. And these influences on our behaviors may occur without our being aware of them.

Stages of Memory: Sensory, Short-Term, and Long-Term Memory

Another way of understanding memory is to think about it in terms of stages that describe the length of time that information remains available to us. According to this approach (see Figure 10.4.3), information begins in *sensory memory*, moves to *short-term memory*, and eventually moves to *long-term memory*. But not all information makes it through all three stages; most of it is forgotten. Whether the information moves from shorter-duration memory into longer-duration memory or whether it is lost from memory entirely depends on how the information is attended to and processed.

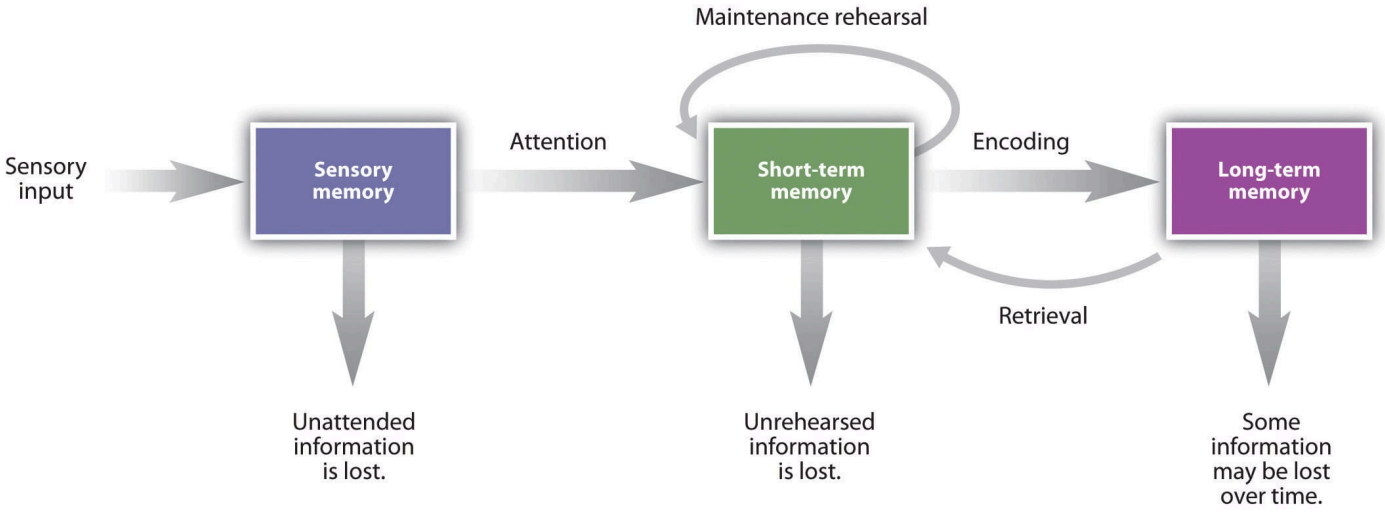

Figure 6.20.8.3: Memory Duration. Memory can characterized in terms of stages—the length of time that information remains available to us.

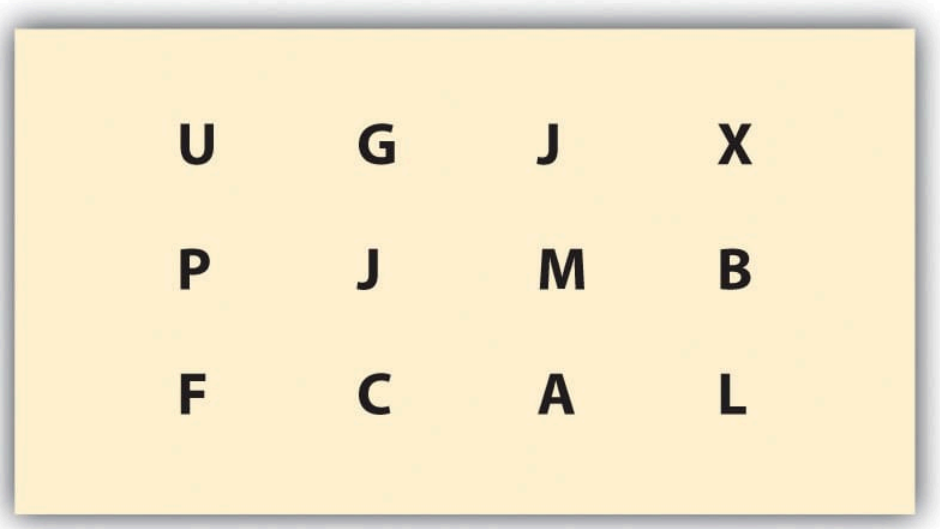

Source: Adapted from Atkinson, R. C., & Shiffrin, R. M. (1968). Human memory: A proposed system and its control processes. In K. Spence (Ed.), The psychology of learning and motivation (Vol. 2). Oxford, England: Academic Press.

Sensory Memory

Sensory memory refers to *the brief storage of sensory information*. Sensory memory is a memory buffer that lasts only very briefly and then, unless it is attended to and passed on for more processing, is forgotten. The purpose of sensory memory is to give the brain some time to process the incoming sensations, and to allow us to see the world as an unbroken stream of events rather than as individual pieces.

Visual sensory memory is known as **iconic memory**. Iconic memory was first studied by the psychologist George Sperling (1960). In his research, Sperling showed participants a display of letters in rows, similar to that shown in Figure 10.4.3, below. However, the display lasted only about 50 milliseconds (1/20 of a second). Then, Sperling gave his participants a recall test in which they were asked to name all the letters that they could remember. On average, the participants could remember only about one-quarter of the letters that they had seen.

Figure 6.20.8.4: Measuring Iconic Memory.

Adapted from Sperling, G. (1960). The information available in brief visual presentation. Psychological Monographs, 74(11), 1–29.

Sperling (1960) showed his participants displays such as this one for only 1/20th of a second. He found that when he cued the participants to report one of the three rows of letters, they could do it, even if the cue was given shortly after the display had been removed. The research demonstrated the existence of iconic memory.

Sperling reasoned that the participants had seen all the letters but could remember them only very briefly, making it impossible for them to report them all. To test this idea, in his next experiment he first showed the same letters, but then *after the display had been removed*, he signaled to the participants to report the letters from either the first, second, or third row. In this condition, the participants now reported almost all the letters in that row. This finding confirmed Sperling's hunch: Participants had access to all of the letters in their iconic memories, and if the task was short enough, they were able to report on the part of the display he asked them to. The "short enough" is the length of iconic memory, which turns out to be about 250 milliseconds (¼ of a second).

Auditory sensory memory is known as **echoic memory**. In contrast to iconic memories, which decay very rapidly, echoic memories can last as long as 4 seconds (Cowan, Lichty, & Grove, 1990). This is convenient as it allows you—among other things—to remember the words that you said at the beginning of a long sentence when you get to the end of it, and to take notes on your psychology professor's most recent statement even after he or she has finished saying it.

In some people iconic memory seems to last longer, a phenomenon known as *eidetic imagery* (or "photographic memory") in which people can report details of an image over long periods of time. These people, who often suffer from psychological disorders such as autism, claim that they can "see" an image long after it has been presented, and can often report accurately on that image. There is also some evidence for eidetic memories in hearing; some people report that their echoic memories persist for unusually long periods of time. The composer Wolfgang Amadeus Mozart may have possessed eidetic memory for music, because even when he was very young and had not yet had a great deal of musical training, he could listen to long compositions and then play them back almost perfectly (Solomon, 1995).

Short-Term Memory

Most of the information that gets into sensory memory is forgotten, but information that we turn our attention to, with the goal of remembering it, may pass into *short-term memory*. **Short-term memory (STM)** is *the place where small amounts of information can be temporarily kept for more than a few seconds but usually for less than one minute* (Baddeley, Vallar, & Shallice, 1990). Information in short-term memory is not stored permanently. Although often conceptualized as an intermediate stage between snesory memory and long-term memory, it is also used when we are working on a task, such as doing a long division problem, where the task requires that we keep some itmes of information in mind. For this reason, it is often called **working memory**.

Although it is called "memory," working memory is not a store of memory like STM but rather a set of memory procedures or operations. Imagine, for instance, that you are asked to participate in a task such as this one, which is a measure of working memory (Unsworth & Engle, 2007). Each of the following questions appears individually on a computer screen and then

disappears after you answer the question:

Is 10 × 2 – 5 = 15? (Answer YES OR NO) Then remember “S”
Is 12 ÷ 6 – 2 = 1? (Answer YES OR NO) Then remember “R”
Is 10 × 2 = 5? (Answer YES OR NO) Then remember “P”
Is 8 ÷ 2 – 1 = 1? (Answer YES OR NO) Then remember “T”
Is 6 × 2 – 1 = 8? (Answer YES OR NO) Then remember “U”
Is 2 × 3 – 3 = 0? (Answer YES OR NO) Then remember “Q”

To successfully accomplish the task, you have to answer each of the math problems correctly and at the same time remember the letter that follows the task. Then, after the six questions, you must list the letters that appeared in each of the trials in the correct order (in this case S, R, P, T, U, Q).

To accomplish this difficult task you need to use a variety of skills. You clearly need to use STM, as you must keep the letters in storage until you are asked to list them. But you also need a way to make the best use of your available attention and processing. For instance, you might decide to use a strategy of “repeat the letters twice, then quickly solve the next problem, and then repeat the letters twice again including the new one.” Keeping this strategy (or others like it) going is the role of working memory’s *central executive*—the part of working memory that directs attention and processing. The central executive will make use of whatever strategies seem to be best for the given task. For instance, the central executive will direct the rehearsal process, and at the same time direct the visual cortex to form an image of the list of letters in memory. You can see that although STM is involved, the processes that we use to operate on the material in memory are also critical.

Short-term memory is limited in both the length and the amount of information it can hold. Peterson and Peterson (1959) found that when people were asked to remember a list of three-letter strings and then were immediately asked to perform a distracting task (counting backward by threes), the material was quickly forgotten (see Figure 10.4.4), such that by 18 seconds it was virtually gone.

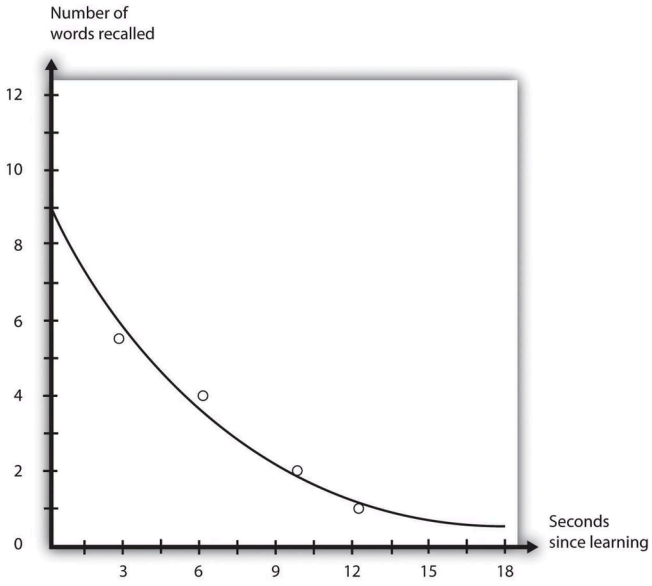

Figure 6.20.8.5: . STM Decay. Peterson and Peterson (1959) found that information that was not rehearsed decayed quickly from memory. Source: Adapted from Peterson, L., & Peterson, M. J. (1959). Short-term retention of individual verbal items. Journal of Experimental Psychology, 58(3), 193–198.

One way to prevent the decay of information from short-term memory is to use working memory to rehearse it. **Maintenance rehearsal** is *the process of repeating information mentally or out loud with the goal of keeping it in memory*. We engage in maintenance rehearsal to keep a something that we want to remember (e.g., a person’s name, e-mail address, or phone number) in mind long enough to write it down, use it, or potentially transfer it to long-term memory.

If we continue to rehearse information it will stay in STM until we stop rehearsing it, but there is also a capacity limit to STM. Try reading each of the following rows of numbers, one row at a time, at a rate of about one number each second. Then when you have finished each row, close your eyes and write down as many of the numbers as you can remember.

019

3586

10295

861059

1029384

75674834

657874104

6550423897

If you are like the average person, you will have found that on this test of working memory, known as a *digit span test*, you did pretty well up to about the fourth line, and then you started having trouble. I bet you missed some of the numbers in the last three rows, and did pretty poorly on the last one.

The digit span of most adults is between five and nine digits, with an average of about seven. The cognitive psychologist George Miller (1956) referred to "seven plus or minus two" pieces of information as the "magic number" in short-term memory. But if we can only hold a maximum of about nine digits in short-term memory, then how can we remember larger amounts of information than this? For instance, how can we ever remember a 10-digit phone number long enough to dial it?

One way we are able to expand our ability to remember things in STM is by using a memory technique called *chunking*. **Chunking** is *the process of organizing information into smaller groupings (chunks), thereby increasing the number of items that can be held in STM*. For instance, try to remember this string of 12 letters:

XOFCBANNCVTM

You probably won't do that well because the number of letters is more than the magic number of seven.

Now try again with this one:

MTVCNNABCFOX

Would it help you if I pointed out that the material in this string could be chunked into four sets of three letters each? I think it would, because then rather than remembering 12 letters, you would only have to remember the names of four television stations. In this case, chunking changes the number of items you have to remember from 12 to only four. This works because you are already very familiar with the letter triplets that are used to refer to these well known TV networks. That knowledge which is already fixed in your memory can be brought to the task at hand to make the memory task easier.

Experts rely on chunking to help them process complex information. Herbert Simon and William Chase (1973) showed chess masters and chess novices various positions of pieces on a chessboard for a few seconds each. The experts did a lot better than the novices in remembering the positions because they were able to see the "big picture." They didn't have to remember the position of each of the pieces individually, but chunked the pieces into several larger layouts. But when the researchers showed both groups random chess positions—positions that would be very unlikely to occur in real games—both groups did equally poorly, because in this situation the experts lost their ability to organize the layouts (see Figure 10.4.6. "Possible and Impossible Chess Positions," below). The same occurs for basketball. Basketball players recall actual basketball positions much better than do nonplayers, but only when the positions make sense in terms of what is happening on the court, or what is likely to happen in the near future, and thus can be chunked into bigger units (Didierjean & Marmèche, 2005).

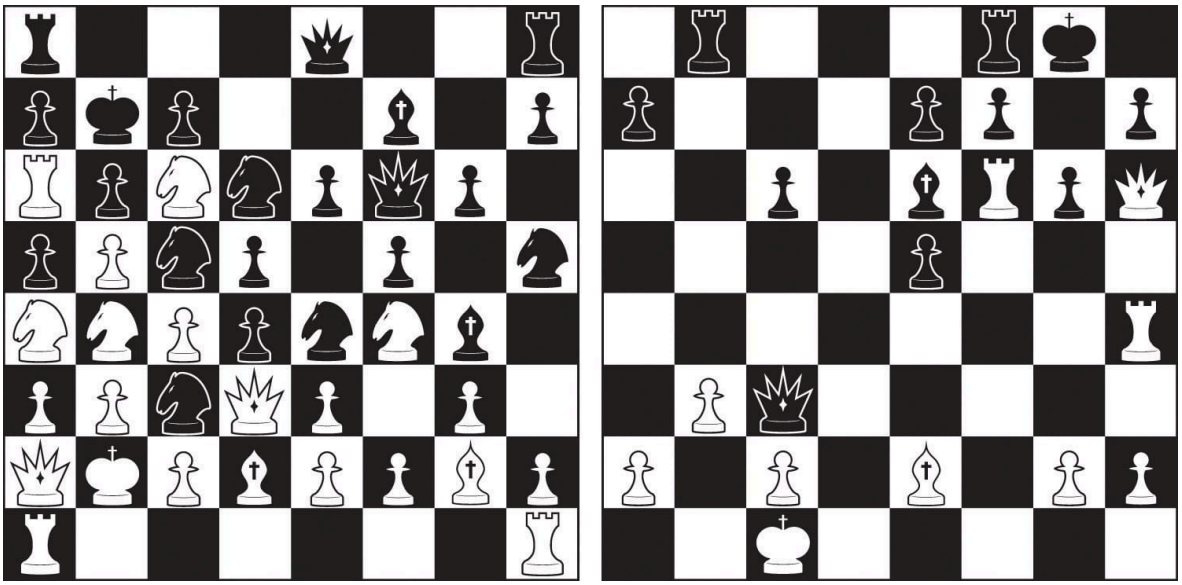

Figure 6.20.8.6: Possible and Impossible Chess Positions. Experience matters: Experienced chess players are able to recall the positions of the game on the right much better than are those who are chess novices. But the experts do no better than the novices in remembering the positions on the left, which cannot occur in a real game.

Long-Term Memory

If information makes it past short term-memory it may enter **long-term memory (LTM)**, *memory storage that can hold information for days, months, and years*. The capacity of long-term memory is large, and there is no known limit to what we can remember (Wang, Liu, & Wang, 2003). Although we may forget at least some information after we learn it, other things will stay with us forever. In the next section we will discuss the principles of long-term memory.

KEY TAKEAWAYS

- Memory refers to the ability to store and retrieve information over time.
- For some things our memory is very good, but our active cognitive processing of information assures that memory is never an exact replica of what we have experienced.
- Explicit memory refers to experiences that can be intentionally and consciously remembered, and it is measured using recall, recognition, and relearning. Explicit memory includes episodic and semantic memories.
- Measures of relearning (also known as savings) assess how much more quickly information is learned when it is studied again after it has already been learned but then forgotten.
- Implicit memory refers to the influence of experience on behavior, even if the individual is not aware of those influences. The three types of implicit memory are procedural memory, classical conditioning, and priming.
- Information processing begins in sensory memory, moves to short-term memory, and eventually moves to long-term memory.
- Maintenance rehearsal and chunking are used to keep information in short-term memory.
- The capacity of long-term memory is large, and there is no known limit to what we can remember.

EXERCISES AND CRITICAL THINKING

1. List some situations in which sensory memory is useful for you. What do you think your experience of the stimuli would be like if you had no sensory memory?
2. Describe a situation in which you need to use working memory to perform a task or solve a problem. How do your working memory skills help you?

The Structure of LTM: Categories, Prototypes, and Schemas

Memories that are stored in LTM are not isolated but rather are linked together into **categories**—*networks of associated memories that have features in common with each other*. Forming categories, and using categories to guide behavior, is a fundamental part of human nature. Associated concepts within a category are connected through *spreading activation*, which occurs when activating one element of a category activates other associated elements. For instance, because tools are associated in a category, reminding people of the word "screwdriver" will help them remember the word "wrench." And, when people have learned lists of words that come from different categories, they do not recall the information haphazardly. If they have just remembered the word "wrench," they are more likely to remember the word "screwdriver" next than they are to remember the word "dahlia," because the words are organized in memory by category and because "dahlia" is activated by spreading activation from "wrench" (Srull & Wyer, 1989).

Some categories have *defining features* that must be true of all members of the category. For instance, all members of the category "triangles" have three sides, and all members of the category "birds" lay eggs. But most categories are not so well-defined; the members of the category share some common features, but it is impossible to define which are or are not members of the category. For instance, there is no clear definition of the category "tool." Some examples of the category, such as a hammer and a wrench, are clearly and easily identified as category members, whereas other members are not so obvious. Is an ironing board a tool? What about a car?

Members of categories (even those with defining features) can be compared to the category **prototype**, which is *the member of the category that is most average or typical of the category*. Some category members are more prototypical of, or similar to, the category than others. For instance, some category members (robins and sparrows) are highly prototypical of the category "birds," whereas other category members (penguins and ostriches) are less prototypical. We retrieve information that is prototypical of a category faster than we retrieve information that is less prototypical (Rosch, 1975).

Mental categories are sometimes referred to as **schemas**—*patterns of knowledge in long-term memory that help us organize information*. We have schemas about objects (that a triangle has three sides and may take on different angles), about people (that Sam is friendly, likes to golf, and always wears sandals), about events (the particular steps involved in ordering a meal at a restaurant), and about social groups (we call these group schemas *stereotypes*).

Schemas are important in part because they help us remember new information by providing an organizational structure for it. Read the following paragraph (Bransford & Johnson, 1972) and then try to write down everything you can remember.

> The procedure is actually quite simple. First you arrange things into different groups. Of course, one pile may be sufficient depending on how much there is to do. If you have to go somewhere else due to lack of facilities, that is the next step; otherwise you are pretty well set. It is important not to overdo things. That is, it is better to do too few things at once than too many. In the short run this may not seem important, but complications can easily arise. A mistake can be expensive as well. At first the whole procedure will seem complicated. Soon, however, it will become just another facet of life. It is difficult to foresee any end to the necessity for this task in the immediate future, but then one never can tell. After the procedure is completed, one arranges the materials into different groups again. Then they can be put into their appropriate places. Eventually they will be used once more and the whole cycle will then have to be repeated. However, that is part of life.

It turns out that people's memory for this information is quite poor, unless they have been told ahead of time that the information describes "doing the laundry," in which case their memory for the material is much better. This demonstration of the role of schemas in memory shows how our existing knowledge can help us organize new information, and how this organization can improve encoding, storage, and retrieval.

Counterfactual Thinking

In addition to influencing our judgments about ourselves and others, the ease with which we can retrieve potential experiences from memory can have an important effect on our own emotions. If we can easily imagine an outcome that is better than what actually happened, then we may experience sadness and disappointment; on the other hand, if we can easily imagine that a result might have been worse than what actually happened, we may be more likely to experience happiness and satisfaction. *The tendency to think about and experience events according to "what might have been"* is known as **counterfactual thinking** (Kahneman & Miller, 1986; Roese, 2005).

Imagine, for instance, that you were participating in an important contest, and you won the silver (second-place) medal. How would you feel? Certainly you would be happy that you won the silver medal, but wouldn't you also be thinking about what might have happened if you had been just a little bit better—you might have won the gold medal! On the other hand, how might you feel if you won the bronze (third-place) medal? If you were thinking about the *counterfactuals* (the "what might have beens") perhaps the idea of not getting any medal at all would have been highly accessible; you'd be happy that you got the medal that you did get, rather than coming in fourth.

Figure 6.20.8.7: Counterfactual Thinking. Does the bronze medalist look happier to you than the silver medalist? Medvec, V. H., Madey, S. F., & Gilovich, T. (1995). When less is more: Counterfactual thinking and satisfaction among Olympic medalists. Journal of Personality & Social Psychology, 69(4), 603–610. found that, on average, bronze medalists were happier. Source: Photo courtesy of kinnigurl, *http://commons.wikimedia.org/wiki/ File:2010_Winter_Olympic_Men%27s_Snowboard_ Cross_medalists.jpg*.

Tom Gilovich and his colleagues (Medvec, Madey, & Gilovich, 1995) investigated this idea by videotaping the responses of athletes who won medals in the 1992 Summer Olympic Games. They videotaped the athletes both as they learned that they had won a silver or a bronze medal and again as they were awarded the medal. Then the researchers showed these videos, without any sound, to raters who did not know which medal which athlete had won. The raters were asked to indicate how they thought the athlete was feeling, using a range of feelings from "agony" to "ecstasy." The results showed that the bronze medalists were, on average, rated as happier than were the silver medalists. In a follow-up study, raters watched interviews with many of these same athletes as they talked about their performance. The raters indicated what we would expect on the basis of counterfactual thinking—the silver medalists talked about their disappointments in having finished second rather than first, whereas the bronze medalists focused on how happy they were to have finished third rather than fourth.

You might have experienced counterfactual thinking in other situations. Once I was driving across country, and my car was having some engine trouble. I really wanted to make it home when I got near the end of my journey; I would have been extremely disappointed if the car broke down only a few miles from my home. Perhaps you have noticed that once you get close to finishing something, you feel like you really need to get it done. Counterfactual thinking has even been observed in juries. Jurors who were asked to award monetary damages to others who had been in an accident offered them substantially more in compensation if they barely avoided injury than they offered if the accident seemed inevitable (Miller, Turnbull, & McFarland, 1988).

6.20.9: Chapter 10- The Psychology of Memory Encoding, Storage, and Retrieval

Memory (Encoding, Storage, Retrieval)

By Kathleen B. McDermott and Henry L. Roediger III, Washington University in St. Louis

(Adapted and Modified by Kenneth A. Koenigshofer, PhD., Chaffey College)

“Memory” is a single term that reflects a number of different abilities: holding information briefly while working with it (working memory), remembering episodes of one’s life (episodic memory), and our general knowledge of facts of the world (semantic memory), among other types. Remembering episodes involves three processes: encoding information (learning it, by perceiving it and relating it to past knowledge), storing it (maintaining it over time), and then retrieving it (accessing the information when needed). Failures can occur at any stage, leading to forgetting or to having false memories. The key to improving one’s memory is to improve processes of encoding and to use techniques that guarantee effective retrieval. Good encoding techniques include relating new information to what one already knows, forming mental images, and creating associations among information that needs to be remembered. The key to good retrieval is developing effective cues that will lead the rememberer back to the encoded information. Classic mnemonic systems, known since the time of the ancient Greeks and still used by some today, can greatly improve one’s memory abilities.

Learning Objectives

1. Define and note differences between the following forms of memory: working memory, episodic memory, semantic memory, collective memory.
2. Describe the three stages in the process of learning and remembering.
3. Describe strategies that can be used to enhance the original learning or encoding of information.
4. Describe strategies that can improve the process of retrieval.
5. Describe why the classic mnemonic device, the method of loci, works so well.

Introduction

In 2013, Simon Reinhard sat in front of 60 people in a room at Washington University, where he memorized an increasingly long series of digits. On the first round, a computer generated 10 random digits—6 1 9 4 8 5 6 3 7 1—on a screen for 10 seconds. After the series disappeared, Simon typed them into his computer. His recollection was perfect. In the next phase, 20 digits appeared on the screen for 20 seconds. Again, Simon got them all correct. No one in the audience (mostly professors, graduate students, and undergraduate students) could recall the 20 digits perfectly. Then came 30 digits, studied for 30 seconds; once again, Simon didn’t misplace even a single digit. For a final trial, 50 digits appeared on the screen for 50 seconds, and again, Simon got them all right. In fact, Simon would have been happy to keep going. His record in this task—called “forward digit span”—is 240 digits!

Figure 6.20.9.1: In some ways memory is like file drawers where you store mental information. Memory is also a series of processes: how does that information get filed to begin with and how does it get retrieved when needed? [Image: M Cruz, https://goo.gl/DhOMgp, CC BY-SA 4.0, https://goo.gl/SWjq94]

When most of us witness a performance like that of Simon Reinhard, we think one of two things: First, maybe he's cheating somehow. (No, he is not.) Second, Simon must have abilities more advanced than the rest of humankind. After all, psychologists established many years ago that the normal memory span for adults is about 7 digits, with some of us able to recall a few more and others a few less (Miller, 1956). That is why the first phone numbers were limited to 7 digits—psychologists determined that many errors occurred (costing the phone company money) when the number was increased to even 8 digits. But in normal testing, no one gets 50 digits correct in a row, much less 240. So, does Simon Reinhard simply have a photographic memory? He does not. Instead, Simon has taught himself simple strategies for remembering that have greatly increased his capacity for remembering virtually any type of material—digits, words, faces and names, poetry, historical dates, and so on. Twelve years earlier, before he started training his memory abilities, he had a digit span of 7, just like most of us. Simon has been training his abilities for about 10 years as of this writing, and has risen to be in the top two of "memory athletes." In 2012, he came in second place in the World Memory Championships (composed of 11 tasks), held in London. He currently ranks second in the world, behind another German competitor, Johannes Mallow. In this module, we reveal what psychologists and others have learned about memory, and we also explain the general principles by which you can improve your own memory for factual material.

Varieties of Memory

Figure 6.20.9.2: To be a good chess player you have to learn to increase working memory so you can plan ahead for several offensive moves while simultaneously anticipating - through use of memory - how the other player could counter each of your planned moves. [Image: karpidis, https://goo.gl/EhzMKM, CC BY-SA 2.0, https://goo.gl/jSSrcO]

For most of us, remembering digits relies on *short-term memory,* or *working memory*—the ability to hold information in our minds for a brief time and work with it (e.g., multiplying 24 x 17 without using paper would rely on working memory). Another type of memory is **episodic memory**—the ability to remember the episodes of our lives. If you were given the task of recalling everything you did 2 days ago, that would be a test of episodic memory; you would be required to mentally travel through the day in your mind and note the main events. **Semantic memory** is our storehouse of more-or-less permanent knowledge, such as the meanings of words in a language (e.g., the meaning of "parasol") and the huge collection of facts about the world (e.g., there are 196 countries in the world, and 206 bones in your body). *Collective memory* refers to the kind of memory that people in a group share (whether family, community, schoolmates, or citizens of a state or a country). For example, residents of small towns often strongly identify with those towns, remembering the local customs and historical events in a unique way. That is, the community's collective memory passes stories and recollections between neighbors and to future generations, forming a memory system unto itself.

Psychologists continue to debate the classification of types of memory, as well as which types rely on others (Tulving, 2007), but for this module we will focus on episodic memory. Episodic memory is usually what people think of when they hear the word "memory." For example, when people say that an older relative is "losing her memory" due to Alzheimer's disease, the type of memory-loss they are referring to is the inability to recall events, or episodic memory. (Semantic memory is actually preserved in early-stage Alzheimer's disease.) Although remembering specific events that have happened over the course of one's entire life (e.g., your experiences in sixth grade) can be referred to as **autobiographical memory**, we will focus primarily on the episodic memories of more recent events.

Three Stages of the Learning/Memory Process

Psychologists distinguish between three necessary stages in the learning and memory process: **encoding**, **storage**, and **retrieval** (Melton, 1963). Encoding is defined as the initial learning of information; storage refers to maintaining information over time; retrieval is the ability to access information when you need it. If you meet someone for the first time at a party, you need to encode her name (Lyn Goff) while you associate her name with her face. Then you need to maintain the information over time. If you see her a week later, you need to recognize her face and have it serve as a cue to retrieve her name. Any successful act of remembering requires that all three stages be intact. However, two types of errors can also occur. Forgetting is one type: you see the person you met at the party and you cannot recall her name. The other error is misremembering (false recall or false recognition): you see someone who looks like Lyn Goff and call the person by that name (false recognition of the face). Or, you might see the real Lyn Goff, recognize her face, but then call her by the name of another woman you met at the party (misrecall of her name).

Whenever forgetting or misremembering occurs, we can ask, at which stage in the learning/memory process was there a failure?—though it is often difficult to answer this question with precision. One reason for this inaccuracy is that the three stages are not as discrete as our description implies. Rather, all three stages depend on one another. How we encode information determines how it will be stored and what cues will be effective when we try to retrieve it. And too, the act of retrieval itself also changes the way information is subsequently remembered, usually aiding later recall of the retrieved information. The central point for now is that the three stages—encoding, storage, and retrieval—affect one another, and are inextricably bound together.

Encoding

Encoding refers to the initial experience of perceiving and learning information. Psychologists often study recall by having participants study a list of pictures or words. Encoding in these situations is fairly straightforward. However, "real life" encoding is much more challenging. When you walk across campus, for example, you encounter countless sights and sounds—friends passing by, people playing Frisbee, music in the air. The physical and mental environments are much too rich for you to encode all the happenings around you or the internal thoughts you have in response to them. So, an important first principle of encoding is that it is selective: we attend to some events in our environment and we ignore others. A second point about encoding is that it is prolific; we are always encoding the events of our lives—attending to the world, trying to understand it. Normally this presents no problem, as our days are filled with routine occurrences, so we don't need to pay attention to everything. But if something does happen that seems strange—during your daily walk across campus, you see a giraffe—then we pay close attention and try to understand why we are seeing what we are seeing.

Figure 6.20.9.3: A giraffe in the context of a zoo or its natural habitat may register as nothing more than ordinary, but put it in another setting - in the middle of a campus or a busy city - and its level of distinctiveness increases dramatically. Distinctiveness is a key attribute to remembering events. [Image: Colin J Babb, https://goo.gl/Cci2yl, CC BY-SA 2.0, https://goo.gl/jSSrcO]

Right after your typical walk across campus (one without the appearance of a giraffe), you would be able to remember the events reasonably well if you were asked. You could say whom you bumped into, what song was playing from a radio, and so on. However, suppose someone asked you to recall the same walk a month later. You wouldn't stand a chance. You would likely be able to recount the basics of a typical walk across campus, but not the precise details of that particular walk. Yet, if you had seen a giraffe during that walk, the event would have been fixed in your mind for a long time, probably for the rest of your life. You would tell your friends about it, and, on later occasions when you saw a giraffe, you might be reminded of the day you saw one on campus. Psychologists have long pinpointed **distinctiveness**—having an event stand out as quite different from a background of similar events—as a key to remembering events (Hunt, 2003).

In addition, when vivid memories are tinged with strong emotional content, they often seem to leave a permanent mark on us. Public tragedies, such as terrorist attacks, often create vivid memories in those who witnessed them. But even those of us not directly involved in such events may have vivid memories of them, including memories of first hearing about them. For example, many people are able to recall their exact physical location when they first learned about the assassination or accidental death of a national figure. The term **flashbulb memory** was originally coined by Brown and Kulik (1977) to describe this sort of vivid memory of finding out an important piece of news. The name refers to how some memories seem to be captured in the mind like

a flash photograph; because of the distinctiveness and emotionality of the news, they seem to become permanently etched in the mind with exceptional clarity compared to other memories.

Take a moment and think back on your own life. Is there a particular memory that seems sharper than others? A memory where you can recall unusual details, like the colors of mundane things around you, or the exact positions of surrounding objects? Although people have great confidence in flashbulb memories like these, the truth is, our objective accuracy with them is far from perfect (Talarico & Rubin, 2003). That is, even though people may have great confidence in what they recall, their memories are not as accurate (e.g., what the actual colors were; where objects were truly placed) as they tend to imagine. Nonetheless, all other things being equal, distinctive and emotional events are well-remembered.

Details do not leap perfectly from the world into a person's mind. We might say that we went to a party and remember it, but what we remember is (at best) what we encoded. As noted above, the process of encoding is selective, and in complex situations, relatively few of many possible details are noticed and encoded. The process of encoding always involves **recoding**—that is, taking the information from the form it is delivered to us and then converting it in a way that we can make sense of it. For example, you might try to remember the colors of a rainbow by using the acronym ROY G BIV (red, orange, yellow, green, blue, indigo, violet). The process of recoding the colors into a name can help us to remember. However, recoding can also introduce errors—when we accidentally add information during encoding, then remember that *new* material as if it had been part of the actual experience (as discussed below).

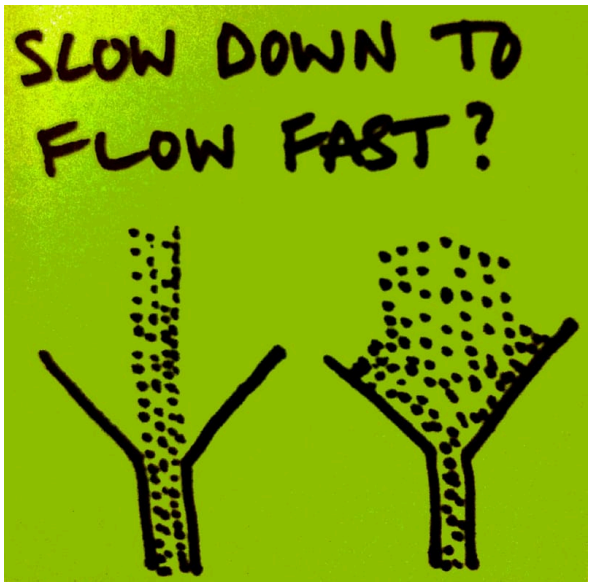

Figure 6.20.9.4: Although it requires more effort, using images and associations can improve the process of recoding. [Image: psd, https://goo.gl/9xjcDe, CC BY 2.0, https://goo.gl/9uSnqN]

Psychologists have studied many recoding strategies that can be used during study to improve retention. First, research advises that, as we study, we should think of the meaning of the events (Craik & Lockhart, 1972), and we should try to relate new events to information we already know. This helps us form associations that we can use to retrieve information later. Second, imagining events also makes them more memorable; creating vivid images out of information (even verbal information) can greatly improve later recall (Bower & Reitman, 1972). Creating imagery is part of the technique Simon Reinhard uses to remember huge numbers of digits, but we can all use images to encode information more effectively. The basic concept behind good encoding strategies is to form distinctive memories (ones that stand out), and to form links or associations among memories to help later retrieval (Hunt & McDaniel, 1993). Using study strategies such as the ones described here is challenging, but the effort is well worth the benefits of enhanced learning and retention.

We emphasized earlier that encoding is selective: people cannot encode all information they are exposed to. However, recoding can add information that was not even seen or heard during the initial encoding phase. Several of the recoding processes, like forming associations between memories, can happen without our awareness. This is one reason people can sometimes remember events that did not actually happen—because during the process of recoding, details got added. One common way of inducing false memories in the laboratory employs a word-list technique (Deese, 1959; Roediger & McDermott, 1995). Participants hear lists of 15 words, like *door, glass, pane, shade, ledge, sill, house, open, curtain, frame, view, breeze, sash, screen,* and *shutter.* Later, participants are given a test in which they are shown a list of words and asked to pick out the ones they'd heard earlier. This second list contains some words from the first list (e.g., *door, pane, frame*) and some words not from the list (e.g., *arm, phone,*

bottle). In this example, one of the words on the test is *window*, which—importantly—does not appear in the first list, but which is related to other words in that list. When subjects were tested, they were reasonably accurate with the studied words (*door*, etc.), recognizing them 72% of the time. However, when *window* was on the test, they falsely recognized it as having been on the list 84% of the time (Stadler, Roediger, & McDermott, 1999). The same thing happened with many other lists the authors used. This phenomenon is referred to as the DRM (for Deese-Roediger-McDermott) effect. One explanation for such results is that, while students listened to items in the list, the words triggered the students to think about *window*, even though *window* was never presented. In this way, people seem to encode events that are not actually part of their experience.

Because humans are creative, we are always going beyond the information we are given: we automatically make associations and infer from them what is happening. But, as with the word association mix-up above, sometimes we make false memories from our inferences—remembering the inferences themselves as if they were actual experiences. To illustrate this, Brewer (1977) gave people sentences to remember that were designed to elicit *pragmatic inferences*. Inferences, in general, refer to instances when something is not explicitly stated, but we are still able to guess the undisclosed intention. For example, if your friend told you that she didn't want to go out to eat, you may infer that she doesn't have the money to go out, or that she's too tired. With *pragmatic* inferences, there is usually *one* particular inference you're likely to make. Consider the statement Brewer (1977) gave her participants: "The karate champion hit the cinder block." After hearing or seeing this sentence, participants who were given a memory test tended to remember the statement as having been, "The karate champion *broke* the cinder block." This remembered statement is not necessarily a *logical* inference (i.e., it is perfectly reasonable that a karate champion could hit a cinder block without breaking it). Nevertheless, the *pragmatic* conclusion from hearing such a sentence is that the block was likely broken. The participants remembered this inference they made while hearing the sentence in place of the actual words that were in the sentence (see also McDermott & Chan, 2006).

Encoding—the initial registration of information—is essential in the learning and memory process. Unless an event is encoded in some fashion, it will not be successfully remembered later. However, just because an event is encoded (even if it is encoded well), there's no guarantee that it will be remembered later.

Storage

Figure 6.20.9.5: Memory traces, or engrams, are NOT perfectly preserved recordings of past experiences. The traces are combined with current knowledge to reconstruct what we think happened in the past. [Simon Bierdwald, https://goo.gl/JDhdCE, CC BY-NC-SA 2.0, https://goo.gl/jSSrcO]

Every experience we have changes our brains. That may seem like a bold, even strange, claim at first, but it's true. We encode each of our experiences within the structures of the nervous system, making new impressions in the process—and each of those impressions involves changes in the brain. Psychologists (and neurobiologists) say that experiences leave **memory traces**, or **engrams** (the two terms are synonyms). Memories have to be stored somewhere in the brain, so in order to do so, the brain biochemically alters itself and its neural tissue. Just like you might write yourself a note to remind you of something, the brain "writes" a memory trace, changing its own physical composition to do so. The basic idea is that events (occurrences in our environment) create engrams through a process of **consolidation**: the neural changes that occur after learning to create the memory trace of an experience. Although neurobiologists are concerned with exactly what neural processes change when

memories are created, for psychologists, the term *memory trace* simply refers to the physical change in the nervous system (whatever that may be, exactly) that represents our experience.

Although the concept of engram or memory trace is extremely useful, we shouldn't take the term too literally. It is important to understand that memory traces are not perfect little packets of information that lie dormant in the brain, waiting to be called forward to give an accurate report of past experience. Memory traces are not like video or audio recordings, capturing experience with great accuracy; as discussed earlier, we often have errors in our memory, which would not exist if memory traces were perfect packets of information. Thus, it is wrong to think that remembering involves simply "reading out" a faithful record of past experience. Rather, when we remember past events, we reconstruct them with the aid of our memory traces—but also with our current belief of what happened. For example, if you were trying to recall for the police who started a fight at a bar, you may not have a memory trace of who pushed whom first. However, let's say you remember that one of the guys held the door open for you. When thinking back to the start of the fight, this knowledge (of how one guy was friendly to you) may unconsciously influence your memory of what happened in favor of the nice guy. Thus, memory is a construction of what you actually recall and what you believe happened. In a phrase, remembering is reconstructive (we reconstruct our past with the aid of memory traces) not reproductive (a perfect reproduction or recreation of the past).

Psychologists refer to the time between learning and testing as the retention interval. Memories can consolidate during that time, aiding retention. However, experiences can also occur that undermine the memory. For example, think of what you had for lunch yesterday—a pretty easy task. However, if you had to recall what you had for lunch 17 days ago, you may well fail (assuming you don't eat the same thing every day). The 16 lunches you've had since that one have created **retroactive interference**. Retroactive interference refers to new activities (i.e., the subsequent lunches) during the retention interval (i.e., the time between the lunch 17 days ago and now) that interfere with retrieving the specific, older memory (i.e., the lunch details from 17 days ago). But just as newer things can interfere with remembering older things, so can the opposite happen. *Proactive interference* is when past memories interfere with the encoding of new ones. For example, if you have ever studied a second language, often times the grammar and vocabulary of your native language will pop into your head, impairing your fluency in the foreign language.

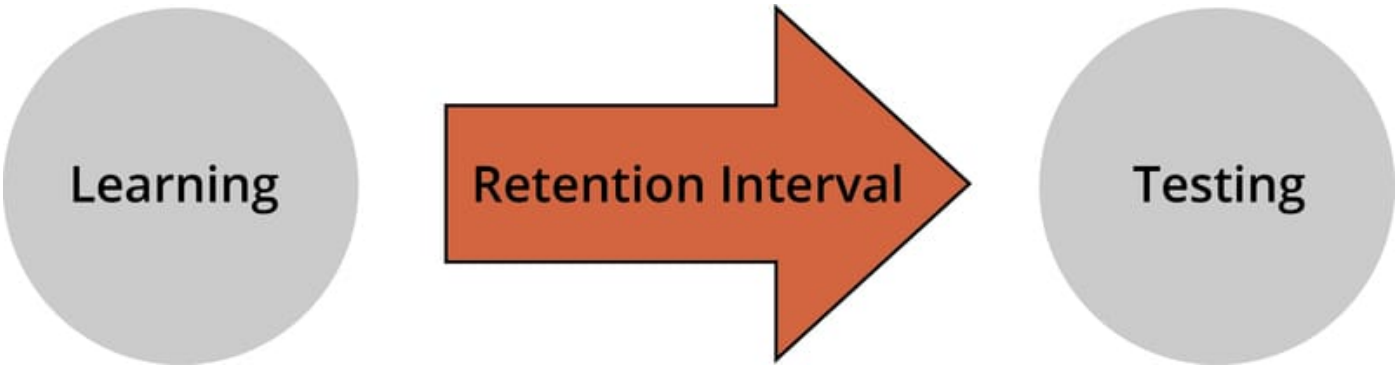

Figure 6.20.9.6:

Retroactive interference is one of the main causes of forgetting (McGeoch, 1932). In the module *Eyewitness Testimony and Memory Biases* http://noba.to/uy49tm37 Elizabeth Loftus describes her fascinating work on eyewitness memory, in which she shows how memory for an event can be changed via misinformation supplied during the retention interval. For example, if you witnessed a car crash but subsequently heard people describing it from their own perspective, this new information may interfere with or disrupt your own personal recollection of the crash. In fact, you may even come to remember the event happening exactly as the others described it! This **misinformation effect** in eyewitness memory represents a type of retroactive interference that can occur during the retention interval (see Loftus [2005] for a review). Of course, if correct information is given during the retention interval, the witness's memory will usually be improved.

Although interference may arise between the occurrence of an event and the attempt to recall it, *the effect itself is always expressed when we retrieve memories*, the topic to which we turn next.

Retrieval

Endel Tulving argued that "the key process in memory is retrieval" (1991, p. 91). Why should retrieval be given more prominence than encoding or storage? For one thing, if information were encoded and stored but could not be retrieved, it would be useless.

As discussed previously in this module, we encode and store thousands of events—conversations, sights and sounds—every day, creating memory traces. However, we later access only a tiny portion of what we've taken in. Most of our memories will never be used—in the sense of being brought back to mind, consciously. This fact seems so obvious that we rarely reflect on it. All those events that happened to you in the fourth grade that seemed so important then? Now, many years later, you would struggle to remember even a few. You may wonder if the traces of those memories still exist in some latent form. Unfortunately, with currently available methods, it is impossible to know.

Psychologists distinguish information that is available in memory from that which is accessible (Tulving & Pearlstone, 1966). *Available* information is the information that is stored in memory—but precisely how much and what types are stored cannot be known. That is, all we can know is what information we can retrieve—*accessible* information. The assumption is that accessible information represents only a tiny slice of the information available in our brains. Most of us have had the experience of trying to remember some fact or event, giving up, and then—all of a sudden!—it comes to us at a later time, even after we've stopped trying to remember it. Similarly, we all know the experience of failing to recall a fact, but then, if we are given several choices (as in a multiple-choice test), we are easily able to recognize it.

Figure 6.20.9.7: We can't know the entirety of what is in our memory, but only that portion we can actually retrieve. Something that cannot be retrieved now and which is seemingly gone from memory may, with different cues applied, reemerge. [Image: Ores2k, https://goo.gl/1du8Qe, CC BY-NC-SA 2.0, https://goo.gl/jSSrcO]

What factors determine what information can be retrieved from memory? One critical factor is the type of hints, or *cues*, in the environment. You may hear a song on the radio that suddenly evokes memories of an earlier time in your life, even if you were not trying to remember it when the song came on. Nevertheless, the song is closely associated with that time, so it brings the experience to mind.

The general principle that underlies the effectiveness of retrieval cues is the **encoding specificity principle** (Tulving & Thomson, 1973): when people encode information, they do so in specific ways. For example, take the song on the radio: perhaps you heard it while you were at a terrific party, having a great, philosophical conversation with a friend. Thus, the song became part of that whole complex experience. Years later, even though you haven't thought about that party in ages, when you hear the song on the radio, the whole experience rushes back to you. In general, the encoding specificity principle states that, to the extent a retrieval cue (the song) matches or overlaps the memory trace of an experience (the party, the conversation), it will be effective in evoking the memory. A classic experiment on the encoding specificity principle had participants memorize a set of words in a unique setting. Later, the participants were tested on the word sets, either in the same location they learned the words or a different one. As a result of encoding specificity, the students who took the test in the same place they learned the words were actually able to recall more words (Godden & Baddeley, 1975) than the students who took the test in a new setting.

One caution with this principle, though, is that, for the cue to work, it can't match too many other experiences (Nairne, 2002; Watkins, 1975). Consider a lab experiment. Suppose you study 100 items; 99 are words, and one is a picture—of a penguin, item 50 in the list. Afterwards, the cue "recall the picture" would evoke "penguin" perfectly. No one would miss it. However, if the *word* "penguin" were placed in the same spot among the other 99 words, its memorability would be exceptionally worse. This outcome shows the power of distinctiveness that we discussed in the section on encoding: one picture is perfectly recalled from among

99 words because it stands out. Now consider what would happen if the experiment were repeated, but there were 25 pictures distributed within the 100-item list. Although the picture of the penguin would still be there, the probability that the cue "recall the picture" (at item 50) would be useful for the penguin would drop correspondingly. Watkins (1975) referred to this outcome as demonstrating the **cue overload principle**. That is, to be effective, a retrieval cue cannot be overloaded with too many memories. For the cue "recall the picture" to be effective, it should only match one item in the target set (as in the one-picture, 99-word case).

To sum up how memory cues function: for a retrieval cue to be effective, a match must exist between the cue and the desired target memory; furthermore, to produce the best retrieval, the cue-target relationship should be distinctive. Next, we will see how the encoding specificity principle can work in practice.

Psychologists measure memory performance by using production tests (involving recall) or recognition tests (involving the selection of correct from incorrect information, e.g., a multiple-choice test). For example, with our list of 100 words, one group of people might be asked to recall the list in any order (a free recall test), while a different group might be asked to circle the 100 studied words out of a mix with another 100, unstudied words (a recognition test). In this situation, the recognition test would likely produce better performance from participants than the recall test.

We usually think of recognition tests as being quite easy, because the cue for retrieval is a copy of the actual event that was presented for study. After all, what could be a better cue than the exact target (memory) the person is trying to access? In most cases, this line of reasoning is true; nevertheless, recognition tests do not provide perfect indexes of what is stored in memory. That is, you can fail to recognize a target staring you right in the face, yet be able to recall it later with a different set of cues (Watkins & Tulving, 1975). For example, suppose you had the task of recognizing the surnames of famous authors. At first, you might think that being given the actual last name would always be the best cue. However, research has shown this not necessarily to be true (Muter, 1984). When given names such as Tolstoy, Shaw, Shakespeare, and Lee, subjects might well say that Tolstoy and Shakespeare are famous authors, whereas Shaw and Lee are not. But, when given a cued recall test using first names, people often recall items (produce them) that they had failed to recognize before. For example, in this instance, a cue like *George Bernard* _____ often leads to a recall of "Shaw," even though people initially failed to recognize *Shaw* as a famous author's name. Yet, when given the cue "William," people may not come up with Shakespeare, because William is a common name that matches many people (the cue overload principle at work). This strange fact—that recall can sometimes lead to better performance than recognition—can be explained by the encoding specificity principle. As a cue, *George Bernard* _____ matches the way the famous writer is stored in memory better than does his surname, Shaw, does (even though it is the target). Further, the match is quite distinctive with *George Bernard* _____, but the cue *William* _____ is much more overloaded (Prince William, William Yeats, William Faulkner, will.i.am).

The phenomenon we have been describing is called the *recognition failure of recallable words*, which highlights the point that a cue will be most effective depending on how the information has been encoded (Tulving & Thomson, 1973). The point is, the cues that work best to evoke retrieval are those that recreate the event or name to be remembered, whereas sometimes even the target itself, such as *Shaw* in the above example, is not the best cue. Which cue will be most effective depends on how the information has been encoded.

Whenever we think about our past, we engage in the act of retrieval. We usually think that retrieval is an objective act because we tend to imagine that retrieving a memory is like pulling a book from a shelf, and after we are done with it, we return the book to the shelf just as it was. However, research shows this assumption to be false; far from being a static repository of data, the memory is constantly changing. In fact, every time we retrieve a memory, it is altered. For example, the act of retrieval itself (of a fact, concept, or event) makes the retrieved memory much more likely to be retrieved again, a phenomenon called the *testing effect* or the *retrieval practice effect* (Pyc & Rawson, 2009; Roediger & Karpicke, 2006). However, retrieving some information can actually cause us to forget other information related to it, a phenomenon called *retrieval-induced forgetting* (Anderson, Bjork, & Bjork, 1994). Thus the act of retrieval can be a double-edged sword—strengthening the memory just retrieved (usually by a large amount) but harming related information (though this effect is often relatively small).

As discussed earlier, retrieval of distant memories is reconstructive. We weave the concrete bits and pieces of events in with assumptions and preferences to form a coherent story (Bartlett, 1932). For example, if during your 10th birthday, your dog got to your cake before you did, you would likely tell that story for years afterward. Say, then, in later years you misremember where the dog actually found the cake, but repeat that error over and over during subsequent retellings of the story. Over time, that inaccuracy would become a basic fact of the event in your mind. Just as retrieval practice (repetition) enhances accurate memories, so will it strengthen errors or false memories (McDermott, 2006). Sometimes memories can even be manufactured just from hearing a vivid story. Example of a mneumonic system created by a student to study cranial nerves. [Image: Kelidimari, https://goo.gl/kiA1kP, CC BY-SA 3.0, https://goo.gl/SCkRfm]

How did Simon Reinhard remember those digits? He uses “memory palaces” (elaborate scenes with discrete places) combined with huge sets of images for digits. For example, imagine mentally walking through the home where you grew up and identifying as many distinct areas and objects as possible. Simon has hundreds of such memory palaces that he uses. Next, for remembering digits, he has memorized a set of 10,000 images. Every four-digit number for him immediately brings forth a mental image. So, for example, 6187 might recall Michael Jackson. When Simon hears all the numbers coming at him, he places an image for every four digits into locations in his memory palace. He can do this at an incredibly rapid rate, faster than 4 digits per 4 seconds when they are flashed visually, as in the demonstration at the beginning of the module. As noted, his record is 240 digits, recalled in exact order. Simon also holds the world record in an event called “speed cards,” which involves memorizing the precise order of a shuffled deck of cards. Simon was able to do this in 21.19 seconds! Again, he uses his memory palaces, and he encodes groups of cards as single images.

Many books exist on how to improve memory using mnemonic devices, but all involve forming distinctive encoding operations and then having an infallible set of memory cues. We should add that to develop and use these memory systems takes a great amount of time and concentration. The World Memory Championships are held every year and the records keep improving. However, for most common purposes, just keep in mind that to remember well you need to encode information in a distinctive way and to have good cues for retrieval. You can adapt a system that will meet most any purpose.

Discussion Questions

1. Mnemonists like Simon Reinhard develop mental “journeys,” which enable them to use the method of loci. Develop your own journey, which contains 20 places, in order, that you know well. One example might be: the front walkway to your parents’ apartment; their doorbell; the couch in their living room; etc. Be sure to use a set of places that you know well and that have a natural order to them (e.g., the walkway comes before the doorbell). Now you are more than halfway toward being able to memorize a set of 20 nouns, in order, rather quickly. As an optional second step, have a friend make a list of 20 such nouns and read them to you, slowly (e.g., one every 5 seconds). Use the method to attempt to remember the 20 items.
2. Recall a recent argument or misunderstanding you have had about memory (e.g., a debate over whether your girlfriend/boyfriend had agreed to something). In light of what you have just learned about memory, how do you think about it? Is it possible that the disagreement can be understood by one of you making a pragmatic inference?
3. Think about what you’ve learned in this module and about how you study for tests. On the basis of what you have learned, is there something you want to try that might help your study habits?

Vocabulary

Autobiographical memory
Memory for the events of one’s life.

Consolidation
The process occurring after encoding that is believed to stabilize memory traces.

Cue overload principle
The principle stating that the more memories that are associated to a particular retrieval cue, the less effective the cue will be in prompting retrieval of any one memory.

Distinctiveness
The principle that unusual events (in a context of similar events) will be recalled and recognized better than uniform (nondistinctive) events.

Encoding
The initial experience of perceiving and learning events.

Encoding specificity principle
The hypothesis that a retrieval cue will be effective to the extent that information encoded from the cue overlaps or matches information in the engram or memory trace.

Engram
the physical change in the nervous system representing memory of an event or fact; also, memory trace.

Episodic memory
Memory for events in a particular time and place.

Flashbulb memory
Vivid personal memories of receiving the news of some momentous (and usually emotional) event.

Memory traces
the change in the nervous system representing memory an event or fact; also engram.

Misinformation effect
When erroneous information occurring after an event is remembered as having been part of the original event.

Mnemonic devices
A strategy for remembering large amounts of information, usually involving imaging events occurring on a journey or with some other set of memorized cues.

Recoding
The ubiquitous process during learning of taking information in one form and converting it to another form, usually one more easily remembered.

Retrieval
The process of accessing stored information.

Retroactive interference
The phenomenon whereby events that occur after some particular event of interest will usually cause forgetting of the original event.

Semantic memory
The more or less permanent store of knowledge that people have.

Storage
The stage in the learning/memory process that bridges encoding and retrieval; the persistence of memory over time.

6.20.10: Chapter 10- Psychological Factors Affecting Learning, Memory, and Forgetting

Forgetting

Learning Objectives

1. Identify five reasons we forget and give examples of each.
2. Describe how forgetting can be viewed as an adaptive process.
3. Explain the difference between anterograde and retrograde amnesia.

Overview

This section explores the causes of everyday forgetting. Forgetting is viewed as an adaptive process that allows us to be efficient in terms of the information we retain.

Introduction

Chances are that you have experienced memory lapses and been frustrated by them. You may have had trouble remembering the definition of a key term on an exam or found yourself unable to recall the name of an actor from one of your favorite TV shows. Maybe you forgot to call your aunt on her birthday or you routinely forget where you put your cell phone. Oftentimes, the bit of information we are searching for comes back to us, but sometimes it does not. Clearly, forgetting seems to be a natural part of life. Why do we forget? And is forgetting always a bad thing?

Figure 6.20.10.1: Forgetting can often be obnoxious or even embarrassing. But as we explore this module, you'll learn that forgetting is important and necessary for everyday functionality. [Image: jazbeck, https://goo.gl/nkRrJy, CC BY 2.0, https://goo.gl/BRvSA7]

Causes of Forgetting

One very common and obvious reason why you cannot remember a piece of information is because you did not learn it in the first place. If you fail to encode information into memory, you are not going to remember it later on. Usually, **encoding** failures occur because we are distracted or are not paying attention to specific details. For example, people have a lot of trouble recognizing an

actual penny out of a set of drawings of very similar pennies, or lures, even though most of us have had a lifetime of experience handling pennies (Nickerson & Adams, 1979). However, few of us have studied the features of a penny in great detail, and since we have not attended to those details, we fail to recognize them later. Similarly, it has been well documented that distraction during learning impairs later memory (e.g., Craik, Govoni, Naveh-Benjamin, & Anderson, 1996). Most of the time this is not problematic, but in certain situations, such as when you are studying for an exam, failures to encode due to distraction can have serious repercussions.

Another proposed reason why we forget is that memories fade, or **decay**, over time. It has been known since the pioneering work of Hermann Ebbinghaus (1885/1913) that as time passes, memories get harder to recall. Ebbinghaus created more than 2,000 nonsense syllables, such as *dax*, *bap*, and *rif*, and studied his own memory for them, learning as many as 420 lists of 16 nonsense syllables for one experiment. He found that his memories diminished as time passed, with the most forgetting happening early on after learning. His observations and subsequent research suggested that if we do not rehearse a memory and the neural representation of that memory is not reactivated over a long period of time, the memory representation (the engram) may disappear entirely or fade to the point where it can no longer be accessed. As you might imagine, it is hard to definitively prove that a memory has decayed as opposed to it being inaccessible for another reason. Critics argued that forgetting must be due to processes other than simply the passage of time, since disuse of a memory does not always guarantee forgetting (McGeoch, 1932). More recently, some memory theorists have proposed that recent memory traces may be degraded or disrupted by new experiences (Wixted, 2004).

Memory traces need to be **consolidated**, or transferred from the **hippocampus** to more durable representations in the **cortex,** in order for them to last (McGaugh, 2000). When the consolidation process is interrupted by the encoding of other experiences, the memory trace for the original experience does not get fully developed and thus is forgotten.

Figure 6.20.10.2: At times, we will completely blank on something we're certain we've learned - people we went to school with years ago for example. However, once we get the right retrieval cue (a name perhaps), the memory (faces or experiences) rushes back to us like it was there all along. [Image: sbhsclass84, https://goo.gl/sHZyQI, CC BY-SA 2.0, https://goo.gl/rxiUsF]

Both encoding failures and decay account for more permanent forms of forgetting, in which the memory trace does not exist, but forgetting may also occur when a memory exists yet we temporarily cannot access it. This type of forgetting, failure of retrieval, may occur when we lack the appropriate **retrieval** cues for bringing the memory to mind. You have probably had the frustrating experience of forgetting your password for an online site. Usually, the password has not been permanently forgotten; instead, you just need the right reminder to remember what it is. For example, if your password was "pizza0525," and you received the password hints "favorite food" and "Mom's birthday," you would easily be able to retrieve it. Retrieval hints can bring back to mind seemingly forgotten memories (Tulving & Pearlstone, 1966). One real-life illustration of the importance of retrieval cues comes from a study showing that whereas people have difficulty recalling the names of high school classmates years after graduation, they are easily able to recognize the names and match them to the appropriate faces (Bahrick, Bahrick, & Wittinger, 1975). The names are powerful enough retrieval cues that they bring back the memories of the faces that went with them. The fact that the presence of the right retrieval cues is critical for remembering adds to the difficulty in proving that a memory is permanently forgotten as opposed to temporarily unavailable.

Retrieval failures can also occur because other memories are blocking or getting in the way of recalling the desired memory. This blocking is referred to as **interference**. For example, you may fail to remember the name of a town you visited with your family on summer vacation because the names of other towns you visited on that trip or on other trips come to mind instead. Those memories then prevent the desired memory from being retrieved. Interference is also relevant to the example of forgetting a password: passwords that we have used for other websites may come to mind and interfere with our ability to retrieve the desired password. Interference can be either proactive, in which old memories block the learning of new related memories, or retroactive, in which new memories block the retrieval of old related memories. For both types of interference, competition between memories seems to be key (Mensink & Raaijmakers, 1988). Your memory for a town you visited on vacation is unlikely to interfere with your ability to remember an Internet password, but it is likely to interfere with your ability to remember a different town's name. Competition between memories can also lead to forgetting in a different way. Recalling a desired memory in the face of competition may result in the inhibition of related, competing memories (Levy & Anderson, 2002). You may have difficulty recalling the name of Kennebunkport, Maine, because other Maine towns, such as Bar Harbor, Winterport, and Camden, come to mind instead. However, if you are able to recall Kennebunkport despite strong competition from the other towns, this may actually change the competitive landscape, weakening memory for those other towns' names, leading to forgetting of them instead.

Box 1. Five Impediments to Remembering

1. Encoding failures - we don't learn the information in the first place
2. Decay - memories fade over time
3. Inadequate retrieval cues - we lack sufficient reminders
4. Interference - other memories get in the way
5. Trying not to remember - we deliberately attempt to keep things out of mind

Figure 6.20.10.3: Causes of forgetting.

Finally, some memories may be forgotten because *we deliberately attempt to keep them out of mind*. Over time, by actively trying not to remember an event, we can sometimes successfully keep the undesirable memory from being retrieved either by inhibiting the undesirable memory or generating diversionary thoughts (Anderson & Green, 2001). Imagine that you slipped and fell in your high school cafeteria during lunch time, and everyone at the surrounding tables laughed at you. You would likely wish to avoid thinking about that event and might try to prevent it from coming to mind. One way that you could accomplish this is by thinking of other, more positive, events that are associated with the cafeteria. Eventually, this memory may be suppressed to the point that it would only be retrieved with great difficulty (Hertel & Calcaterra, 2005).

Adaptive Forgetting

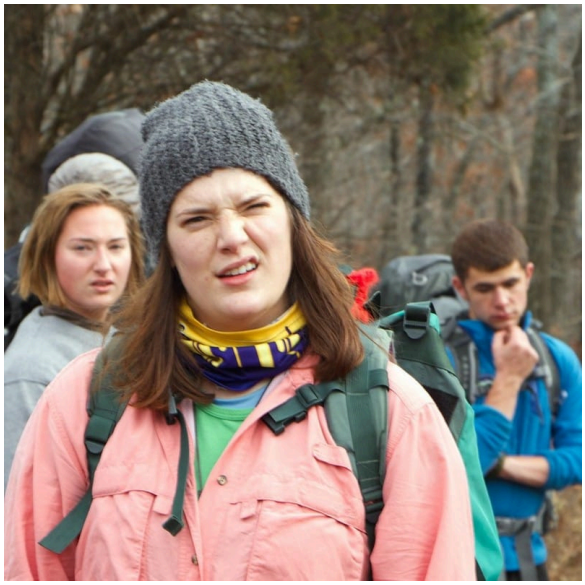

Figure 6.20.10.4: Could you imagine being unable to forget every path you have taken while hiking? Each new trip, you would be walking around the forest for days, incapable of distinguishing today's path from the prior ones. [Image: Dan Trew, https://goo.gl/8fJWWE, CC BY-SA 2.0, https://goo.gl/rxiUsF]

We have explored five different causes of forgetting. Together they can account for the day-to-day episodes of forgetting that each of us experience. Typically, we think of these episodes in a negative light and view forgetting as a memory failure. Is forgetting ever good? Most people would reason that forgetting that occurs in response to a deliberate attempt to keep an event out of mind is a good thing. No one wants to be constantly reminded of falling on their face in front of all of their friends. However, beyond that, it can be argued that forgetting is adaptive, allowing us to be efficient and hold onto only the most relevant memories (Bjork, 1989; Anderson & Milson, 1989). Shereshevsky, or "S," the mnemonist studied by Alexander Luria (1968), was a man who almost never forgot. His memory appeared to be virtually limitless. He could memorize a table of 50 numbers in under 3 minutes and recall the numbers in rows, columns, or diagonals with ease. He could recall lists of words and passages that he had memorized over a decade before. Yet Shereshevsky found it difficult to function in his everyday life because he was constantly distracted by a flood of details and associations that sprung to mind. His case history suggests that remembering everything is not always a good thing. You may occasionally have trouble remembering where you parked your car, but imagine if every time you had to find your car, every single former parking space came to mind. The task would become impossibly difficult to sort through all of those irrelevant memories. Thus, forgetting is adaptive in that it makes us more efficient. The price of that efficiency is those moments when our memories seem to fail us (Schacter, 1999).

Conclusion

Just as the case study of the mnemonist Shereshevsky illustrates what a life with a near perfect memory would be like, amnesiac patients show us what a life without memory would be like. Each of the mechanisms we discussed that explain everyday forgetting—encoding failures, decay, insufficient retrieval cues, interference, and intentional attempts to forget—help to keep us highly efficient, retaining the important information and for the most part, forgetting the unimportant.

Discussion Questions

1. Is forgetting good or bad? Do you agree with the authors that forgetting is an adaptive process? Why or why not?
2. Can we ever prove that something is forgotten? Why or why not?
3. Which of the five reasons for forgetting do you think explains the majority of incidences of forgetting?

The fading of memories with the passage of time.

Declarative memory
Conscious memories for facts and events.

Dissociative amnesia
Loss of autobiographical memories from a period in the past in the absence of brain injury or disease.

Encoding
Process by which information gets into memory.

Interference
Other memories get in the way of retrieving a desired memory

Retrieval
Process by which information is accessed from memory and utilized.

Factors Influencing Learning

By Aaron Benjamin, University of Illinois at Urbana-Champaign

Modified by Kenneth A. Koenigshofer, PhD., Chaffey College

Learning is a complex process that defies easy definition and description. This module reviews some of the characteristics of learners and of encoding activities that seem to affect how well people can acquire new memories, knowledge, or skills.

Learning Objectives

- Consider what kinds of activities constitute learning.
- Name multiple forms of learning.
- List some individual differences that affect learning.
- Describe the effect of various encoding activities on learning.

Introduction

What do you do when studying for an exam? Do you read your class notes and textbook? Do you try to find a quiet place without distraction? Do you use flash cards to test your knowledge? The choices you make reveal your theory of learning, but there is no reason to limit yourself to your own intuitions. There is a vast science of learning, in which researchers from psychology, education, and neuroscience study basic principles of learning and memory.

Figure 6.20.10.5: When you study for a test, you incorporate your past knowledge into learning this new knowledge. That is, depending on your previous experiences, you will "learn" the material in different ways. [Image: UBC Learning Commons, https://goo.gl/eT0jvd, CC BY 2.0, https://goo.gl/BRvSA7]

In fact, learning is much broader than you might think. Consider: Is listening to music a form of learning? We know that your brain's response to auditory information changes with your experience with that information, a form of learning called auditory **perceptual learning** (Polley, Steinberg, & Merzenich, 2006). When we exhibit changes in behavior without having intended to learn something, that is called **implicit learning** (Seger, 1994), and when we exhibit changes in our behavior that reveal the influence of past experience even though we are not attempting to use that experience, that is called **implicit memory** (Richardson-Klavehn & Bjork, 1988).

Other well-studied forms of learning include the types of learning that are general across species. We can't ask a slug to learn a poem or a lemur to learn to bat left-handed, but we can assess learning in other ways. For example, we can look for a change in our responses to things when we are repeatedly stimulated. If you live in a house with a grandfather clock, you know that what was once an annoying and intrusive sound is now probably barely audible to you. Similarly, poking an earthworm again and again is likely to lead to a reduction in its retraction from your touch. These phenomena are forms of **nonassociative learning**, in which single repeated exposure leads to a change in behavior (Pinsker, Kupfermann, Castelluci, & Kandel, 1970). When our response lessens with exposure, it is called **habituation**, and when it increases (like it might with a particularly annoying laugh), it is called **sensitization**. Animals can also learn about relationships between things, such as when an alley cat learns that the sound of janitors working in a restaurant precedes the dumping of delicious new garbage (an example of stimulus-stimulus learning called **classical conditioning**), or when a dog learns to roll over to get a treat (a form of stimulus-response learning called **operant conditioning**). These forms of learning will be covered in the module on Conditioning and Learning (http://noba.to/ajxhcqdr).

Here, we'll review some of the conditions that affect learning, with a focus on the type of explicit learning we do when trying to learn something.

Learners

One well-studied and important variable is **working memory** capacity. Working memory describes the form of memory we use to hold onto information temporarily. Working memory is used, for example, to keep track of where we are in the course of a complicated math problem, and what the relevant outcomes of prior steps in that problem are. Higher scores on working memory measures are predictive of better reasoning skills (Kyllonen & Christal, 1990), reading comprehension (Daneman & Carpenter, 1980), and even better control of attention (Kane, Conway, Hambrick, & Engle, 2008).

Figure 6.20.10.6: Research attests that we can hold between 5 and 9 individual pieces of information in our working memory at once. This is partly why in the 1950s Bell Labs developed a 7-digit phone number system. [Image: Diamondmagna, https://goo.gl/xeUxfw, CC BY-SA 3.0, https://goo.gl/eLCn2O]

Anxiety also affects the quality of learning. For example, people with math anxiety have a smaller capacity for remembering math-related information in working memory, such as the results of carrying a digit in arithmetic (Ashcraft & Kirk, 2001). Having students write about their specific anxiety seems to reduce the worry associated with tests and increases performance on math tests (Ramirez & Beilock, 2011).

Another factor to consider is the role of expertise. Though there probably is a finite capacity on our ability to store information (Landauer, 1986), having more knowledge or expertise actually enhances our ability to learn new information. A classic example is comparing a chess master with a chess novice on their ability to learn and remember the positions of pieces on a chessboard (Chase & Simon, 1973). In that experiment, the master remembered the location of many more pieces than the novice, even after only a very short glance. Maybe chess masters are just smarter than the average chess beginner, and have better memory? No: The advantage the expert exhibited only was apparent when the pieces were arranged in a plausible format for an ongoing chess game; when the pieces were placed randomly, both groups did equally poorly. Expertise allowed the master to **chunk** (Simon, 1974) multiple pieces into a smaller number of pieces of information—but only when that information was structured in such a way so as to allow the application of that expertise by exploiting memory of familiar chunks (in this case, groups of chess pieces in familiar configurations).

Encoding Activities

What we do when we're learning is very important. We've all had the experience of reading something and suddenly coming to the realization that we don't remember a single thing, even the sentence that we just read. *How* we go about **encoding** information determines a lot about how much we remember.

Merely intending to learn something is not enough. When a learner actively processes the material, encoding and memory are improved; for example, reading words and evaluating their meaning leads to better learning than reading them and evaluating the way that the words look or sound (Craik & Lockhart, 1972). If you are trying to learn a list of words, just evaluating each word for its part of speech (i.e., noun, verb, adjective) helps you *recall* the words—that is, it helps you remember and write down more of the words later. But it actually impairs your ability to *recognize* the words—to judge on a later list which words are the ones that you studied (Eagle & Leiter, 1964). So this is a case in which **incidental learning**—that is, learning without the intention to learn—is better than **intentional learning**.

Such examples are not particularly rare and are not limited to recognition. Nairne, Pandeirada, and Thompson (2008) showed, for example, that survival processing—thinking about and rating each word in a list for its relevance in a survival scenario—led to much higher recall than just the intention to learn (and also higher, in fact, than other encoding activities that are also known

to lead to high levels of recall). Interacting with the material to be learned, thinking about it and processing it in terms of its meaning for something important like survival, improves recall. To process the material you have to attend to it and you also form connections or associations which may imporve recall.

If you are studying for a final exam next week and plan to spend a total of five hours, what is the best way to distribute your study? The evidence is clear that *spacing* one's repetitions apart in time is superior than *massing* them all together (Baddeley & Longman, 1978; Bahrick, Bahrick, Bahrick, & Bahrick, 1993; Melton, 1967).

A similar advantage is evident for the practice of interleaving multiple skills to be learned: For example, baseball batters improved more when they faced a mix of different types of pitches than when they faced the same pitches blocked by type (Hall, Domingues, & Cavazos, 1994). Students also showed better performance on a test when different types of mathematics problems were interleaved rather than grouped during learning (Taylor & Rohrer, 2010).

One final factor that merits discussion is the role of testing. Educators and students often think about testing as a way of assessing knowledge, and this is indeed an important use of tests. But tests themselves affect memory, because retrieval is one of the most powerful ways of enhancing learning (Roediger & Butler, 2013). Self-testing is an underutilized and potent means of making learning more durable.

Conclusion

To wrap things up, let's think back to the questions we began the module with. What might you now do differently when preparing for an exam? Hopefully, you will think about testing yourself frequently, developing an accurate sense of what you do and do not know, how you are likely to use the knowledge, and using the scheduling of study sessions to your advantage. If you are learning a new skill or new material, using the scientific study of learning as a basis for the study and practice decisions you make is a good bet.

Discussion Questions

1. How would you best design a computer program to help someone learn a new foreign language? Think about some of the principles of learning outlined in this module and how those principles could be instantiated in "rules" in a computer program.
2. In what kinds of situations not discussed here might you find a benefit of forgetting on learning?

Vocabulary

Chunk
The process of grouping information together using our knowledge.

Classical conditioning
Describes stimulus-stimulus associative learning.

Encoding
The pact of putting information into memory.

Habituation
Occurs when the response to a stimulus decreases with exposure.

Implicit learning
Occurs when we acquire information without intent that we cannot easily express.

Implicit memory
A type of long-term memory that does not require conscious thought to encode. It's the type of memory one makes without intent.

Incidental learning
Any type of learning that happens without the intention to learn.

Intentional learning
Any type of learning that happens when motivated by intention.

Metacognition
Describes the knowledge and skills people have in monitoring and controlling their own learning and memory.

Nonassociative learning
Occurs when a single repeated exposure leads to a change in behavior.

Operant conditioning
Describes stimulus-response associative learning.

Perceptual learning
Occurs when aspects of our perception changes as a function of experience.

Sensitization
Occurs when the response to a stimulus increases with exposure

Transfer-appropriate processing
A principle that states that memory performance is superior when a test taps the same cognitive processes as the original encoding activity.

Working memory
The form of memory we use to hold onto information temporarily, usually for the purposes of manipulation.

6.20.11: Chapter 14- Traditional Models of Human Intelligence

Learning Objectives

1. Discuss two common tests for measuring intelligence.
2. Describe at least one “type” of intelligence.
3. Describe Carroll's three-stratum theory of intelligence and name the factor at the top level in this theory.
4. Discuss intelligence in simple terms
5. Name a brain network thought to be associated with intelligence

Overview

The development of tests to measure intelligence has had a major impact on the development of ideas about the nature and structure of human intelligence, and its biological basis in the brain. Most theories of human intelligence are based on data derived from intelligence tests which is analyzed using factor analysis, a mathematical method for analyzing patterns of correlations among different measures of mental abilities. In module 14.2, we have already discussed how this method, invented and used by Spearman (1904), revealed the "g" factor in human intelligence.

To understand current thinking and research about the biological basis of human intelligence, it is essential to gain at least a general familiarity with the major theoretical models of human intelligence psychologists have developed. The theories we examine in this module are based to a large extent on intelligence testing and factor analysis, while others are more intuitive. This section introduces key historical figures, major theories of intelligence, and common assessment strategies used to measure human intelligence.

In section 14.2, we discussed a number of enduring, across-generation, universal regularities of the environment which have been incorporated by evolution into brain organization and intelligence. As described in that section, these enduring facts about how the world works include innate, genetically internalized information about objects in three-dimensional space, the passage of time, daily cycles of light and dark, causality relations (forming basis for causal logic and inference), similarity relations (leading to category formation and categorical logic and inference), and predictive relations, based on covariation of events, allowing human and animal brains to mentally project the organism into future time. All of these invariant properties of the world must be included in the brain's neural models or cognitive maps of the world if the brain is to effectively guide adaptive behavior.

When we examine the traditional models of intelligence in this section, you will recognize that each focuses on only one, or a few of the facets of intelligence discussed in the evolutionary approach taken in section 14.2. In a sense, each theory discussed in this section is akin to the fable of the blind men trying to describe an elephant. Each blind man only knows that part of the elephant which he happens to feel and so each man has a different and incomplete understanding of the whole. Likewise, each theory of intelligence focuses on only part of the complex of processes that we collectively refer to as "intelligence." Nevertheless, each theory makes a contribution, and each, in one or more ways, is related to the evolutionary discussion in section 14.2.

For example, as you will see, emotional intelligence, including Gardner's intra- and inter-personal intelligence, is related to neural representations of the contingencies of the social environment--brain mechanisms for which are the focus of the new field of **social cognitive neuroscience.** Gardner's multiple intelligences include spatial intelligence related to representation of objects in three-dimensional space, abilities which require portions of **parietal cortex** and **hippocampus**. At Level III in Carroll's theory of intelligence is "g," general intelligence, related to representations of causal, similarity, and predictive relations, likely involving the **frontoparietal network** (Jung & Haier, 2007). Of these theories, the first, Carroll's three-stratum theory of human intelligence is by far the most widely accepted and most productive in terms of explanatory power and empirical evidence. With this background, we are better prepared to examine the traditional models of intelligence in this module and, perhaps more importantly for this course, we will be better prepared to understand the biological bases of intelligence and thinking, a primary focus of this chapter.

Introduction

Every year hundreds of grade school students converge on Washington, D.C., for the annual Scripps National Spelling Bee. The "bee" is an elite event in which children as young as 8 square off to spell words like "cymotrichous" and "appoggiatura." Most people who watch the bee think of these kids as being "smart" and you likely agree with this description.

Figure 6.20.11.1: A participant in the Scripps National Spelling Bee. (CC BY-NC 2.0; Scripps National Spelling Bee via Flickr)

What makes a person intelligent? Is it heredity (two of the 2014 contestants in the bee have siblings who have previously won)(National Spelling Bee, 2014a)? Is it interest and motivation (the most frequently listed favorite subject among spelling bee competitors is math)(NSB, 2014b)? By the end of the module you should be able to define intelligence, discuss methods for measuring intelligence, and describe theories of intelligence. In addition, we will tackle the politically thorny issue of whether there are differences in intelligence between groups such as men and women. As you read through this module, note that we discuss possible links between each theory of intelligence and the material from the previous module on adaptation, evolution and the brain mechanisms of intelligence. Recall that all of the information processing done by the brain, including that involving what we term intelligence and thinking, can have no effect at all on the outside world unless that neural activity converges onto and acts on the motor neurons in the spinal cord and medulla which stimulate the muscles to generate movement, behavior. Intelligence and cognition, as discussed in the last module, are part of the elaborate control systems which guide movement into adaptive patterns of behavior.

Defining and Measuring Intelligence

When you think of "smart people" you likely have an intuitive sense of the qualities that make them intelligent. Maybe you think they have a good memory, or that they can think quickly, or that they simply know a whole lot of information. Indeed, people who exhibit such qualities appear very intelligent. That said, it seems that intelligence must be more than simply knowing facts and being able to remember them. One point in favor of this argument is the idea of animal intelligence. It will come as no surprise to you that a dog, which can learn commands and tricks seems smarter than a snake that cannot. In fact, researchers and lay people generally agree with one another that primates—monkeys and apes (including humans)—are among the most intelligent animals (see comparisons among species on cognitive abilities in module 10.1). Apes such as chimpanzees are capable of complex problem solving and sophisticated communication (Kohler, 1924).

Scientists point to the social nature of primates as one evolutionary source of their intelligence. Primates live together in troops or family groups and are, therefore, highly social creatures. As such, primates tend to have brains that are better developed for communication and long term thinking than most other animals. For instance, the complex social environment has led primates to develop deception, altruism, numerical concepts, and "theory of mind" (a sense of the self as a unique individual separate from others in the group and understanding that others have minds; Gallup, 1982; Hauser, MacNeilage & Ware, 1996). [Also see module on Theory of Mind later in this chapter and at http://noba.to/a8wpytg3]

The question of what constitutes human intelligence is one of the oldest inquiries in psychology. When we talk about intelligence

we typically mean intellectual ability. This broadly encompasses the ability to learn, remember and use new information, to solve problems and to adapt to novel situations. As discussed in module 10.1, an early scholar of intelligence, Charles Spearman, proposed that intelligence was one thing, a "general factor" sometimes known as simply "g." He based this conclusion on the observation that people who perform well in one intellectual area such as verbal ability also tend to perform well in other areas such as logic and reasoning (Spearman, 1904).

Francis Galton, a contemporary of Spearman and a cousin of Charles Darwin, was among those who pioneered psychological measurement (Hunt, 2009). Galton was particularly interested in intelligence, which he thought was heritable in much the same way that height and eye color are. He conceived of several rudimentary methods for assessing whether his hypothesis was true. For example, he carefully tracked the family tree of the top-scoring Cambridge students over the previous 40 years. Although he found specific families disproportionately produced top scholars, intellectual achievement could still be the product of economic status, family culture or other non-genetic factors. Galton was also, possibly, the first to popularize the idea that the heritability of psychological traits could be studied by looking at identical and fraternal twins. Although his methods were crude by modern standards, Galton established intelligence as a variable that could be measured (Hunt, 2009).

Figure 6.20.11.2: Alfred Binet (public domain)

The person best known for formally pioneering the measurement of intellectual ability is Alfred Binet. Like Galton, Binet was fascinated by individual differences in intelligence. For instance, he blindfolded chess players and saw that some of them had the ability to continue playing using only their memory (most likely involving use of a type of cognitive map, perhaps involving **parietal and prefrontal cortex**) to keep the many positions of the pieces in mind (Binet, 1894). Binet was particularly interested in the development of intelligence, a fascination that led him to observe children carefully in the classroom setting.

Along with his colleague Theodore Simon, Binet created a test of children's intellectual capacity. They created individual test items that should be answerable by children of given ages. For instance, a child who is three should be able to point to her mouth and eyes, a child who is nine should be able to name the months of the year in order, and a twelve year old ought to be able to name sixty words in three minutes. Their assessment became the first "IQ test."

Intelligence tests

Some examples of the types of items you might see on an intelligence test.

1. Which of the following is most similar to 1313323?
   A. ACACCBC
   B. CACAABC
   C. ABABBCA
   D. ACACCDC

2. Jenny has some chocolates. She eats two and gives half of the remainder to Lisa. If Lisa Has six chocolates how many does Jenny have in the beginning?
   A. 6
   B. 12
   C. 14
   D. 18
3. Which of the following items is not like the others in the list: duck, raft, canoe, stone, rubber ball
   A. Duck
   B. Canoe
   C. Stone
   D. Rubber ball
4. What do steam and ice have in common?
   A. They can both harm skin
   B. They are both made from water
   C. They are both found in the kitchen
   D. They are both the products of water at extreme temperatures

"IQ" or "intelligence quotient" is a name given to the score of the Binet-Simon test. The score is derived by dividing a child's mental age (the score from the test) by their chronological age to create an overall quotient. These days, the phrase "IQ" does not apply specifically to the Binet-Simon test and is used to generally denote intelligence or a score on any intelligence test. In the early 1900s the Binet-Simon test was adapted by a Stanford professor named Lewis Terman to create what is, perhaps, the most famous intelligence test in the world, the Stanford-Binet (Terman, 1916). The major advantage of this new test was that it was standardized. Based on a large sample of children Terman was able to plot the scores in a normal distribution, shaped like a "bell curve" (see Fig. 1). To understand a normal distribution think about the height of people. Most people are average in height with relatively fewer being tall or short, and fewer still being extremely tall or extremely short. Terman (1916) laid out intelligence scores in exactly the same way, allowing for easy and reliable categorizations and comparisons between individuals.

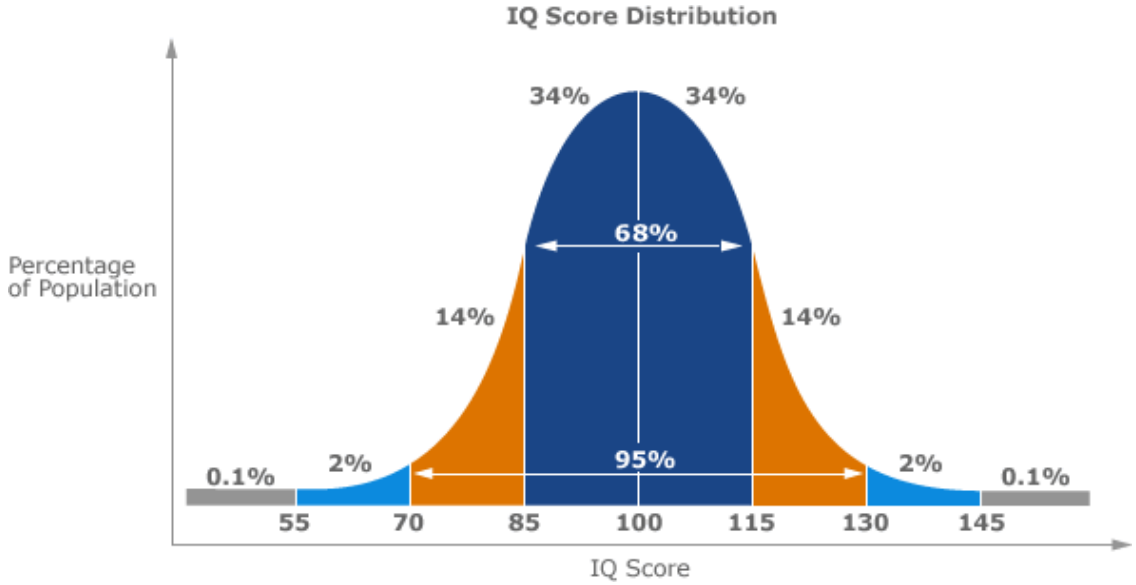

Figure 6.20.11.3: A graph of IQ Score Distribution: 68% of the population will score between 85 - 115, 95% will score between 70 - 130, 2% will score below 70, 2% will score above 130, 0.1% will score below 55 and 0.1% will score above 145.

Looking at another modern intelligence test—the Wechsler Adult Intelligence Scale (WAIS)—can provide clues to a definition of intelligence itself. Motivated by several criticisms of the Stanford-Binet test, psychologist David Wechsler sought to create a superior measure of intelligence. He was critical of the way that the Stanford-Binet relied so heavily on verbal ability and was also suspicious of using a single score to capture all of intelligence. To address these issues Wechsler created a test that tapped a wide range of intellectual abilities. This understanding of intelligence—that it is made up of a pool of specific abilities—is a notable departure from Spearman's concept of general intelligence. The WAIS assesses people's ability to remember, compute, understand language, reason well, and process information quickly (Wechsler, 1955). However, as we will see below, these two approaches were integrated by Carroll (1993) in his model of intelligence.

One interesting by-product of measuring intelligence for so many years is that we can chart changes over time. Over the last 80 years we have been measuring human intelligence, when new waves of people are asked to take older intelligence tests they tend to outperform the original sample from years ago on which the test was normed. This gain in measured average intelligence is known as the “Flynn Effect,” named after James Flynn, the researcher who first identified it (Flynn, 1987). Several hypotheses have been put forth to explain the Flynn Effect including better nutrition (healthier brains!), greater familiarity with testing in general, and more exposure to visual stimuli. Today, there is no perfect agreement among psychological researchers about the causes of these increases in average scores on intelligence tests over the past 80 years. Keep in mind that these intelligence tests were originally designed to predict school performance. Could it be that improvements over the years in public education, or some other social variable, may, at least in part, account for the Flynn Effect?

Types of Intelligence

David Wechsler’s approach to testing intellectual ability was based on the fundamental idea that there are many aspects to intelligence. Other scholars have echoed this idea by going so far as to suggest that there are actually even different types of intelligence. You likely have heard distinctions made between “street smarts” and “book learning.” The former refers to practical wisdom accumulated through experience while the latter indicates formal education. A person high in street smarts might have a superior ability to catch a person in a lie, to persuade others, or to think quickly under pressure. A person high in book learning, by contrast, might have a large vocabulary and be able to remember a large number of facts. Although psychologists don’t use street smarts or book smarts as professional terms some do believe that there are different types of intelligence.

Carroll's Three-Stratum Model

There are many ways to parse apart the concept of intelligence. Many scholars believe that a theory proposed by Carroll (1993) provides the best and most comprehensive model of human intelligence. Carroll divided human intelligence into three levels, or strata, descending from the most abstract down to the most specific (see Figures 10.2.4 and 10.2.5). Carroll called the highest level (stratum III) the general intelligence factor “g,” following Spearman's (1904) original concept of a general intelligence factor, evolutionary origins of which were discussed in module 10.1. Below stratum III were more specific stratum II categories which are different subsets of "g" such as fluid intelligence (Gf), crystallized intelligence (Gc), broad visual perception (Gv), processing speed, and a number of others (see Figure 10.2.5). Each of these, in turn, can be sub-divided into very specific components such as spatial scanning, reaction time, and word fluency.

Thinking of intelligence as Carroll (1993) does, as a collection of specific mental abilities, has helped researchers conceptualize this topic in new ways. For example, Horn and Cattell (1966) were first to distinguish between “fluid” and “crystallized” intelligence, both of which are on stratum II of Carroll’s model. Fluid intelligence refers to basic processes of reasoning and other mental activities that are only minimally dependent upon prior learning and experience (such as education). Fluid intelligence is the ability to think and reason flexibly and abstractly to solve problems and encompasses the ability to see complex relationships. This is closest to the concept of general intelligence discussed in module 10.1 and most likely involves the **parietofrontal network** described in that module.

Crystallized intelligence, on the other hand, refers to learned procedures and knowledge and includes the ability to use language, and skills and knowledge accumulated from experience (see chapter on learning and memory for discussion of neural mechanisms of learning). Crystallized intelligence is characterized as acquired knowledge and the ability to retrieve it. Fluid intelligence helps you tackle complex, abstract challenges in your daily life, whereas crystallized intelligence helps you overcome concrete, straightforward problems (Cattell, 1963). The latter increases with age. In general, older people have a relatively superior store of knowledge that can be put to use to solve problems.

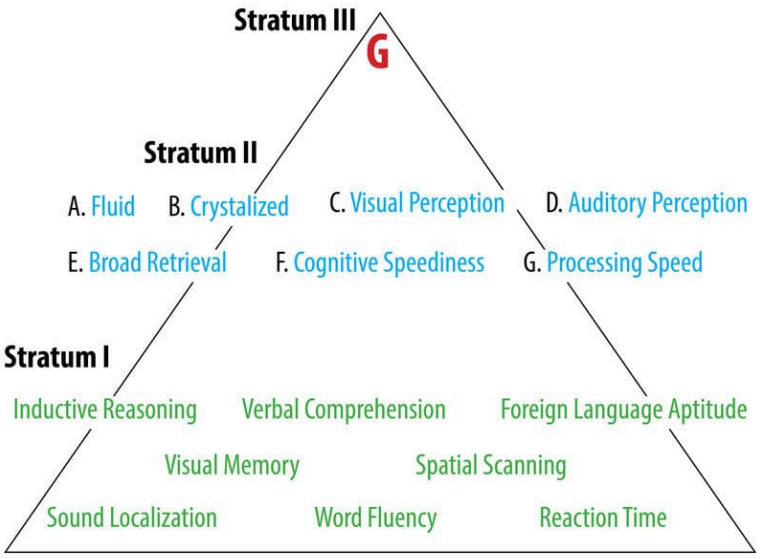

Figure 6.20.11.4: A Simplified Summary of Carroll's Model of Intelligence. Stratum I: inductive reasoning, verbal comprehension, foreign languange aptitude, visual memory, spatial scanning, sound localization, word fluency and reaction time. Stratum II: fluid, crystallized, visual perception, auditory perception, broad retrieval, cognitive speediness, processing speed. Stratum III: G (i.e. g, general intelligence).

Carroll's **three-stratum theory** is based on a factor-analytic study of the correlation of individual-difference variables from data such as psychological tests, school grades, and competence ratings from more than 460 datasets. These analyses suggested a three-layered model where each layer accounts for the variations in the correlations within the previous layer.

The three layers (strata) are defined as representing narrow, broad, and general cognitive ability. The factors describe stable and observable differences among individuals in their performance of cognitive tasks. Carroll argues further that they are not mere artifacts of a mathematical process, but likely reflect **neurophysiological factors that explain the differences in ability (e.g., nerve firing rates, processing efficiency as proposed by Haier and discussed below, conduction velocity, etc).**

Carroll's taxonomy of intelligence distinguishes between level factors and speed factors. The tasks dependent upon level factors can be sorted by difficulty and individuals' scores are differentiated by whether they have acquired the skill to perform the tasks. Tasks that contribute to speed factors are distinguished by the relative speed with which individuals can complete them. Carroll suggests that the distinction between level and speed factors may be the broadest taxonomy of cognitive tasks that can be offered.

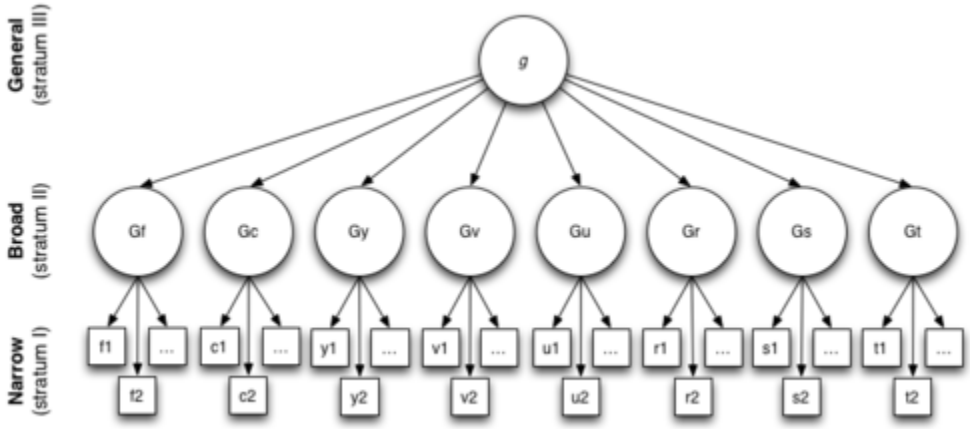

Figure 6.20.11.5: Carroll's three-stratum model. Key: fluid intelligence (Gf), crystallized intelligence (Gc), general memory and learning (Gy), broad visual perception (Gv), broad auditory perception (Gu), broad retrieval ability (Gr), broad cognitive speediness (Gs), and processing speed (Gt). Carroll regarded the broad abilities as different "flavors" of *g*.

Gardener's Multiple Intelligences Theory

Howard Gardner, a Harvard psychologist and former student of Erik Erikson, is another figure in psychology who is well-known for championing the notion that there are different types of intelligence. In Gardner's theory, each person possesses at least eight intelligences. Among these eight intelligences, a person typically excels in some and falters in others (Gardner, 1983). Gardner's theory is appropriately, called "multiple intelligences." Gardner's theory is based on the idea that people process information through different "channels" and these are relatively independent of one another. He has identified 8 common intelligences including 1) logic-math, 2) spatial, 3) music-rhythm, 4) verbal-linguistic, 5) bodily-kinesthetic, 6) interpersonal, 7) intrapersonal, and 8) naturalistic (Gardner, 1985). Many people are attracted to Gardner's theory because it suggests that people each learn in unique ways. There are now many Gardner-influenced schools in the world. Gardener's idea of different intelligences involving different "channels" suggests separate specialized brain mechanisms for these different cognitive abilities. This is consistent with what evolutionary psychologists refer to as a **modular model** of the mind, brain, and intelligence. On this view the mind/brain consists of a large collection of specialized information processing modules or mini-computers each evolved to process a particular kind of information needed to solve a particular category of adaptive problem (Ermer, et al., 2007). This model is consistent with the concept of **localization of function**, the hypothesis that different psychological functions are anatomically localized to different areas of the brain.

Gardner's Mulitiple Intelligences

Intelligence Type	Characteristics	Representative Career
Linguistic intelligence	Perceives different functions of language, different sounds and meanings of words, may easily learn multiple languages	Journalist, novelist, poet, teacher
Logical-mathematical intelligence	Capable of seeing numerical patterns, strong ability to use reason and logic	Scientist, mathematician
Musical intelligence	Understands and appreciates rhythm, pitch, and tone; may play multiple instruments or perform as a vocalist	Composer, performer
Bodily kinesthetic intelligence	High ability to control the movements of the body and use the body to perform various physical tasks	Dancer, athlete, athletic coach, yoga instructor
Spatial intelligence	Ability to perceive the relationship between objects and how they move in space	Choreographer, sculptor, architect, aviator, sailor
Interpersonal intelligence	Ability to understand and be sensitive to the various emotional states of others	Counselor, social worker, salesperson
Intrapersonal intelligence	Ability to access personal feelings and motivations, and use them to direct behavior and reach personal goals	Key component of personal success over time
Naturalist intelligence	High capacity to appreciate the natural world and interact with the species within it	Biologist, ecologist, environmentalist

Note that Gardener's Bodily kinesthetic intelligence and Spatial intelligence are likely to both involve the **parietal lobe**, while his Linguistic intelligence involves **Broca's and Wernicke's areas**, prominent language areas of the brain to be discussed later in this chapter. It is also likely that Gardener's Logical-mathematical intelligence requires processing in the **frontoparietal network** (Jung & Haier, 2007).

It has been suggested that Gardner simply relabeled what other theorists called "cognitive styles" as "intelligences" (Morgan, 1996). Furthermore, developing traditional measures of Gardner's intelligences is extremely difficult (Furnham, 2009; Gardner & Moran, 2006; Klein, 1997).

Gardner's inter- and intrapersonal intelligences are often combined into a single type: emotional intelligence.

Emotional Intelligence

Emotional intelligence encompasses the ability to understand the emotions of yourself and others, show empathy, understand social relationships and cues, and regulate your own emotions and respond in culturally appropriate ways (Parker, Saklofske, & Stough, 2009). People with high emotional intelligence typically have well-developed social skills and Goleman claims it can be a better predictor of success than traditional intelligence (Goleman, 1995). However, emotional intelligence is difficult to measure and study empirically, with some researchers pointing out inconsistencies in how it is defined and described (Locke, 2005; Mayer, Salovey, & Caruso, 2004).

Regardless of the specific definition of emotional intelligence, studies have shown a link between this concept and job performance (Lopes, Grewal, Kadis, Gall, & Salovey, 2006). In fact, emotional intelligence is similar to more traditional notions of cognitive intelligence with regards to workplace success.

Emotional intelligence, as defined by Parker, et al. (2009), likely involves the **anterior cingulate cortex (ACC)**, the **limbic system**, and the **prefrontal cortex** and the connections between them (Stevens, et al., 2011).

Sternberg's Triarchic Model of Human Intelligence

Robert Sternberg developed another theory of intelligence, which he titled the **triarchic theory of intelligence** because it sees intelligence as comprised of three parts (Sternberg, 1988): practical, creative, and analytical intelligence (Figure).

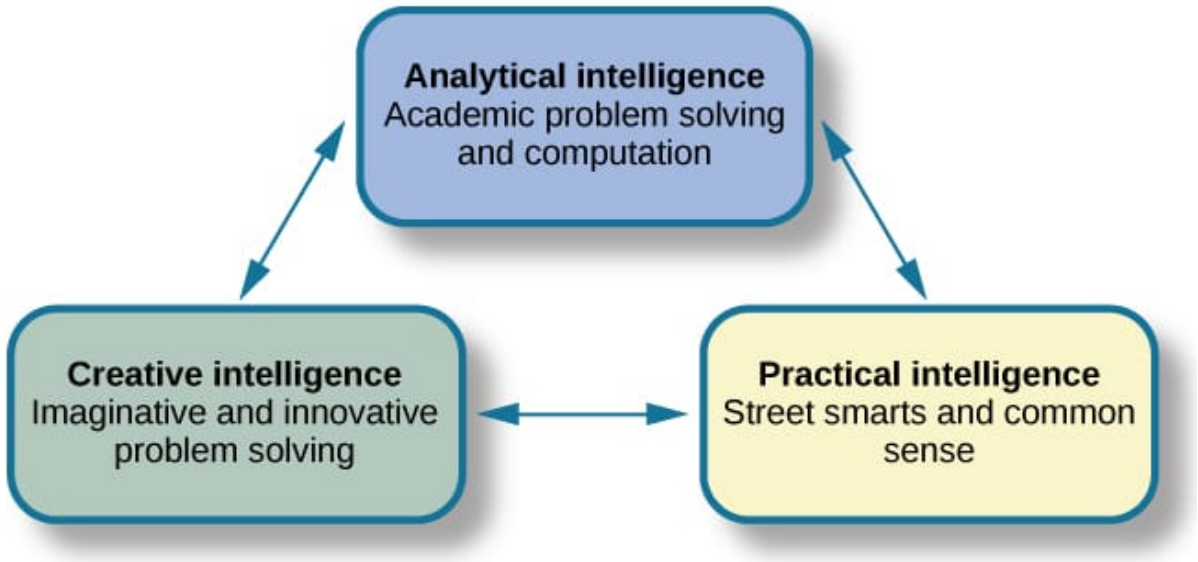

Figure 6.20.11.6: Sternberg's theory identifies three types of intelligence: practical (street smarts and common sense), creative (imaginative and innovative problem solving), and analytical (academic problem solving and computation). (What are Intelligence and Creativity? by OpenStax Colleg licensed CC BY-NC 4.0 via OER Commons)

Practical intelligence, as proposed by Sternberg, is sometimes compared to "street smarts." Being practical means you find solutions that work in your everyday life by applying knowledge based on your experiences. This type of intelligence appears to be separate from traditional understanding of IQ; individuals who score high in practical intelligence may or may not have comparable scores in creative and analytical intelligence (Sternberg, 1988).

Analytical intelligence is closely aligned with academic problem solving and computations. Sternberg says that analytical intelligence is demonstrated by an ability to analyze, evaluate, judge, compare, and contrast.

Creative intelligence is marked by inventing or imagining a solution to a problem or situation. Creativity in this realm can include finding a novel solution to an unexpected problem or producing a beautiful work of art or a well-developed short story. Imagine for a moment that you are camping in the woods with some friends and realize that you've forgotten your camp coffee pot. The person in your group who figures out a way to successfully brew coffee for everyone would be credited as having higher creative intelligence.

Intelligence and Creativity

Creativity is the ability to generate, create, or discover new ideas, solutions, and possibilities. Very creative people often have intense knowledge about something, work on it for years, look at novel solutions, seek out the advice and help of other experts, and take risks. Although creativity is often associated with the arts, it can be found in every area of life, from the way you decorate your residence to a new way of understanding how a cell works.

Dr. Tom Steitz, the Sterling Professor of Biochemistry and Biophysics at Yale University, has spent his career looking at the structure and specific aspects of RNA molecules and how their interactions could help produce antibiotics and ward off diseases. As a result of his lifetime of work, he won the Nobel Prize in Chemistry in 2009. He wrote, "Looking back over the development

and progress of my career in science, I am reminded how vitally important good mentorship is in the early stages of one's career development and constant face-to-face conversations, debate and discussions with colleagues at all stages of research. Outstanding discoveries, insights and developments do not happen in a vacuum" (Steitz, 2010, para. 39). Based on Steitz's comment, it becomes clear that someone's creativity, although an individual strength, benefits from interactions with others.

Creativity is often assessed as a function of one's ability to engage in divergent thinking. Divergent thinking can be described as thinking "outside the box;" it allows an individual to arrive at unique, multiple solutions to a given problem. In contrast, convergent thinking describes the ability to provide a correct, well-established answer or standard solution to a problem (Cropley, 2006; Gilford, 1967).

Brain Correlates of Intelligence and Creativity

Jung and Haier (2013) report a number of brain correlates of intelligence and creativity. However, they argue against the idea of one brain area for one cognitive function. Instead, as discussed in the prior module, they argue that brain networks involving multiple brain areas are involved in cognition, especially in complex psychological processes such as intelligence and creativity. Nevertheless, they recognize that brain injury and lesion studies reveal brain structures that are necessary, though not sufficient, for certain psychological functions. They give three examples: 1) Phineas Gage, who survived an iron rod passing through his **frontal lobe** resulting in personality and emotional changes as well as impaired judgement and loss of many social inhibitions; 2) "Tan," whose brain damage led to identification of Broca's area for language expression; and 3) H.M., whose bilateral surgical removal of **temporal lobe** structures including **hippocampus** revealed the role of hippocampus and related structures in formation of new long-term explicit memories and their retrieval.

Within this context, Jung and Haier (2013) note some interesting observations from post-mortem examination of the brain of the famous theoretical physicist, Albert Einstein (whose work led to the equation, $E=mc^2$), and what it might suggest about brain mechanisms in creativity. Einstein's brain was unremarkable in many ways. Its size and weight were within the normal range for a man of his age, and frontal and temporal lobe morphology and corpus callosum area were no different from control brains. However, there was one pronounced difference. According to Jung and Haier, Einstein's brain was missing the parietal operculum, the typical location of the secondary somatosensory cortex, resulting in a larger inferior parietal lobule. In Einstein's brain, the **inferior parietal lobule** was approximately 15% wider than in the brains of normal controls. According to Jung and Haier, this region of brain is associated with "visuospatial cognition, mathematical reasoning, and imagery of movement . . . and its expansion was noted in other cases of prominent physicists and mathematicians." They add that further examination of this area of Einstein's brain revealed that rather than more neurons, this region of his brain had a much larger number of **glial cells**, which provide nutrition to neurons, perhaps indicating an unusually large amount of activity among neurons in this region of his brain.

Significantly, as described in the prior module, **parietal cortex** has strong linkages with **prefrontal cortex** forming a **frontoparietal network**: the **inferior parietal lobule** is primarily **connected with dorsolateral prefrontal cortex** (Bruner, 2010), associated, in part, with abilities for abstract thought, while **upper parietal regions**, according to Bruner, as discussed in module 14.2, are associated in the literature with functions such as abstract representation, internal mental images, "imagined world[s],. . . and thought experiment" (i.e., imagination). Jung and Haier detail another study of Einstein's **right prefrontal association cortex**, where researchers found **greater packing density of neurons** (same number of neurons in a smaller space), which was interpreted as **shorter conduction times between cortical neurons in Einstein's brain** compared to control brains. Jung and Haier conclude that **Einstein's brain differed from controls in the frontoparietal network**. These authors have proposed that the **frontoparietal network is crucial to human intelligence**; furthermore they hypothesized that differences among people in the efficiency of neural communication between the frontal and parietal regions of cortex accounts for differences in intelligence in humans (Jung & Haier, 2007). In part, this idea is based on their finding that **high IQ people** show **less activity** in these brain areas during a complex cognitive task, while lower IQ people show more brain activity, suggesting that high IQ is related to **efficiency** in neural information processing operations. Moreover, higher IQ and ability for abstraction are both inversely correlated with cerebral glucose metabolic rate (Haier et al., 1988, 1992, 2003, 2004), suggesting an efficiency model of individual differences in *g* in which superior **ability for abstraction increases processing efficiency**. In their **Parietal-Frontal Integration Theory (P-FIT)** of the neural basis of intelligence, after sensory processing, information "is then fed forward to the **angular, supramarginal, and inferior parietal cortices**, wherein structural symbolism and/or abstraction are generated and manipulated. The **parietal cortex** then **interacts with frontal regions** that serve to **hypothesis test various solutions** to a given problem." They add that "the **anterior cingulate** is involved in response selection as well as inhibition of competing responses. This process is critically dependent on the fidelity of underlying **white matter** needed to facilitate rapid and error-free transmission of data **between frontal and parietal lobes**" (Jung & Haier, 2013, p. 239). They also note that research in genetics shows that "intelligence and brain structure (i.e., gray and white matter) share common genes" (p. 240).

Regarding creativity specifically, these authors refer to a theory by Flaherty (2005) which proposes a **frontotemporal system**

driven by **dopaminergic limbic activity** which provides the drive for creative expression whether art, music, writing, science, etc. and as measured by tests of divergent thinking. Jung and Haier (2013) explain that the **temporal lobe normally inhibits the frontal lobe** so that lesion or mild dysfunction of the temporal lobe releases activity from the frontal lobe by disinhibition causing increased interactions of frontal lobe with other brain regions, sometimes leading to increased creative outputs from neurological patients with left side damage. They argue that this and other data from "three structural studies point to a decidedly left lateralized, frontosubcortical, and disinhibitory network of brain regions underlying creative cognition and achievement" (p. 244). They add that this model, which still requires much more empirical investigation, "appears to include the frontal and temporal lobes, with cortical “tone” being modulated via interactions between the frontal lobes, basal ganglia and thalamus (part of the dopamine system) through white-matter pathways" (p. 244). Although this model is speculative for such a complex form of cognition as creativity, it can guide continuing research into how humans develop creative intellectual and artistic products.

Inferior parietal lobule

Blue: Angular gyrus. **LS**: Lateral sulcus (Sylvian fissure). **CS**: Central sulcus. **IPS**: Intraparietal sulcus. **STS**:Superior temporal sulcus. **PN**: Preoccipital notch.

Summary

Intelligence is a complex concept involving multiple mental abilities, including, according to Carroll, Spearman's g factor, itself composed of a number of subtypes identified by mathematical analysis of patterns of correlations among scores on different cognitive tasks. Additional models of human intelligence include Gardner's multiple intelligences, emotional intelligence, and Sternberg's triarchic theory of intelligence, each consistent with the view that intelligence is comprised of many interacting factors. Creativity seems to be another facet of intelligence. It may be explained as arising from imagination involving visual-like mental manipulations to explore alternative actions and their probable outcomes (see discussion module 10.1). One way to understand why there is such diversity in conceptions and theories of intelligence among psychologists is that each is focusing on only one or a few aspects of the multiple processes the brain engages in when it generates neural models of the world to guide adaptive behavior. Recall that module 10.1 on Intelligence, Cognition, Language, and Adaptation included discussion of

many complex properties of the social and physical environment that must be neurally modeled by the brain in order for human or animal to successfully navigate the social and physical environments. Each of the traditional theories of human intelligence discussed in this module involve representations of one or only a few of those properties of the social and physical environment. The evolutionary analysis in module 10.1 can unify the divergent models of intelligence described in this module by showing how each focuses on different sets of components of intelligence required for the construction of accurate mental/neural models or "cognitive maps" (Behrens, et al., 2018; Tolman, 1948) of the biologically significant facts of the physical and social worlds in order to guide behavior toward successful adaptation.

Review Questions

1. Fluid intelligence is characterized by _____.
    1. being able to recall information
    2. being able to create artistic pieces
    3. being able to understand and communicate with different cultures
    4. being able to see complex relationships and solve problems
2. Which of the following is not one of Gardner's Multiple Intelligences?
    1. creative
    2. spatial
    3. linguistic
    4. musical
3. Which theorist put forth the triarchic theory of intelligence?
    1. Goleman
    2. Gardner
    3. Sternberg
    4. Steitz
4. When you are examining data to look for trends, which type of intelligence are you using most?
    1. practical
    2. analytical
    3. emotional
    4. creative

Video: Hank Green gives a fun and interesting overview of the concept of intelligence in this installment of the Crash Course series.

Vocabulary

G (or g)

Short for “general factor” and is often used to be synonymous with intelligence itself.

IQ

Short for “intelligence quotient.” This is a score, typically obtained from a widely used measure of intelligence that is meant to rank a person’s intellectual ability against that of others.

Norm

Assessments are given to a representative sample of a population to determine the range of scores for that population. These “norms” are then used to place an individual who takes that assessment on a range of scores in which he or she is compared to the population at large.

Standardize

Assessments that are given in the exact same manner to all people . With regards to intelligence tests standardized scores are individual scores that are computed to be referenced against normative scores for a population (see “norm”).

6.20.12: Chapter 14- Problem Solving, Categories and Concepts

Learning Objectives

1. Define problem types
2. Describe problem solving strategies
3. Define algorithm and heuristic
4. Describe the role of insight in problem solving
5. Explain some common roadblocks to effective problem solving
6. What is meant by a search problem
7. Describe means-ends analysis
8. How do analogies and restructuring contribute to problem solving
9. Explain how experts solve problems and what gives them an advantage over non-experts
10. Describe the brain mechanisms in problem solving

Overview

In this section we examine problem-solving strategies. People face problems every day—usually, multiple problems throughout the day. Sometimes these problems are straightforward: To double a recipe for pizza dough, for example, all that is required is that each ingredient in the recipe be doubled. Sometimes, however, the problems we encounter are more complex. For example, say you have a work deadline, and you must mail a printed copy of a report to your supervisor by the end of the business day. The report is time-sensitive and must be sent overnight. You finished the report last night, but your printer will not work today. What should you do? First, you need to identify the problem and then apply a strategy, usually a set of steps, for solving the problem.

Defining Problems

We begin this module on Problem Solving by giving a short description of what psychologists regard as a problem. Afterwards we are going to present different approaches towards problem solving, starting with gestalt psychologists and ending with modern search strategies connected to artificial intelligence. In addition we will also consider how experts do solve problems and finally we will have a closer look at two topics: The neurophysiological background on the one hand and the question what kind of role can be assigned to evolution regarding problem solving on the other.

The most basic definition is “A problem is any given situation that differs from a desired goal”. This definition is very useful for discussing problem solving in terms of evolutionary adaptation, as it allows to understand every aspect of (human or animal) life as a problem. This includes issues like finding food in harsh winters, remembering where you left your provisions, making decisions about which way to go, repeating and varying all kinds of complex movements by learning, and so on. Though all these problems were of crucial importance during the evolutionary process that created us the way we are, they are by no means solved exclusively by humans. We find a most amazing variety of different solutions for these problems of adaptation in animals as well (just consider, e.g., by which means a bat hunts its prey, compared to a spider).

However, for this module, we will mainly focus on abstract problems that humans may encounter (e.g. playing chess or doing an assignment in college). Furthermore, we will not consider those situations as abstract problems that have an obvious solution: Imagine a college student, let's call him Knut. Knut decides to take a sip of coffee from the mug next to his right hand. He does not even have to think about how to do this. This is not because the situation itself is trivial (a robot capable of recognizing the mug, deciding whether it is full, then grabbing it and moving it to Knut’s mouth would be a highly complex machine) but because in the context of all possible situations it is so trivial that it no longer is a problem our consciousness needs to be bothered with. The problems we will discuss in the following all need some conscious effort, though some seem to be solved without us being able to say how exactly we got to the solution. Still we will find that often the strategies we use to solve these problems are applicable to more basic problems, as well as the more abstract ones such as completing a reading or writing assignment for a college class.

Non-trivial, abstract problems can be divided into two groups:

Well-defined Problems

For many abstract problems it is possible to find an algorithmic solution. We call all those problems well-defined that can be properly formalized, which comes along with the following properties:

- The problem has a clearly defined given state. This might be the line-up of a chess game, a given formula you have to solve, or the set-up of the towers of Hanoi game (which we will discuss later).
- There is a finite set of operators, that is, of rules you may apply to the given state. For the chess game, e.g., these would be the rules that tell you which piece you may move to which position.
- Finally, the problem has a clear goal state: The equations is resolved to x, all discs are moved to the right stack, or the other player is in checkmate.

Not surprisingly, a problem that fulfills these requirements can be implemented algorithmically (also see convergent thinking). Therefore many well-defined problems can be very effectively solved by computers, like playing chess.

Ill-defined Problems

Though many problems can be properly formalized (sometimes only if we accept an enormous complexity) there are still others where this is not the case. Good examples for this are all kinds of tasks that involve creativity, and, generally speaking, all problems for which it is not possible to clearly define a given state and a goal state: Formalizing a problem of the kind “Please paint a beautiful picture” may be impossible. Still this is a problem most people would be able to access in one way or the other, even if the result may be totally different from person to person. And while Knut might judge that picture X is gorgeous, you might completely disagree.

Nevertheless ill-defined problems often involve sub-problems that can be totally well-defined. On the other hand, many every-day problems that seem to be completely well-defined involve a great deal of creativity and many ambiguities. For example, suppose Knut has to read some technical material and then write an essay about it.

If we think of Knut's fairly ill-defined task of writing an essay, he will not be able to complete this task without first understanding the text he has to write about. This step is the first sub-goal Knut has to solve. Interestingly, ill-defined problems often involve subproblems that are well-defined.

Knut’s situation could be explained as a classical example of problem solving: He needs to get from his present state – an unfinished assignment – to a goal state - a completed assignment - and has certain operators to achieve that goal. Both Knut’s short and long term memory are active. He needs his short term memory to integrate what he is reading with the information from earlier passages of the paper. His long term memory helps him remember what he learned in the lectures he took and what he read in other books. And of course Knut’s ability to comprehend language enables him to make sense of the letters printed on the paper and to relate the sentences in a proper way.

Same place, different day. Knut is sitting at his desk again, staring at a blank paper in front of him, while nervously playing with a pen in his right hand. Just a few hours left to hand in his essay and he has not written a word. All of a sudden he smashes his fist on the table and cries out: "I need a plan!

How is a problem represented in the mind?

Generally speaking, problem representations are models of the situation as experienced by the agent. Representing a problem means to analyze it and split it into separate components:

- objects, predicates
- state space
- operators
- selection criteria

Therefore the efficiency of Problem Solving depends on the underlying representations in a person's mind. Analyzing the problem domain according to different dimensions, i.e., changing from one representation to another, results in arriving at a new understanding of a problem. This is basically what is described as restructuring.

Insight

There are two very different ways of approaching a *goal-oriented situation*. In one case an organism readily *reproduces* the response to the given problem from past experience. This is called **reproductive thinking**.

The second way requires *something new and different* to achieve the goal, prior learning is of little help here. Such **productive thinking** is (sometimes) argued to involve **insight**. Gestalt psychologists even state that insight problems are a separate category of problems in their own right.

Tasks that might involve insight usually have certain features – they require something new and non-obvious to be done and in most cases they are difficult enough to predict that the initial solution attempt will be unsuccessful. When you solve a problem of this kind you often have a so called **"AHA-experience"** – the solution pops up all of a sudden. At one time you do not have any ideas of the answer to the problem, you do not even feel to make any progress trying out different ideas, but in the next second the problem is solved.

Fixation

Sometimes, previous experience or familiarity can even make problem solving more difficult. This is the case whenever habitual directions get in the way of finding new directions – an effect called **fixation**.

Functional fixedness

Functional fixedness concerns the solution of *object-use problems*. The basic idea is that when the usual way of using an object is emphasised, it will be far more difficult for a person to use that object in a novel manner.

An example is the **two-string problem**: Knut is left in a room with a chair and a pair of pliers given the task to bind two strings together that are hanging from the ceiling. The problem he faces is that he can never reach both strings at a time because they are just too far away from each other. What can Knut do?

Figure 6.20.12.1: Put the two strings together by tying the pliers to one of the strings and then swing it toward the other one.

Mental fixedness

Functional fixedness as involved in the examples above illustrates a **mental set** – a person's tendency to respond to a given task in a manner based on past experience. Because Knut maps an object to a particular function he has difficulties to *vary the way of use* (pliers as pendulum's weight).

Problem-Solving Strategies

When you are presented with a problem—whether it is a complex mathematical problem or a broken printer, how do you solve it? Before finding a solution to the problem, the problem must first be clearly identified. After that, one of many problem solving strategies can be applied, hopefully resulting in a solution. Regardless of strategy, you will likely be guided, consciously or unconsciously, by your knowledge of cause-effect relations among the elements of the problem and the similarity of the problem to previous problems you have solved before. As discussed in earlier sections of this chapter, innate dispositions of the brain to look for and represent causal and similarity relations are key components of general intelligence (Koenigshofer, 2017).

A problem-solving strategy is a plan of action used to find a solution. Different strategies have different action plans associated with them. For example, a well-known strategy is trial and error. The old adage, "If at first you don't succeed, try, try again" describes trial and error. In terms of your broken printer, you could try checking the ink levels, and if that doesn't work, you could check to make sure the paper tray isn't jammed. Or maybe the printer isn't actually connected to your laptop. When using trial and error, you would continue to try different solutions until you solved your problem. Although trial and error is not typically one of the most time-efficient strategies, it is a commonly used one.

Table 1: Problem-Solving Strategies

Method	Description	Example
Trial and error	Continue trying different solutions until problem is solved	Restarting phone, turning off WiFi, turning off bluetooth in order to determine why your phone is malfunctioning
Algorithm	Step-by-step problem-solving formula	Instruction manual for installing new software on your computer
Heuristic	General problem-solving framework	Working backwards; breaking a task into steps

Another type of strategy is an algorithm. An algorithm is a problem-solving formula that provides you with step-by-step instructions used to achieve a desired outcome (Kahneman, 2011). You can think of an algorithm as a recipe with highly detailed instructions that produce the same result every time they are performed. Algorithms are used frequently in our everyday lives, especially in computer science. When you run a search on the Internet, search engines like Google use algorithms to decide which entries will appear first in your list of results. Facebook also uses algorithms to decide which posts to display on your newsfeed. Can you identify other situations in which algorithms are used?

A heuristic is another type of problem solving strategy. While an algorithm must be followed exactly to produce a correct result, a heuristic is a general problem-solving framework (Tversky & Kahneman, 1974). You can think of these as mental shortcuts that are used to solve problems. A "rule of thumb" is an example of a heuristic. Such a rule saves the person time and energy when making a decision, but despite its time-saving characteristics, it is not always the best method for making a rational decision. Different types of heuristics are used in different types of situations, but the impulse to use a heuristic occurs when one of five conditions is met (Pratkanis, 1989):

- When one is faced with too much information
- When the time to make a decision is limited
- When the decision to be made is unimportant
- When there is access to very little information to use in making the decision
- When an appropriate heuristic happens to come to mind in the same moment

Working backwards is a useful heuristic in which you begin solving the problem by focusing on the end result. Consider this example: You live in Washington, D.C. and have been invited to a wedding at 4 PM on Saturday in Philadelphia. Knowing that Interstate 95 tends to back up any day of the week, you need to plan your route and time your departure accordingly. If you want to be at the wedding service by 3:30 PM, and it takes 2.5 hours to get to Philadelphia without traffic, what time should you leave your house? You use the working backwards heuristic to plan the events of your day on a regular basis, probably without even thinking about it.

Another useful heuristic is the practice of accomplishing a large goal or task by breaking it into a series of smaller steps. Students often use this common method to complete a large research project or long essay for school. For example, students typically brainstorm, develop a thesis or main topic, research the chosen topic, organize their information into an outline, write a rough draft, revise and edit the rough draft, develop a final draft, organize the references list, and proofread their work before turning in the project. The large task becomes less overwhelming when it is broken down into a series of small steps.

Problem Solving as a Search Problem

The idea of regarding problem solving as a search problem originated from Alan Newell and Herbert Simon while trying to design computer programs which could solve certain problems. This led them to develop a program called General Problem Solver which was able to solve any well-defined problem by creating heuristics on the basis of the user's input. This input consisted of objects and operations that could be done on them.

As we already know, every problem is composed of an initial state, intermediate states and a goal state (also: desired or final state), while the initial and goal states characterise the situations before and after solving the problem. The intermediate states describe any possible situation between initial and goal state. The set of operators builds up the transitions between the states. A solution is defined as the sequence of operators which leads from the initial state across intermediate states to the goal state.

The simplest method to solve a problem, defined in these terms, is to search for a solution by just trying one possibility after another (also called trial and error).

As already mentioned above, an organised search, following a specific strategy, might not be helpful for finding a solution to some ill-defined problem, since it is impossible to formalise such problems in a way that a search algorithm can find a solution.

As an example we could just take Knut and his essay: he has to find out about his own opinion and formulate it and he has to make sure he understands the sources texts. But there are no predefined operators he can use, there is no panacea how to get to an opinion and even not how to write it down.

Means-End Analysis

In Means-End Analysis you try to reduce the difference between initial state and goal state by creating sub-goals until a sub-goal can be reached directly (in computer science, what is called recursion works on this basis).

An example of a problem that can be solved by Means-End Analysis is the "Towers of Hanoi"

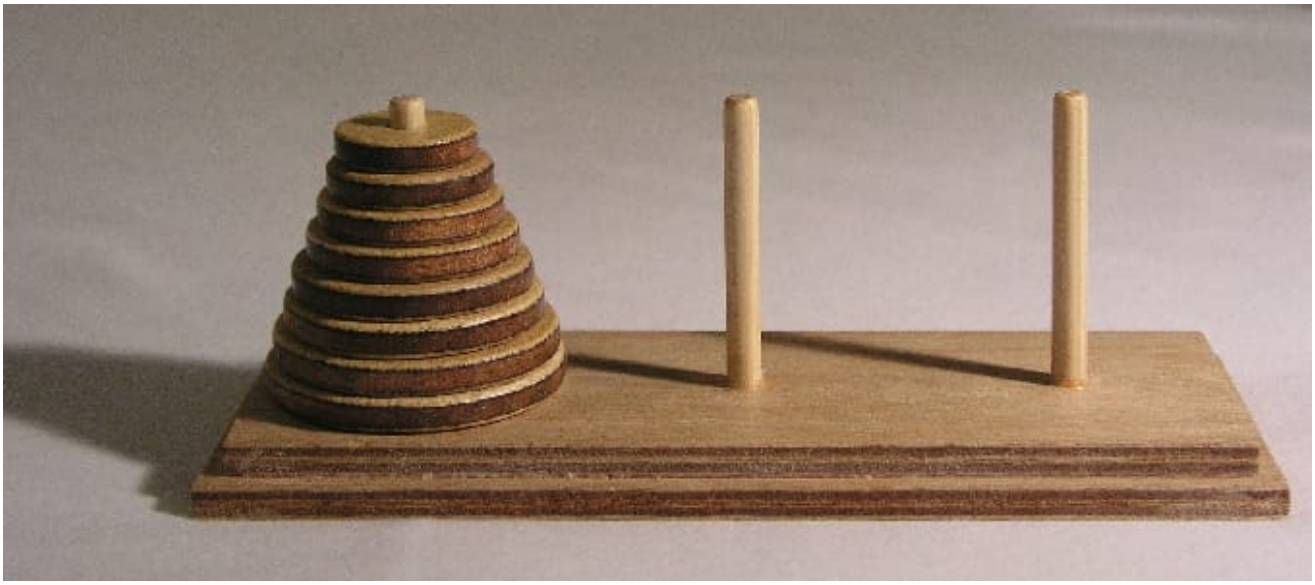

Figure 6.20.12.2: Towers of Hanoi with 8 discs – A well defined problem (image from Wikimedia Commons; https://commons.wikimedia.org/wiki/F..._of_Hanoi.jpeg, by User:Evanherk.licensed under the Creative Commons Attribution-Share Alike 3.0 Unported license).

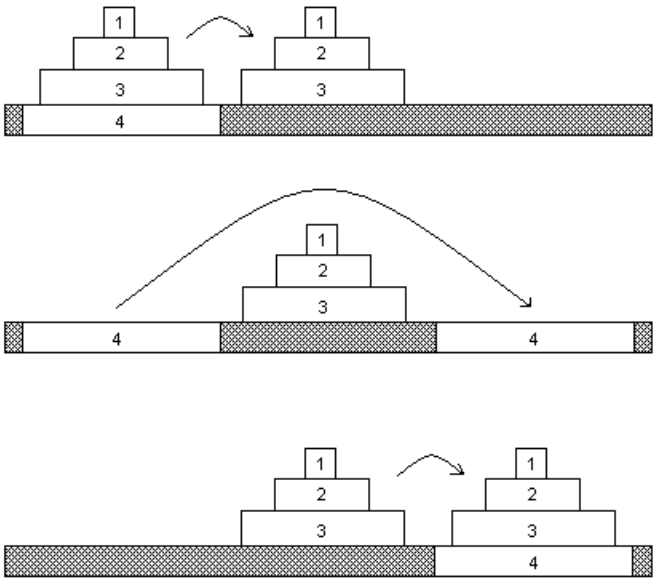

The initial state of this problem is described by the different sized discs being stacked in order of size on the first of three pegs (the “start-peg“). The goal state is described by these discs being stacked on the third pegs (the “end-peg“) in exactly the same order.

Figure 6.20.12.3: This animation shows the solution of the game "Tower of Hanoi" with four discs. (image from Wikimedia Commons; https://commons.wikimedia.org/wiki/F...of_Hanoi_4.gif; by André Karwath aka Aka; licensed under the Creative Commons Attribution-Share Alike 2.5 Generic license).

There are three operators:

- You are allowed to move one single disc from one peg to another one
- You are only able to move a disc if it is on top of one stack
- A disc cannot be put onto a smaller one.

In order to use Means-End Analysis we have to create sub-goals. One possible way of doing this is described in the picture:

1. Moving the discs lying on the biggest one onto the second peg.

2. Shifting the biggest disc to the third peg.

3. Moving the other ones onto the third peg, too

You can apply this strategy again and again in order to reduce the problem to the case where you only have to move a single disc – which is then something you are allowed to do.

Strategies of this kind can easily be formulated for a computer; the respective algorithm for the Towers of Hanoi would look like this:

1. move n-1 discs from A to B

2. move disc #n from A to C

3. move n-1 discs from B to C

where n is the total number of discs, A is the first peg, B the second, C the third one. Now the problem is reduced by one with each recursive loop.

Means-end analysis is important to solve everyday-problems – like getting the right train connection: You have to figure out where you catch the first train and where you want to arrive, first of all. Then you have to look for possible changes just in case you do not get a direct connection. Third, you have to figure out what are the best times of departure and arrival, on which platforms you leave and arrive and make it all fit together.

Analogies

Analogies describe similar structures and interconnect them to clarify and explain certain relations. In a recent study, for example, a song that got stuck in your head is compared to an itching of the brain that can only be scratched by repeating the song over and over again. Useful analogies appears to be based on a psychological mapping of relations between two very disparate types of problems that have abstract relations in common. Applied to STEM problems, Gray and Holyoak (2021) state: "Analogy is a powerful tool for fostering conceptual understanding and transfer in STEM and other fields. Well-constructed analogical comparisons focus attention on the causal-relational structure of STEM concepts, and provide a powerful capability to draw inferences based on a well-understood source domain that can be applied to a novel target domain." Note that similarity between problems of different types in their abstract relations, such as causation, is a key feature of reasoning, problem-solving and inference when forming and using analogies. Recall the discussion of general intelligence in module 14.2. There, similarity relations, causal relations, and predictive relations between events were identified as key components of general intelligence, along with ability to visualize in imagination possible future actions and their probable outcomes prior to commiting to actual behavior in the physical world (Koenigshofer, 2017).

Restructuring by Using Analogies

One special kind of restructuring, the way already mentioned during the discussion of the Gestalt approach, is analogical problem solving. Here, to find a solution to one problem – the so called target problem, an analogous solution to another problem – the source problem, is presented.

An example for this kind of strategy is the radiation problem posed by K. Duncker in 1945:

As a doctor you have to treat a patient with a malignant, inoperable tumour, buried deep inside the body. There exists a special kind of ray, which is perfectly harmless at a low intensity, but at the sufficient high intensity is able to destroy the tumour – as well as the healthy tissue on his way to it. What can be done to avoid the latter?

When this question was asked to participants in an experiment, most of them couldn't come up with the appropriate answer to the problem. Then they were told a story that went something like this:

A General wanted to capture his enemy's fortress. He gathered a large army to launch a full-scale direct attack, but then learned, that all the roads leading directly towards the fortress were blocked by mines. These roadblocks were designed in such a way, that it was possible for small groups of the fortress-owner's men to pass them safely, but every large group of men would initially set them off. Now the General figured out the following plan: He divided his troops into several smaller groups and made each of them march down a different road, timed in such a way, that the entire army would reunite exactly when reaching the fortress and could hit with full strength.

Here, the story about the General is the source problem, and the radiation problem is the target problem. The fortress is analogous to the tumour and the big army corresponds to the highly intensive ray. Consequently a small group of soldiers represents a ray at low intensity. The solution to the problem is to split the ray up, as the general did with his army, and send the now harmless rays towards the tumour from different angles in such a way that they all meet when reaching it. No healthy tissue is damaged but the

tumour itself gets destroyed by the ray at its full intensity.

M. Gick and K. Holyoak presented Duncker's radiation problem to a group of participants in 1980 and 1983. Only 10 percent of them were able to solve the problem right away, 30 percent could solve it when they read the story of the general before. After given an additional hint – to use the story as help – 75 percent of them solved the problem.

With this results, Gick and Holyoak concluded, that analogical problem solving depends on three steps:

1. **Noticing** that an analogical connection exists between the source and the target problem.
2. **Mapping** corresponding parts of the two problems onto each other (fortress → tumour, army → ray, etc.)
3. **Applying** the mapping to generate a parallel solution to the target problem (using little groups of soldiers approaching from different directions → sending several weaker rays from different directions)

Schemas

The concept that links the target problem with the analogy (the “source problem“) is called problem schema. Gick and Holyoak obtained the activation of a schema on their participants by giving them two stories and asking them to compare and summarize them. This activation of problem schemata is called “schema induction“.

The two presented texts were picked out of six stories which describe analogical problems and their solution. One of these stories was "The General."

After solving the task the participants were asked to solve the radiation problem. The experiment showed that in order to solve the target problem reading of two stories with analogical problems is more helpful than reading only one story: After reading two stories 52% of the participants were able to solve the radiation problem (only 30% were able to solve it after reading only one story, namely: “The General“).

The process of using a schema or analogy, i.e. applying it to a novel situation, is called *transduction*. One can use a common strategy to solve problems of a new kind.

To create a good schema and finally get to a solution using the schema is a problem-solving skill that requires practice and some background knowledge.

How Do Experts Solve Problems?

With the term expert we describe someone who devotes large amounts of his or her time and energy to one specific field of interest in which he, subsequently, reaches a certain level of mastery. It should not be of surprise that experts tend to be better in solving problems in their field than novices (people who are beginners or not as well trained in a field as experts) are. They are faster in coming up with solutions and have a higher success rate of right solutions. But what is the difference between the way experts and non-experts solve problems? Research on the nature of expertise has come up with the following conclusions:

When it comes to problems that are situated outside the experts' field, their performance often does not differ from that of novices.

Knowledge: An experiment by Chase and Simon (1973a, b) dealt with the question how well experts and novices are able to reproduce positions of chess pieces on chessboards when these are presented to them only briefly. The results showed that experts were far better in reproducing actual game positions, but that their performance was comparable with that of novices when the chess pieces were arranged randomly on the board. Chase and Simon concluded that the superior performance on actual game positions was due to the ability to recognize familiar patterns: A chess expert has up to 50,000 patterns stored in his memory. In comparison, a good player might know about 1,000 patterns by heart and a novice only few to none at all. This very detailed knowledge is of crucial help when an expert is confronted with a new problem in his field. Still, it is not pure size of knowledge that makes an expert more successful. Experts also organise their knowledge quite differently from novices.

Organization: In 1982 M. Chi and her co-workers took a set of 24 physics problems and presented them to a group of physics professors as well as to a group of students with only one semester of physics. The task was to group the problems based on their similarities. As it turned out the students tended to group the problems based on their surface structure (similarities of objects used in the problem, e.g. on sketches illustrating the problem), whereas the professors used their deep structure (the general physical principles that underlay the problems) as criteria. By recognizing the actual structure of a problem experts are able to

connect the given task to the relevant knowledge they already have (e.g. another problem they solved earlier which required the same strategy).

Analysis: Experts often spend more time analyzing a problem before actually trying to solve it. This way of approaching a problem may often result in what appears to be a slow start, but in the long run this strategy is much more effective. A novice, on the other hand, might start working on the problem right away, but often has to realise that he reaches dead ends as he chose a wrong path in the very beginning.

Creative Cognition

Divergent Thinking

The term divergent thinking describes a way of thinking that does not lead to one goal, but is open-ended. Problems that are solved this way can have a large number of potential 'solutions' of which none is exactly 'right' or 'wrong', though some might be more suitable than others.

Solving a problem like this involves indirect and productive thinking and is mostly very helpful when somebody faces an ill-defined problem, i.e. when either initial state or goal state cannot be stated clearly and operators are either insufficient or not given at all.

The process of divergent thinking is often associated with creativity, and it undoubtedly leads to many creative ideas. Nevertheless, researches have shown that there is only modest correlation between performance on divergent thinking tasks and other measures of creativity. Additionally it was found that in processes resulting in original and practical inventions things like searching for solutions, being aware of structures and looking for analogies are heavily involved, too.

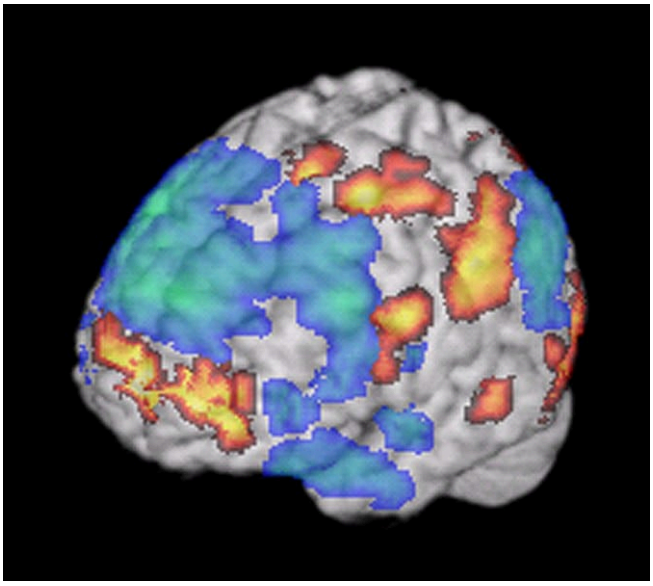

Figure 6.20.12.4: functional MRI images of the brains of musicians playing improvised jazz revealed that a large brain region involved in monitoring one's performance shuts down during creative improvisation, while a small region involved in organizing self-initiated thoughts and behaviors is highly activated (Image and modified caption from Wikimedia Commons. File:Creative Improvisation (24130148711).jpg; https://commons.wikimedia.org/wiki/F...130148711).jpg; by NIH Image Gallery; *As a work of the U.S. federal government, the image is in the* ***public domain***.

Convergent Thinking

Convergent thinking patterns are problem solving techniques that unite different ideas or fields to find a solution. The focus of this mindset is speed, logic and accuracy, also identification of facts, reapplying existing techniques, gathering information. The most important factor of this mindset is: there is only one correct answer. You only think of two answers, namely right or wrong. This type of thinking is associated with certain science or standard procedures. People with this type of thinking have logical thinking, are able to memorize patterns, solve problems and work on scientific tests. Most school subjects sharpen this type of

thinking ability.

Research shows that the creative process involves both types of thought processes.

Brain Mechanisms in Problem Solving

Presenting Neurophysiology in its entirety would be enough to fill several books. Instead, let's focus only on the aspects that are especially relevant to problem solving. Still, this topic is quite complex and problem solving cannot be attributed to one single brain area. Rather there are systems or networks of several brain areas working together to perform a specific problem solving task. This is best shown by an example, playing chess:

Task	Location of Brain activity
• Identifying chess pieces • determining location of pieces • Thinking about making a move • Remembering a pieces move • Planning and executing strategies	• Pathway from Occipital to Temporal Lobe (also called the "what"-pathway of visual processing) • Pathway from Occipital to parietal Lobe (also called the "where"-pathway of visual processing) • Premotor area • Hippocampus (forming new memories) • Prefrontal cortex

Table 2: Brain areas involved in a complex cognitive task.

One of the key tasks, namely **planning and executing strategies**, is performed by the prefrontal cortex (PFC), which also plays an important role for several other tasks correlated with problem solving. This can be made clear from the effects of damage to the PFC on ability to solve problems.

Patients with a lesion in this brain area have difficulty switching from one behavioral pattern to another. A well known example is the wisconsin card-sorting task. A patient with a PFC lesion who is told to separate all blue cards from a deck, would continue sorting out the blue ones, even if the experimenter next told him to sort out all brown cards. Transferred to a more complex problem, this person would most likely fail, because he is not flexible enough to change his strategy after running into a dead end or when the problem changes.

Another example comes from a young homemaker, who had a tumour in the frontal lobe. Even though she was able to cook individual dishes, preparing a whole family meal was an impossible task for her.

Mushiake et al. (2009) note that to achieve a goal in a complex environment, such as problem-solving situations like those above, we must plan multiple steps of action. When planning a series of actions, we have to anticipate future outcomes that will occur as a result of each action, and, in addition, we must mentally organize the temporal sequence of events in order to achieve the goal. These researchers investigated the role of **lateral prefrontal cortex** (PFC) in problem solving in monkeys. They found that "PFC neurons reflected final goals and immediate goals during the preparatory period. [They] also found some PFC neurons reflected each of *all* the forthcoming steps of actions during the preparatory period and they increased their [neural] activity step by step during the execution period. [Furthermore, they] found that the transient increase in synchronous activity of PFC neurons was involved in goal subgoal transformations. [They concluded] that the PFC is involved primarily in the dynamic representation of multiple future events that occur as a consequence of behavioral actions in problem-solving situations" (Mushiake et al., 2009, p. 1). In other words, the **prefrontal cortex** represents in our imagination the sequence of events following each step that we take in solving a particular problem, guiding us step by step to the solution.

As the examples above illustrate, the structure of our brain is of great importance regarding problem solving, i.e. cognitive life.

But how was our cognitive apparatus designed? How did perception-action integration as a central species-specific property of humans come about? The answer, as argued extensively in earlier sections of this book, is, of course, natural selection and other forces of genetic evolution. Clearly, animals and humans with genes facilitating brain organization that led to good problem solving skills would be favored by natural selection over genes responsible for brain organization less adept at solving problems. We became equipped with brains organized for effective problem solving because flexible abilities to solve a wide range of problems presented by the environment enhanced ability to survive, to compete for resources, to escape predators, and to reproduce (see chapter on Evolution and Genetics in this text).

In short, good problem solving mechanisms in brains designed for the real world gave a competitive advantage and increased biological fitness. Consequently, humans (and many other animals to a lesser degree) have "innate ability to problem-solve in the real world. Solving real world problems in real time given constraints posed by one's environment is crucial for survival . . . Real world problem solving (RWPS) is different from those that occur in a classroom or in a laboratory during an experiment. They are often dynamic and discontinuous, accompanied by many starts and stops . . . Real world problems are typically ill-defined, and even when they are well-defined, often have open-ended solutions . . . RWPS is quite messy and involves a tight interplay between problem solving, creativity, and insight . . . In psychology and neuroscience, *problem-solving* broadly refers to the inferential steps taken by an agent [human, animal, or computer] that leads from a given state of affairs to a desired goal state" (Sarathy, 2018, p. 261-2). According to Sarathy (2018), the initial stage of RWPS requires defining the problem and generating a representation of it in working memory. This stage involves activation of parts of the "**prefrontal cortex (PFC)**, **default mode network (DMN)**, and the **dorsal anterior cingulate cortex (dACC)**." The **DMN includes the medial prefrontal cortex, posterior cingulate cortex, and the inferior parietal lobule.** Other **structures sometimes considered part of the network are the lateral temporal cortex, hippocampal formation, and the precuneus.** This network of structures is called "default mode" because these structures show increased activity when one is ***not*** engaged in focused, attentive, goal-directed actions, but rather a "resting state" (a baseline default state) and show decreased neural activity when one is focused and attentive to a particular goal-directed behavior (Raichle, et al., 2001).

Moral Reasoning

Jeurissen, et al., (2014) examined a special type of reasoning, moral reasoning, using TMS (Transcranial Magnetic Stimulation). The **dorsolateral prefrontal cortex (DLPFC)** and **temporal-parietal junction (TPJ)** have both been shown to be involved in moral judgments, but this study by Jeurissen, et al., (2014) uses TMS to tease out the different roles these brain areas play in different scenarios involving moral dilemmas.

Moral dilemmas have been categorized by researchers as **moral-impersonal** (e.g., trolley or switch dilemma--**save** the lives of **five** workmen at the expense of the life of **one by switching train** to another track) and **moral-personal** dilemmas (e.g., footbridge dilemma--**push a strange**r in front of a train **to save** the lives of **five** others). In the first scenario, the person just pulls a switch resulting in death of one person to save five, but in the second, the person pushes the victim to their death to save five others.

Dual-process theory proposes that moral decision-making involves two components: an **automatic emotional response** and a **voluntary** application of a **utilitarian decision-rule** (in this case, one death to save five people is worth it). The thought of being responsible for the death of another person elicits an aversive emotional response, but at the same time, cognitive reasoning favors the utilitarian option. **Decision making and social cognition** are often **associated with** the **DLPFC. Neurons** in the **prefrontal cortex** have been found to be involved in cost-benefit analysis and categorize stimuli based on the predicted consequences.

Theory-of-mind (TOM) is a cognitive mechanism which is used when one tries to understand and explain the knowledge, beliefs, and intention of others. **TOM** and **empathy** are often associated with **TPJ functioning**.

In the article by Jeurissen, et al., (2014), brain activity is measured by BOLD. BOLD refers to **Blood-oxygen-level-dependent imaging**, or **BOLD-contrast imaging,** which is a way to measure neural activity in different brain areas in MRI images**.**

Greene et al., 2001 (Links to an external site.), 2004 (Links to an external site.) reported that activity in the **prefrontal cortex** is thought to be important for the **cognitive reasoning process**, which can counteract the automatic emotional response that occurs in moral dilemmas like the one in Jeurissen, et al., (2014). Greene et al. (2001) (Links to an external site.) found that the **medial portions** of the **medial frontal gyrus,** the **posterior cingulate gyrus,** and the **bilateral angular gyrus** showed a **higher BOLD** response in the **moral-personal condition** than the moral-impersonal condition. The **right middle frontal gyrus** and the **bilateral parietal lobes** showed a **lower BOLD** response in the **moral-personal condition** than in the moral impersonal. Furthermore, Greene et al. (2004) (Links to an external site.) showed an **increased BOLD** response for the bilateral **amygdale** in

personal compared to the impersonal dilemmas.

Given the role of the prefrontal cortex in moral decision-making, Jeurissen, et al., (2014) **hypothesized** that when **magnetically stimulating prefrontal cortex**, they will **selectively influence** the decision process of the **moral personal dilemmas** because the **cognitive reasoning** for which the **DLPFC** is important is **disrupted**, thereby **releasing** the **emotional component** making it more influential in the resolution of the dilemma. Because the **activity** in the **TPJ** is related to **emotional processing and theory of mind** (Saxe and Kanwisher, 2003 (Links to an external site.); Young et al., 2010 (Links to an external site.)), Jeurissen, et al., (2014) **hypothesized** that when **magnetically stimulating** this area, the **TPJ,** during a moral decision, this will **selectively influence** the decision process of **moral-impersonal** dilemmas.

Results of this study by Jeurissen, et al., (2014) showed an **important role** of the **TPJ** in **moral judgment**. Experiments using fMRI (Greene et al., 2004 (Links to an external site.)), have found the **cingulate cortex** to be involved in **moral judgment**. In earlier studies, the cingulate cortex was found to be involved in the **emotional** response. Since the **moral-personal** dilemmas are **more emotionall**y salient, the **higher activity** observed for **TPJ** in the **moral-personal** condition **(more emotional)** is **consistent with this** view. **Another area** that is hypothesized to be associated with the **emotional** response is the **temporal cortex**. In this study by Jeurissen, et al., (2014)**, magnetic stimulation** of the **right DLPFC** and **right TPJ** shows **roles for right DLPFC (reasoning and utilitarian) and right TPJ (emotion) in moral impersonal and moral personal dilemmas respectively. TMS over the right DLPFC (disrupting neural activity here) leads to** behavior changes consistent with **less cognitive control over emotion**. After right DLPFC stimulation, participants show less feelings of regret than after magnetic stimulation of the right TPJ. This last finding indicates that the **right DLPFC** is involved in **evaluating** the **outcome** of the decision process. In summary, this experiment by Jeurissen, et al., (2014) adds to evidence of a critical role of **right DLPFC and right TPJ** in **moral decision-making** and supports that hypothesis that the **former** is involved in judgments based on **cognitive reasoning** and **anticipation of outcomes,** whereas the **latter** is involved in **emotional processing** related to **moral dilemmas.**

Summary

Many different strategies exist for solving problems. Typical strategies include trial and error, applying algorithms, and using heuristics. To solve a large, complicated problem, it often helps to break the problem into smaller steps that can be accomplished individually, leading to an overall solution. The brain mechanisms involved in problem solving vary to some degree depending upon the sensory modalities involved in the problem and its solution, however, the prefrontal cortex is one brain region that appears to be centrally involved in all problem-solving. The prefrontal cortex is required for flexible shifts in attention, for representing the problem in working memory, and for holding steps in problem solving in working memory along with representations of future consequences of those actions permitting planning and execution of plans. Also implicated is the Default Mode Network (DMN) including medial prefrontal cortex, posterior cingulate cortex, and the inferior parietal module, and sometimes the lateral temporal cortex, hippocampus, and the precuneus. Moral reasoning involves a different set of brain areas, primarily the dorsolateral prefrontal cortex (DLPFC) and temporal-parietal junction (TPJ).

Review Questions

1. A specific formula for solving a problem is called _____.
   A. an algorithm
   B. a heuristic
   C. a mental set
   D. trial and error
2. A mental shortcut in the form of a general problem-solving framework is called _____.
   A. an algorithm
   B. a heuristic
   C. a mental set
   D. trial and error

Categories and Concepts

By Gregory Murphy, New York University

People form mental concepts of categories of objects, which permit them to respond appropriately to new objects they encounter. Most concepts cannot be strictly defined but are organized around the “best” examples or prototypes, which have the properties most common in the category. Objects fall into many different categories, but there is usually a most salient one, called the basic-level category, which is at an intermediate level of specificity (e.g., chairs, rather than furniture or desk chairs). Concepts are closely related to our knowledge of the world, and people can more easily learn concepts that are consistent with their knowledge. Theories of concepts argue either that people learn a summary description of a whole category or else that they learn exemplars of the category. Recent research suggests that there are different ways to learn and represent concepts and that they are accomplished by different neural systems.

Learning Objectives

1. Understand the problems with attempting to define categories.
2. Understand typicality and fuzzy category boundaries.
3. Learn about theories of the mental representation of concepts.
4. Learn how knowledge may influence concept learning.

Introduction

Figure 6.20.12.2: Although you've (probably) never seen this particular truck before, you know a lot about it because of the knowledge you've accumulated in the past about the features in the category of trucks. [Image: CC0 Public Domain, https://goo.gl/m25gce]

Consider the following set of objects: some dust, papers, a computer monitor, two pens, a cup, and an orange. What do these things have in common? Only that they all happen to be on my desk as I write this. This set of things can be considered a **category**, a set of objects that can be treated as equivalent in some way. But, most of our categories seem much more informative—they share many properties. For example, consider the following categories: trucks, wireless devices, weddings, psychopaths, and trout. Although the objects in a given category are different from one another, they have many commonalities. When you know something is a truck, you know quite a bit about it. The psychology of categories concerns how people learn, remember, and use informative categories such as trucks or psychopaths.

The mental representations we form of categories are called **concepts**. There is a category of trucks in the actual physical world, and I also have a concept of trucks in my head. We assume that people's concepts correspond more or less closely to the actual category, but it can be useful to distinguish the two, as when someone's concept is not really correct.

Concepts are at the core of intelligent behavior. We expect people to be able to know what to do in new situations and when confronting new objects. If you go into a new classroom and see chairs, a blackboard, a projector, and a screen, you know what these things are and how they will be used. You'll sit on one of the chairs and expect the instructor to write on the blackboard or project something onto the screen. You do this *even if you have never seen any of these particular objects before*, because you have concepts of classrooms, chairs, projectors, and so forth, that tell you what they are and what you're supposed to do with them. Furthermore, if someone tells you a new fact about the projector—for example, that it has a halogen bulb—you are likely to extend this fact to other projectors you encounter. In short, *concepts allow* you to extend what you have learned about a limited number of objects to a potentially infinite set of entities (i.e. *generalization*). Notice how *categories and concepts arise from similarity, one of the abstract features of the world that has been genetically internalized into the brain during evolution*, creating *an innate disposition of brains to search for and to represent groupings of similar things, forming one component of general intelligence*. One property of the human brain that distinguishes us from other animals is the high degrees of abstraction in similarity relations that the human brain is capable of encoding compared to the brains of non-human animals (Koenigshofer, 2017).

Simpler organisms, such as *animals and human infants, also have concepts* (Mareschal, Quinn, & Lea, 2010). Squirrels may have

a concept of predators, for example, that is specific to their own lives and experiences. However, animals likely have many fewer concepts and cannot understand complex concepts such as mortgages or musical instruments.

You know thousands of categories, most of which you have learned without careful study or instruction. Although this accomplishment may seem simple, we know that it isn't, because it is difficult to program computers to solve such intellectual tasks. If you teach a learning program that a robin, a swallow, and a duck are all birds, it may not recognize a cardinal or peacock as a bird. However, this shortcoming in computers may be at least partially overcome when the type of processing used is parallel distributed processing as employed in artificial neural networks (Koenigshofer, 2017), discussed in this chapter. As we'll shortly see, the problem for computers is that objects in categories are often surprisingly diverse.

Nature of Categories

Figure 6.20.12.3: Here is a very good dog, but one that does not fit perfectly into a well-defined category where all dogs have four legs. [Image: State Farm, https://goo.gl/KHtu6N, CC BY 2.0, https://goo.gl/BRvSA7]

Traditionally, it has been assumed that categories are *well-defined*. This means that you can give a definition that specifies what is in and out of the category. Such a definition has two parts. First, it provides the *necessary features* for category membership: What must objects have in order to be in it? Second, those features must be *jointly sufficient* for membership: If an object has those features, then it is in the category. For example, if I defined a dog as a four-legged animal that barks, this would mean that every dog is four-legged, an animal, and barks, and also that anything that has all those properties is a dog.

Unfortunately, it has not been possible to find definitions for many familiar categories. Definitions are neat and clear-cut; the world is messy and often unclear. For example, consider our definition of dogs. In reality, not all dogs have four legs; not all dogs bark. I knew a dog that lost her bark with age (this was an improvement); no one doubted that she was still a dog. It is often possible to find some necessary features (e.g., all dogs have blood and breathe), but these features are generally not sufficient to determine category membership (you also have blood and breathe but are not a dog).

Even in domains where one might expect to find clear-cut definitions, such as science and law, there are often problems. For example, many people were upset when Pluto was downgraded from its status as a planet to a dwarf planet in 2006. Upset turned to outrage when they discovered that there was no hard-and-fast definition of planethood: "Aren't these astronomers scientists? Can't they make a simple definition?" In fact, they couldn't. After an astronomical organization tried to make a definition for planets, a number of astronomers complained that it might not include accepted planets such as Neptune and refused to use it. If everything looked like our Earth, our moon, and our sun, it would be easy to give definitions of planets, moons, and stars, but the universe has not conformed to this ideal.

Fuzzy Categories

Borderline Items

Experiments also showed that the psychological assumptions of well-defined categories were not correct. Hampton (1979) asked subjects to judge whether a number of items were in different categories. He did not find that items were either clear members or clear nonmembers. Instead, he found many items that were just barely considered category members and others that were just barely not members, with much disagreement among subjects. Sinks were barely considered as members of the kitchen utensil category, and sponges were barely excluded. People just included seaweed as a vegetable and just barely excluded tomatoes and gourds. Hampton found that members and nonmembers formed a continuum, with no obvious break in people's membership judgments. If categories were well defined, such examples should be very rare. Many studies since then have found such *borderline members* that are not clearly in or clearly out of the category.

Furniture	Fruit
chair	orange
table	banana
desk	pear
bookcase	plum
lamp	strawberry
cushion	pineapple
rug	lemon
stove	honeydew
picture	date
vase	tomato

Table 1. Examples of two categories, with members ordered by typicality (from Rosch & Mervis, 1975)

McCloskey and Glucksberg (1978) found further evidence for borderline membership by asking people to judge category membership twice, separated by two weeks. They found that when people made repeated category judgments such as "Is an olive a fruit?" or "Is a sponge a kitchen utensil?" they changed their minds about borderline items—up to 22 percent of the time. So, not only do people disagree with one another about borderline items, they disagree with themselves! As a result, researchers often say that categories are *fuzzy*, that is, they have unclear boundaries that can shift over time.

Typicality

A related finding that turns out to be most important is that even among items that clearly are in a category, some seem to be "better" members than others (Rosch, 1973). Among birds, for example, robins and sparrows are very **typical**. In contrast, ostriches and penguins are very *atypical* (meaning not typical). If someone says, "There's a bird in my yard," the image you have will be of a smallish passerine bird such as a robin, not an eagle or hummingbird or turkey.

You can find out which category members are typical merely by asking people. Table 1 shows a list of category members in order of their rated typicality. Typicality is perhaps the most important variable in predicting how people interact with categories. The following text box is a partial list of what typicality influences.

We can understand the two phenomena of borderline members and typicality as two sides of the same coin. Think of the most typical category member: This is often called the category *prototype*. Items that are less and less similar to the prototype become less and less typical. At some point, these less typical items become so atypical that you start to doubt whether they are in the category at all. Is a rug really an example of furniture? It's in the home like chairs and tables, but it's also different from most furniture in its structure and use. From day to day, you might change your mind as to whether this atypical example is in or out of the category. So, changes in typicality ultimately lead to borderline members.

Influences of Typicality on Cognition
• **Typical items are judged category members more often** (Hampton, 1979).
• **Speed of categorization is faster for typical items** (Rips, Shoben, & Smith, 1973).
• **Typical members are learned before atypical ones** (Rosch & Mervis, 1975).
• **Learning a category is easier if typical examples are provided** (Mervis & Pani, 1980).
• **In language comprehension, references to typical members are understood more easily** (Garrod & Sanford, 1977).
• **In language production, people tend to say typical items before atypical ones (e.g., "apples and lemons" rather than "lemons and apples")** (Onishi, Murphy, & Bock, 2008).

Table 2:
Text Box 1

Source of Typicality

Intuitively, it is not surprising that robins are better examples of birds than penguins are, or that a table is a more typical kind of furniture than is a rug. But given that robins and penguins are known to be birds, why should one be more typical than the other? One possible answer is the frequency with which we encounter the object: We see a lot more robins than penguins, so they must be more typical. Frequency does have some effect, but it is actually not the most important variable (Rosch, Simpson, & Miller, 1976). For example, I see both rugs and tables every single day, but one of them is much more typical as furniture than the other.

The best account of what makes something typical comes from Rosch and Mervis's (1975) *family resemblance theory*. They proposed that items are likely to be typical if they (a) have the features that are frequent in the category and (b) do not have features frequent in other categories. Let's compare two extremes, robins and penguins. Robins are small flying birds that sing, live in nests in trees, migrate in winter, hop around on your lawn, and so on. Most of these properties are found in many other birds. In contrast, penguins do not fly, do not sing, do not live in nests or in trees, do not hop around on your lawn. Furthermore, they have properties that are common in other categories, such as swimming expertly and having wings that look and act like fins. These properties are more often found in fish than in birds.

Figure 6.20.12.4: When you think of “bird,” how closely does the robin resemble your general figure? [Image: CC0 Public Domain, https://goo.gl/m25gce]

According to Rosch and Mervis, then, it is not because a robin is a very common bird that makes it typical. Rather, it is because the robin has the shape, size, body parts, and behaviors that are very common (i.e. most similar) among birds—and not common among fish, mammals, bugs, and so forth.

In a classic experiment, Rosch and Mervis (1975) made up two new categories, with arbitrary features. Subjects viewed example after example and had to learn which example was in which category. Rosch and Mervis constructed some items that had features that were common in the category and other items that had features less common in the category. The subjects learned the first type of item before they learned the second type. Furthermore, they then rated the items with common features as more typical. In another experiment, Rosch and Mervis constructed items that differed in how many features were shared with a *different* category. The more features were shared, the longer it took subjects to learn which category the item was in. These experiments, and many later studies, support both parts of the family resemblance theory.

Category Hierarchies

Many important categories fall into *hierarchies*, in which more concrete categories are nested inside larger, abstract categories. For example, consider the categories: brown bear, bear, mammal, vertebrate, animal, entity. Clearly, all brown bears are bears; all bears are mammals; all mammals are vertebrates; and so on. Any given object typically does not fall into just one category—it could be in a dozen different categories, some of which are structured in this hierarchical manner. Examples of biological categories come to mind most easily, but within the realm of human artifacts, hierarchical structures can readily be found: desk chair, chair, furniture, artifact, object.

Brown (1958), a child language researcher, was perhaps the first to note that there seems to be a preference for which category we use to label things. If your office desk chair is in the way, you’ll probably say, “Move that chair,” rather than “Move that desk chair” or “piece of furniture.” Brown thought that the use of a single, consistent name probably helped children to learn the name for things. And, indeed, children’s first labels for categories tend to be exactly those names that adults prefer to use (Anglin, 1977).

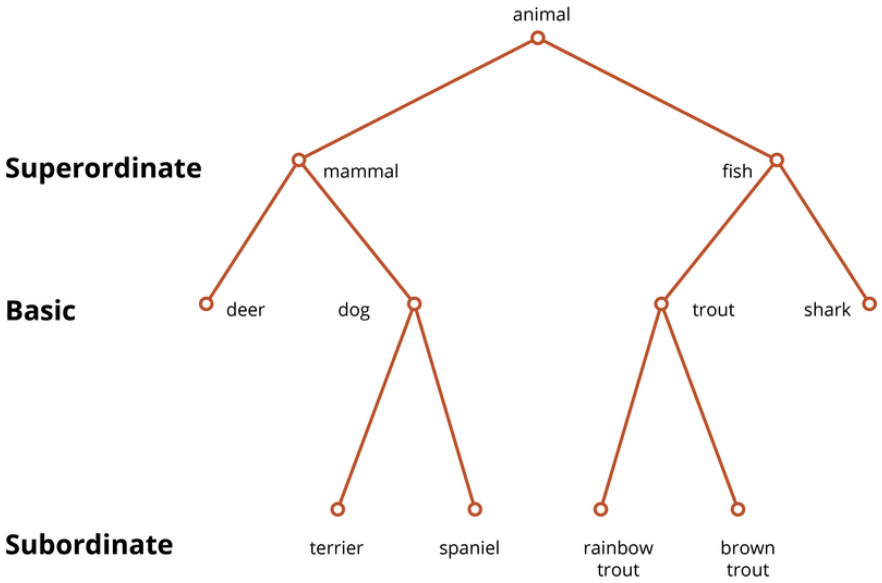

Figure 6.20.12.5: This is a highly simplified illustration of hierarchically organized categories, with the superordinate, basic, and subordinate levels labeled. Keep in mind that there may be even more specific subordinates (e.g., wire-haired terriers) and more general superordinates (e.g., living thing)

This preference is referred to as a preference for the **basic level of categorization**, and it was first studied in detail by Eleanor Rosch and her students (Rosch, Mervis, Gray, Johnson, & Boyes-Braem, 1976). The basic level represents a kind of Goldilocks effect, in which the category used for something is not too small (northern brown bear) and not too big (animal), but is just right (bear). The simplest way to identify an object's basic-level category is to discover how it would be labeled in a neutral situation. Rosch et al. (1976) showed subjects pictures and asked them to provide the first name that came to mind. They found that 1,595 names were at the basic level, with 14 more specific names (*subordinates*) used. Only once did anyone use a more general name (*superordinate*). Furthermore, in printed text, basic-level labels are much more frequent than most subordinate or superordinate labels (e.g., Wisniewski & Murphy, 1989).

The preference for the basic level is not merely a matter of labeling. Basic-level categories are usually easier to learn. As Brown noted, children use these categories first in language learning, and superordinates are especially difficult for children to fully acquire.[1] People are faster at identifying objects as members of basic-level categories (Rosch et al., 1976).

Rosch et al. (1976) initially proposed that basic-level categories cut the world at its joints, that is, merely reflect the big differences between categories like chairs and tables or between cats and mice that exist in the world. However, it turns out that which level is basic is not universal. North Americans are likely to use names like *tree, fish*, and *bird* to label natural objects. But people in less industrialized societies seldom use these labels and instead use more specific words, equivalent to *elm, trout,* and *finch* (Berlin, 1992). Because Americans and many other people living in industrialized societies know so much less than our ancestors did about the natural world, our basic level has "moved up" to what would have been the superordinate level a century ago. Furthermore, experts in a domain often have a preferred level that is more specific than that of non-experts. Birdwatchers see sparrows rather than just birds, and carpenters see roofing hammers rather than just hammers (Tanaka & Taylor, 1991). This all suggests that the preferred level is not (only) based on how different categories are in the world, but that people's knowledge and interest in the categories has an important effect.

One explanation of the basic-level preference is that basic-level categories are more *differentiated:* The category members are similar to one another, but they are different from members of other categories (Murphy & Brownell, 1985; Rosch et al., 1976). (The alert reader will note a similarity to the explanation of typicality I gave above. However, here we're talking about the entire category and not individual members.) Chairs are pretty similar to one another, sharing a lot of features (legs, a seat, a back, similar size and shape); they also don't share that many features with other furniture. Superordinate categories are not as useful because their members are not very similar to one another. What features are common to most furniture? There are very few. Subordinate categories are not as useful, because they're very similar to other categories: Desk chairs are quite similar to dining room chairs and easy chairs. As a result, it can be difficult to decide which subordinate category an object is in (Murphy & Brownell, 1985). Experts can differ from novices in which categories are the most differentiated, because they know different things about the categories, therefore changing how similar the categories are.

[1] This is a controversial claim, as some say that infants learn superordinates before anything else (Mandler, 2004).

However, if true, then it is very puzzling that older children have great difficulty learning the correct meaning of words for superordinates, as well as in learning artificial superordinate categories (Horton & Markman, 1980; Mervis, 1987). However, it seems fair to say that the answer to this question is not yet fully known.

Theories of Concept Representation

Now that we know these facts about the psychology of concepts, the question arises of how concepts are mentally represented. There have been two main answers. The first, somewhat confusingly called the *prototype theory* suggests that people have a *summary representation* of the category, a mental description that is meant to apply to the category as a whole. (The significance of *summary* will become apparent when the next theory is described.) This description can be represented as a set of *weighted features* (Smith & Medin, 1981). The features are weighted by their frequency in the category. For the category of birds, having wings and feathers would have a very high weight; eating worms would have a lower weight; living in Antarctica would have a lower weight still, but not zero, as some birds do live there.

Donker	Blegdav
has thick windows	has steel windows
is red	is purple
divers live there	farmers live there
is under water	is in the desert
get there by submarine	get there by submarine
has fish as pets	has polar bears as pets

Figure 6.20.12.6: If you were asked, “What kind of animal is this?” according to prototype theory, you would consult your summary representations of different categories and then select the one that is most similar to this image—probably a lizard! [Image: Adhi Rachdian, https://goo.gl/dQyUwf, CC BY 2.0, https://goo.gl/BRvSA7]

The idea behind prototype theory is that when you learn a category, you learn a general description that applies to the category as a whole: Birds have wings and usually fly; some eat worms; some swim underwater to catch fish. People can state these generalizations, and sometimes we learn about categories by reading or hearing such statements (“The kimodo dragon can grow to be 10 feet long”).

When you try to classify an item, you see how well it matches that weighted list of features. For example, if you saw something with wings and feathers fly onto your front lawn and eat a worm, you could (unconsciously) consult your concepts and see which ones contained the features you observed. This example possesses many of the highly weighted bird features, and so it should be easy to identify as a bird.

This theory readily explains the phenomena we discussed earlier. Typical category members have more, higher-weighted features. Therefore, it is easier to match them to your conceptual representation. Less typical items have fewer or lower-weighted features (and they may have features of other concepts). Therefore, they don’t match your representation as well (less similarity). This makes people less certain in classifying such items. Borderline items may have features in common with multiple categories or not be very close to any of them. For example, edible seaweed does not have many of the common features of vegetables but also is not close to any other food concept (meat, fish, fruit, etc.), making it hard to know what kind of food it is.

A very different account of concept representation is the *exemplar theory* (**exemplar** being a fancy name for an example; Medin & Schaffer, 1978). This theory denies that there is a summary representation. Instead, the theory claims that your concept of vegetables is remembered examples of vegetables you have seen. This could of course be hundreds or thousands of exemplars over the course of your life, though we don’t know for sure how many exemplars you actually remember.

How does this theory explain classification? When you see an object, you (unconsciously) compare it to the exemplars in your memory, and you judge how **similar** it is to exemplars in different categories. For example, if you see some object on your plate and want to identify it, it will probably activate memories of vegetables, meats, fruit, and so on. In order to categorize this object, you calculate how **similar** it is to each exemplar in your memory. These **similarity scores** are added up for each category. Perhaps the object is very similar to a large number of vegetable exemplars, moderately similar to a few fruit, and only minimally similar to some exemplars of meat you remember. These **similarity scores are compared, and the category with the highest score is chosen**.[2]

Why would someone propose such a theory of concepts? One answer is that in many experiments studying concepts, people learn concepts by seeing exemplars over and over again until they learn to classify them correctly. Under such conditions, it seems likely that people eventually memorize the exemplars (Smith & Minda, 1998). There is also evidence that ***close similarity*** to well-remembered objects has a **large effect on classification**. Allen and Brooks (1991) taught people to classify items by following a rule. However, they also had their subjects study the items, which were richly detailed. In a later test, the experimenters gave people new items that were very similar to one of the old items but were in a different category. That is, they changed one property so that the item no longer followed the rule. They discovered that people were often fooled by such items. **Rather than following the category rule they had been taught, they** seemed to **recognize the new item as being very similar** to an old one and so put it, incorrectly, into the same category.

Many experiments have been done to compare the prototype and exemplar theories. Overall, the **exemplar theory seems to have won most of these comparisons**. However, the experiments are somewhat limited in that they usually involve a small number of exemplars that people view over and over again. It is not so clear that exemplar theory can explain real-world classification in which people do not spend much time learning individual items (how much time do you spend studying squirrels? or chairs?). Also, given that some part of our knowledge of categories is learned through general statements we read or hear, it seems that there must be room for a summary description separate from exemplar memory.

Many researchers would now acknowledge that concepts are represented through multiple cognitive systems. For example, your knowledge of dogs may be in part through general descriptions such as “dogs have four legs.” But you probably also have strong memories of some exemplars (your family dog, Lassie) that influence your categorization. Furthermore, some categories also involve rules (e.g., a strike in baseball). How these systems work together is the subject of current study.

> [2] Actually, the decision of which category is chosen is more complex than this, but the details are beyond this discussion.

Knowledge

The final topic has to do with how concepts fit with our broader knowledge of the world. We have been talking very generally about people learning the features of concepts. For example, they see a number of birds and then learn that birds generally have wings, or perhaps they remember bird exemplars. From this perspective, it makes no difference what those exemplars or features are—people just learn them. But consider two possible concepts of buildings and their features in Table 2.

Donker	Blegdav
has thick windows	has steel windows
is red	is purple
divers live there	farmers live there
is under water	is in the desert
get there by submarine	get there by submarine
has fish as pets	has polar bears as pets

Table 3. Examples of two fictional concepts

Imagine you had to learn these two concepts by seeing exemplars of them, each exemplar having some of the features listed for the concept (as well as some idiosyncratic features). Learning the donker concept would be pretty easy. It seems to be a kind of underwater building, perhaps for deep-sea explorers. Its features seem to go together. In contrast, the blegdav doesn't really make sense. If it's in the desert, how can you get there by submarine, and why do they have polar bears as pets? Why would farmers live in the desert or use submarines? What good would steel windows do in such a building? This concept seems peculiar. In fact, if people are asked to learn new concepts that make sense, such as donkers, they learn them quite a bit faster than concepts such as blegdavs that don't make sense (Murphy & Allopenna, 1994). Furthermore, the features that seem connected to one another (such as being underwater and getting there by submarine) are learned better than features that don't seem related to the others (such as being red).

Such effects demonstrate that when we learn new concepts, we try to connect them to the knowledge we already have about the world. If you were to learn about a new animal that doesn't seem to eat or reproduce, you would be very puzzled and think that you must have gotten something wrong. By themselves, the prototype and exemplar theories don't predict this. They simply say that you learn descriptions or exemplars, and they don't put any constraints on what those descriptions or exemplars are. However, the *knowledge approach* to concepts emphasizes that concepts are meant to tell us about real things in the world, and so our knowledge of the world is used in learning and thinking about concepts.

We can see this effect of knowledge when we learn about new pieces of technology. For example, most people could easily learn about tablet computers (such as iPads) when they were first introduced by drawing on their knowledge of laptops, cell phones, and related technology. Of course, this reliance on past knowledge can also lead to errors, as when people don't learn about features of their new tablet that weren't present in their cell phone or expect the tablet to be able to do something it can't.

One important aspect of people's knowledge about categories is called **psychological essentialism** (Gelman, 2003; Medin & Ortony, 1989). People tend to believe that some categories—most notably natural kinds such as animals, plants, or minerals—have an underlying property that is found only in that category and that causes its other features. Most categories don't actually have essences, but this is sometimes a firmly held belief. For example, many people will state that there is something about dogs, perhaps some specific gene or set of genes, that all dogs have and that makes them bark, have fur, and look the way they do. Therefore, decisions about whether something is a dog do not depend only on features that you can easily see but also on the assumed presence of this cause.

Donker	Blegdav
has thick windows	has steel windows
is red	is purple
divers live there	farmers live there
is under water	is in the desert
get there by submarine	get there by submarine
has fish as pets	has polar bears as pets

Figure 6.20.12.7: Although it may seem natural that different species have an unchangeable "essence," consider evolution and everything's development from common ancestors. [Image: Marc Dragiewicz, https://goo.gl/E9v4eR, CC BY-NC-SA 2.0, https://goo.gl/Toc0ZF]

Belief in an essence can be revealed through experiments describing fictional objects. Keil (1989) described to adults and children a fiendish operation in which someone took a raccoon, dyed its hair black with a white stripe down the middle, and implanted a "sac of super-smelly yucky stuff" under its tail. The subjects were shown a picture of a skunk and told that this is now what the animal looks like. What is it? Adults and children over the age of 4 all agreed that the animal is still a raccoon. It may look and even act like a skunk, but a raccoon cannot change its stripes (or whatever!)—it will always be a raccoon.

Importantly, the same effect was not found when Keil described a coffeepot that was operated on to look like and function as a bird feeder. Subjects agreed that it was now a bird feeder. Artifacts don't have an essence.

Signs of essentialism include (a) objects are believed to be either in or out of the category, with no in-between; (b) resistance to change of category membership or of properties connected to the essence; and (c) for living things, the essence is passed on to progeny.

Essentialism is probably helpful in dealing with much of the natural world, but it may be less helpful when it is applied to humans. Considerable evidence suggests that people think of gender, racial, and ethnic groups as having essences, which serves to emphasize the difference between groups and even justify discrimination (Hirschfeld, 1996). Historically, group differences were described by inheriting the blood of one's family or group. "Bad blood" was not just an expression but a belief that negative properties were inherited and could not be changed. After all, if it is in the nature of "those people" to be dishonest (or clannish or athletic ...), then that could hardly be changed, any more than a raccoon can change into a skunk.

Research on categories of people is an exciting ongoing enterprise, and we still do not know as much as we would like to about how concepts of different kinds of people are learned in childhood and how they may (or may not) change in adulthood. Essentialism doesn't apply only to person categories, but it is one important factor in how we think of groups.

Summary

Concepts are central to our everyday thought. When we are planning for the future or thinking about our past, we think about specific events and objects in terms of their categories. If you're visiting a friend with a new baby, you have some expectations about what the baby will do, what gifts would be appropriate, how you should behave toward it, and so on. Knowing about the category of babies helps you to effectively plan and behave when you encounter this child you've never seen before. Such inferences from knowledge about a category are highly adaptive and an important component of thinking and intelligence.

Learning about those categories is a complex process that involves seeing exemplars (babies), hearing or reading general descriptions ("Babies like black-and-white pictures"), general knowledge (babies have kidneys), and learning the occasional rule (all babies have a rooting reflex). Current research is focusing on how these different processes take place in the brain. It seems likely that these different aspects of concepts are accomplished by different neural structures (Maddox & Ashby, 2004). However,

it is clear that the brain is genetically predisposed to seek out similarities in the environment and to represent groupings of things forming categories that can be used to make inferences about new instances of the category which have never been encountered before. In this way knowledge is organized and expectations from this knowledge allow improved adaptation to newly encountered environmental objects and situations by virtue of their similarity to a known category previously formed (Koenigshofer, 2017).

Another interesting topic is how concepts differ across cultures. As different cultures have different interests and different kinds of interactions with the world, it seems clear that their concepts will somehow reflect those differences. On the other hand, the structure of the physical world also imposes a strong constraint on what kinds of categories are actually useful. The interplay of culture, the environment, and basic cognitive processes in establishing concepts has yet to be fully investigated.

Discussion Questions

1. Pick a couple of familiar categories and try to come up with definitions for them. When you evaluate each proposal (a) is it in fact accurate as a definition, and (b) is it a definition that people might actually use in identifying category members?
2. For the same categories, can you identify members that seem to be “better” and “worse” members? What about these items makes them typical and atypical?
3. Going around the room, point to some common objects (including things people are wearing or brought with them) and identify what the basic-level category is for that item. What are superordinate and subordinate categories for the same items?
4. List some features of a common category such as tables. The knowledge view suggests that you know reasons for why these particular features occur together. Can you articulate some of those reasons? Do the same thing for an animal category.
5. Choose three common categories: a natural kind, a human artifact, and a social event. Discuss with class members from other countries or cultures whether the corresponding categories in their cultures differ. Can you make a hypothesis about when such categories are likely to differ and when they are not?

Vocabulary

Basic-level category
: The neutral, preferred category for a given object, at an intermediate level of specificity.

Category
: A set of entities that are equivalent in some way. Usually the items are similar to one another.

Concept
: The mental representation of a category.

Exemplar
: An example in memory that is labeled as being in a particular category.

Psychological essentialism
: The belief that members of a category have an unseen property that causes them to be in the category and to have the properties associated with it.

Typicality
: The difference in “goodness” of category members, ranging from the most typical (the prototype) to borderline members.

6.20.13: Chapter 14- The Brain and Evolution of Cognition

Learning Objectives

1. Briefly describe two general approaches to human cognition and its evolution: continuity vs. qualitative gap
2. List and briefly describe the theories of the evolution of human intelligence discussed in this module
3. Briefly explain the possible role of cooking in human brain evolution
4. List the brain areas associated most closely with cognition and intelligence in humans and in several other animal groups

Overview

In this module, we examine ideas about the evolutionary origins of human cognition and intelligence. A number of approaches to this issue are discussed. Attempts to understand the relationship between human intelligence and intelligence in other species can be divided into two primary categories. One is based on the assumption of continuity between intelligence in human and non-human animals. The second assumes that there is a qualitative gap between human and non-human animal intelligence. Factors hypothesized to be important in the evolution of human intelligence include bipedalism, encephalization and increased information processing capacity, greater density of cortical neurons per unit of cortical mass, absolute number of neurons in the brain, meat-eating, cooking, complex social organization, "mental time travel," anticipation of future drive states, greater capacity for abstraction and visualization of future, ability to envision future actions and their outcomes, anticipatory cognition, tool use, connectivity between cortical areas and cortical networks, niche construction, and language.

Evolution of Cognition

by Kenneth A. Koenigshofer, Ph.D., Chaffey College

Animals use a range of mechanisms to respond to environmental change. These vary in complexity and sophistication from simple reflexes and simple forms of learning such as habituation to complex learning, reasoning and cognition. Cognition in this comparative context refers to the ability to acquire, process, and retain information to guide behavior and decision-making toward successful adaptation (van Horik & Emery, 2011).

Two different approaches to human cognition have dominated research and theory about evolution of cognition and intelligence. One assumes **continuity** between human and animal cognition and that **differences are primarily a matter of degree**. The **second approach** hypothesizes that there are **major qualitative gaps** or jumps in cognition and intelligence between humans and animals.

Gibson (2002) argues that the differences in cognition and intelligence between humans and other animals are a matter of degree and thus assumes continuity. According to Gibson, human cognition and intelligence exceeds that of other animals because of "increased information processing capacities" of the human brain due to enlargement of the human neocortex, cerebellum, and basal ganglia. Gibson proposes that increased information processing capabilities of the human brain led to development of human language, social cognition, and tool-making.

Herculano-Houzel (2012) offers anatomical data which supports continuity between human and non-human primate brains, thereby supporting Gibson's views. She argues that the human brain is a "scaled-up primate brain." Regarding the cerebral cortex specifically, she notes that "primate cortices contain many more neurons than nonprimate cortices of a similar mass" (Herculano-Houzel, et al., 2015, p. 159). This greater density of cortical neurons in primate cerebral cortex compared to other mammal species means that "primates are . . . subject to a different scaling rule, with more neurons for a given body mass compared to other mammalian clades. . . while larger bodies have neurons in the the ROB [rest of the brain] that are on average larger in proportion to the linear dimension of the body, the number of brain neurons is not dictated simply by body mass" (Herculano-Houzel, et al.,

2015, p. 161). In other words, bigger bodies do not necessarily mean more brain neurons, but perhaps just bigger neurons. More specifically, humans have the largest brain and the largest number of neurons among the primates, perhaps as many as three times the number of neurons found in gorillas and orangutans (which have the next largest living primate brains after humans), yet gorillas can grow to be three times the body size of humans. This larger body size has not resulted in greater numbers of brain neurons in gorillas.

Why did human brains become so much larger, with so many more neurons, than expected for their body size (i.e. greater encephalization) when compared to other primates, and mammals in general? To answer this question, we need to consider the large amount of metabolic energy that a large brain with a large number of neurons requires. The energy required to run a brain increases as a function of the number of neurons that make up the brain. Brains with a lot of neurons require a lot of metabolic energy. Without sufficient energy supplies from the food available to a species, the number of brain neurons can only increase to a limit set by the available metabolic energy gained by feeding. Eating meat is one way to obtain more calories from the environment, and eating cooked meat is even better. Given that "the energetic cost of the brain is a linear function of its numbers of neurons," Fonseca-Azevedo and Herculano-Houzel (2012, p. 18571) argue that "metabolic limitations that result from the number of hours available for feeding and the low caloric yield of raw foods impose a tradeoff between body size and number of brain neurons [in non-human primates] . . . This limitation was probably overcome in Homo erectus with the shift to a cooked diet. Absent the requirement to spend most available hours of the day feeding, the combination of newly freed time and a large number of brain neurons affordable on a cooked diet may thus have been a major positive driving force to the rapid increase in brain size in human evolution." This argument is based on the observation that cooked foods are easier to digest and thus require less metabolic energy to process, leaving more usable energy after digestion compared to uncooked food. The use of fire and the invention of cooking, especially of meat, a concentrated source of metabolic energy (see below), by our ancient ancestors overcame the metabolic limitations that constrained brain size in other primates. This cultural innovation set the stage for larger relative brain size and greater number of brain neurons in human evolution beginning with Homo erectus, the oldest member of genus Homo for which evidence of the use of fire for cooking has been found. In short, eating meat, especially cooked meat, provided the metabolic energy required to support bigger brains with larger numbers of neurons, freeing hominid brain evolution beginning with Homo erectus from the metabolic limitations that prevented increased encephalization in other primates and in mammals in general.

Lakatos and Janka (2008) propose that upright posture and bipedalism in human ancestors freed the hands for evolution of improved manual dexterity leading to tool-making. Weapons improved the hunting of animals. Eating meat, as just discussed, provided more calories and fat in the diet making possible the evolution of larger brains which require large amounts of caloric energy (modern human brains comprise 2% of body weight but consume 20% of the body's metabolic energy). The human brain tripled in size over 3.5 million years from an average of 450 cm^3 in Australopithecinae to 1350 cm^3 in Homo sapiens. The appearance and stabilization of the FOXP2 gene (see last module in this chapter) set the stage for human language, which, according to Lakatos and Janka (p. 220), was the "basis for abrupt evolution of human intelligence," and coincided with the first appearance and the rapid spread of Homo sapiens over the Earth. They point out that the "level of intelligence is related anatomically to the number of cortical neurons and physiologically to the speed of conductivity of neural pathways, the latter being dependent on the degree of myelinization" (p.220). In other words, both the number of neurons and the amount of myelin on axons in a brain (the more myelinated axons, the faster the conduction speeds between neurons and the faster and more efficient information processing becomes, presumably increasing intelligence. In addition, they claim that language provided more effective communication among cooperating hunters and food-gatherers, requiring less energy to achieve effective cooperation, thereby providing competitive advantage in obtaining food. They also suggest that better mental skills, favored in sexual competition for mates, helped stabilize "cleverness" genes. They support the view that major qualitative changes occurred during evolution of human cognition. On their view, evolution of language was the basic condition required for conscious thinking, creating a qualitative change in human cognition which made humans and human cognition different from all other species.

Another hypothesis is the "social brain" theory of the evolution of human cognition. This stems from the observation that primate brains are roughly twice the size expected based on body size, compared to other mammals, and that the size of cerebral cortex is correlated with the size of the primate social group characteristic of a species (Barrett & Henzi, 2005). The basic idea is that living in groups created local competition among members of the social group for scarce resources which would lead to the evolution of cognitive skills to out-wit one's competitors in the social group. Increased cognitive skills would select for even greater cognitive skills because of the increased competition. However, this view of competition among individuals as the driving force in the evolution of primate cognition doesn't take into account mounting evidence that much of primate social behavior, especially in humans, involves altruistic behavior including cooperation, sharing, trade, group defense, and other prosocial behaviors which can evolve when members of a group are inter-dependent for survival and reproduction of viable offspring. This may occur through kin selection (see previous section on kin selection in Chapter 3) or **group selection** wherein natural selection acts on the group as a whole (Barrett & Henzi, 2005). Nevertheless, social life does involve cognitive skills not required in non-social animals, although

monkeys may use less demanding cognitive skills than do apes in their social interactions. A major problem with the social brain hypothesis as an explanation for the evolution of cognition is that the argument "can sometimes appear circular: primates have large brains because their social lives are cognitively demanding, and their lives are cognitively demanding because they have large brains that allow them to produce more complex forms of social behavior" (Barrett & Henzi, 2005).

Reader, et al. (2011) note that there are conflicting hypotheses regarding the nature and structure of primate cognition. One view is that primate cognition is divided into specialized, independently evolving modules ("massive modularity"), each of which processes information using "rules" specific to solution of a specific class of adaptive problem--such as mate selection, or predator avoidance, or securing and maintaining status in one's social group, and so on. The opposite of this modular view of cognition is that primate intelligence is a single general process, attributable to a single 'general intelligence' factor, g, the evolutionary origin of which remains controversial (see Koenigshofer, 2017). Reader, et al. (2011) collected ecologically relevant measures of cognition including reported incidences of behavioral innovation, social learning, tool use, extractive foraging and tactical deception, in 62 primate species. All measures exhibited strong positive associations, after statistically controlling for multiple potential confounds, creating a highly correlated composite of cognitive traits which they took as a species-level measure of general intelligence, which they called, "primate g(S)." They argue that *primate g(S)* suggests that "social, technical and ecological abilities have coevolved in primates, indicative of an across-species general intelligence that includes elements of cultural intelligence," such as social learning ability and tool use. They also reported that primate g(S) correlated "with both brain volume and captive learning performance measures." These researchers conclude that their "findings question the independence of cognitive traits and do not support 'massive modularity' in primate cognition, nor an exclusively social model of primate intelligence" given that no relationship between social group size (complexity) and cognitive performance in lab tests was found. This suggests that social complexity as measured by group size may not have been as important a driver of the evolution of primate general intelligence as is widely believed. "High general intelligence has independently evolved at least four times, with convergent evolution in capuchins, baboons, macaques and great apes" (Reader, Hager, & Laland, 2011, p. 1017). "The strong correlation between distinct measures of primate cognitive performance is strikingly evocative of the correlations in performance on different IQ tests observed in humans. A possible explanation for this correspondence is that the *g* factor reported in humans reflects underlying general processes that evolved in common ancestors and are thus shared in our extant primate relatives" (Reader, Hager, & Laland, 2011, p. 1024). This view is consistent with arguments made in module 14.2 that general intelligence is found in many non-human animals as well as in humans (Koenigshofer, 2017).

Another intriguing hypothesis about the evolution of cognition and the gap or discontinuity between human cognition and cognition in other animals is the concept of mental time travel. "Mental time travel comprises the mental reconstruction of personal events from the past (episodic memory) and the mental construction of possible events in the future" (Suddendorf, Addis, & Corballis, 2011, p. 344). This projection of the self into future-time using visual imagery (i.e. imagination) was discussed as an important component of general intelligence (Koenigshofer, 2017) in module 14.2. According to Suddendorf and colleagues, the ability to "time travel" to the past doesn't occur in human children until about three and a half years old, and is associated with episodic memory, a type of autobiographical memory dependent upon functioning of the prefrontal cortex involving understanding that the memory is of an experience of a past self. This awareness of "pastness" may be beyond the capability of most animals, particularly if they do not have a conscious sense of self. Furthermore, mental time travel requires ability to dissociate from one's current state of mind to generate a personal memory or a projection into possible future states of the world (imagination again). This involves so-called "executive functions" of the frontal lobe. "'Executive function' is an umbrella term for the mental operations which enable an individual to disengage from the immediate context in order to guide behavior by reference to mental models and future goals" (Hughes, Russel, & Robbins, 1994, p. 477, as referenced in Suddendorf, et al., 2011). As was discussed in earlier modules, this ability requires the **prefrontal cortex**. Persons with autism and those with prefrontal damage have difficulty with executive functions. This cognitive impairment is revealed by inability to switch behavior previously employed when changes in the task require, and also by apparent difficulty in using mental models as evidenced by deficits in planning future behavior. Although animals in general certainly anticipate future in various ways, including implicit learning such as conditioning, whether they construct mental models of future is for most species an open question; however, for chimpanzees at least, evidence from Kohler's classic studies showed sudden insight by chimpanzees in problem solving implying "constructive thought with an eye to the future solution of a problem" suggesting mental time travel to the future in these animals. Studies by Jane Goodall of chimpanzee tool-making "also suggest flexible forethought. For example, the chimpanzees at Gombe [in Tanzania] manufactured pointed tools from sticks at one place to use them later for termite fishing at another place that was out of sight (Goodall, 1986)." Furthermore, chimpanzees have been observed to transport stones for cracking open nuts from one region where stones are found to another feeding location when stones are not found. This shows ability to imagine future and to engage in current behavior that anticipates and plans for an expected future.

However, one hypothesis by Bischof (1978, 1985) is that non-human animals cannot anticipate future needs or drive states and so are bound by their present motivational state. For example, a full-bellied lion is no threat to passing zebra, but a full-bellied human may be (Suddendorf, Addis, & Corballis, 2011, p. 349). This difference may reflect a trend in evolution. "Bischof (1985)

suggests that, in the course of evolution, there was a progressively increasing gap between drive and action. Great apes display quite extensive gaps; they can postpone the immediate enactment of their current drive, and make plans to receive gratification at a later point in time." The role of human anticipatory cognition is not only central to human behavior but shapes human society as well (Suddendorf, Addis, & Corballis, 2011, p. 351). For example, we grow, harvest, store, and ship food for future use using all sorts of complex behavioral practices oriented to the future use of the food. We have complex legal systems that are based on the idea that current punishment for a past crime will prevent future crime. We have invented nuclear arsenals ready for launch based on the assumption that such weapons will prevent future attacks on us. We have the institution of marriage which we anticipate will help satisfy our needs for emotional and financial security (including needs for shelter and food), for reproduction of offspring, and for future sexual gratification.

Osvath and Gärdenfors (2005, p. 1), following Bischof's hypothesis, state "Anticipatory cognition, that is, the ability to mentally represent future needs, is a uniquely human trait that has arisen along the hominid line . . . [resulting in] stone tool manufacture, . . . transports over long ranges of tools as well as food and of the use of accumulation spots. . . .[T]his niche promoted the selection for anticipatory cognition, in particular planning for future goals. Once established, anticipatory cognition opened up for further cultural developments, such as long ranging migration, division of labor, and advanced co-operation and communication, all of which one finds evidence for in Homo ergaster/erectus. . . . A distinctive feature of human thinking that contrasts with the cognition of other primates is our capacity to form mental representations of the distant future. . . . planning in primates and other animals suggest that they can only plan for present needs (this is dubbed the Bischof-Kohler hypothesis) . . . "

The evolution of anticipatory cognition resulted in "niche construction," a term from evolutionary biology. "Niche construction can be defined as the systematic changes that organisms bring about in their environments (Day, Laland & Odling-Smee, 2003). A wide variety of organisms construct parts of their environment: spiders making webs, birds building nests, beavers constructing dams and plants altering their chemical surroundings" (Osvath and Gärdenfors (2005, p. 2). Of particular interest is the fact that niche construction "can actually change the evolutionary dynamics" by altering selection pressures leading to "unusual evolutionary dynamics, . . . [including] ecological inheritance. This is characterized by offspring inheriting the altered ecology from its ancestors – an ecology with its own selective pressures. Implementing niche construction in evolutionary theory involves two kinds of modifying processes, natural selection and niche construction, as well as two kinds of descent, genetic and ecological inheritance (Day, Laland & Odling-Smee, 2003)" (Osvath and Gärdenfors (2005, p. 2). According to Osvath and Gärdenfors (2005, p.1), "the cultural niche that was created by the use of Oldowan [stone] tools, including transport of tools and carcasses (Plummer, 2004), has led to a selection for anticipatory cognition, and in particular anticipatory planning." These events produced a qualitative gap in cognitive evolution between humans and apes--our capacity for representation of the distant future, including planning for future needs, capacities which appear to be absent in other animals including our nearest primate relatives, the great apes.

"The ability to envision various actions and their consequences is a necessary requirement for an animal to be capable of planning. . . An organism is planning its actions if it has . . . representations of (1) goal and start situations, (2) sequences of actions, and (3) the outcomes of actions. . . . The hominids have presumably been the most cultural dependent species ever and thus the most powerful and flexible niche constructors (to various degrees, of course, and with Homo sapiens at the present extreme). A consequence of this is that the hominids should exhibit great evolutionary resistance to changes in the natural environment, but also be capable of far-reaching evolutionary change caused by some ground-breaking cultural innovation (Laland, Odling-Smee & Feldman, 2000). The key point is that some of our major cognitive adaptations might not only be a result of new demands from a changing natural environment, but to a larger degree emerge from a highly constructed environment, including both social and artefactual elements. It is not sufficient to look at habitat, climate and other natural ecological factors, when trying to understand how humans evolved" (Osvath and Gärdenfors (2005, p. 2). Niche construction must also be considered, and Osvath and Gärdenfors argue that niche construction played a large role in human cognitive evolution.

They explain further: "Culture is the most forceful medium in niche construction, because culturally transmitted traits spread much more rapidly than genetically transmitted traits do. On one hand, culture can create a very strong selection and thereby increase the rate of evolutionary changes. On the other hand, culture can buffer out particular natural selection pressures (Laland, Odling-Smee & Feldman, 2000). A cultural innovation, constituting a form of niche construction, can create a behavioural drive that accelerates evolution. The same innovation can create a niche that blocks natural selective pressures. For example, humans live in cold climates without having any major biological adaptations to cold, because they rely on the cultural niche created by clothes and external heat sources. The consequence is that the naked human body does not exhibit cold adapted traits to the extent that would be expected from a mammal living in a cold climate. . . The general thesis is that the hominids themselves created a great deal of the selective pressures that eventually made us human."

Another hypothesis about the difference between human and animal cognition emphasizes capacities for abstraction. Ability for high levels of abstraction in causal and similarity relations (Penn et al., 2008) and in covariation detection (Wasserman, 1993b) may be central to the phylogenetically unprecedented achievements of the human intellect (Koenigshofer, 2017), including niche construction. In a review of the comparative literature, Penn et al. (2008) find “no compelling evidence” that any nonhuman animal can reason about the “relation between relations,” something that humans do readily. Neither do they find convincing evidence for analogical reasoning (dependent upon judgments of abstract similarities across domains) in nonhuman animals. Children readily understand the similarity between a dog and its dog house and a bird and its nest. Consistent with Penn et al. (2008), Walker and Gopnik (2014) report that although human toddlers readily detect abstract relational causality quickly with only a few training trials, non-human primates have great difficulty with similar tasks even after hundreds of trials. Penn et al. (2008, p. 123) believe that what distinguishes human cognition from that in non-human animals is “the ability to reason about higher-order relations,” and that this capacity for high levels of abstraction “subserves a wide variety of distinctively human capabilities.”

As discussed in an earlier module, research in molecular genetics suggests one possible explanation for how human ability for high levels of abstraction may have come about during the course of evolution. Pollard (2009) comparing human and chimpanzee genomes found “massive mutations” in humans in the “DNA switches” controlling size and complexity of cerebral cortex, extending the period of prenatal cell division in human cerebral cortex by several days compared to our closest primate relatives. Research using artificial neural networks suggests that increasing cortical complexity leads to sudden leaps in ability for abstraction and rule-like understanding of general principles (Clark, 1993), a hallmark of high intelligence. Findings by Penn et al. (2008) strongly suggest that superior ability for abstraction of relational information may be the key component explaining differences in general intelligence between humans and nonhuman animals. These abilities may involve **anterior dorsolateral prefrontal cortex** in humans (Kroger et al., 2002; Reeber et al., 1998; see Koenigshofer, 2017).

Frontal cortex is found in other mammals as well, so the question remains as to why the human brain with its frontal lobe has capabilities which exceed those of all other animals. In this regard, Roth and Dicke (2012) note "Primates are, on average, more intelligent than other mammals, with great apes and finally humans on top. They generally have larger brains and cortices, and because of higher relative cortex volume and neuron packing density (NPD), they have much more cortical neurons than other mammalian taxa with the same brain size. Likewise, information processing capacity is generally higher in primates due to short interneuronal distance and high axonal conduction velocity [see discussion above of findings by Herculano-Houzel, et al., 2015, and Lakatos and Janka, 2008]. Across primate taxa, differences in intelligence correlate best with differences in number of cortical neurons and synapses plus information processing speed. The human brain stands out by having a large cortical volume with relatively high NPD, high conduction velocity, and high cortical parcellation. All aspects of human intelligence are present at least in rudimentary form in nonhuman primates or some mammals or vertebrates except syntactical language. The latter can be regarded as a very potent 'intelligence amplifier.'" This last point is related to human ability to share knowledge and ideas

facilitating cultural transmission of learned information and cultural evolution.

Another important finding involves the connectivity between cortical areas. For example, prefrontal white matter volume is disproportionately larger in humans than in other primates (Schoenemann, et al., 2005). However, this finding might be related to more gyri in the frontal cortex of humans compared to other primates. Nevertheless, these observations may reflect "connections between cortical areas capable of relaying and processing information at greater speeds, facilitating complex cognitive function" (Schenker, et al., 2005, p.564).

Williams (2020) emphasizes the role of cognitive interactions within human groups to account for the cognitive achievements of humans compared to other animals. According to Williams, General Collective Intelligence (GCI) can be defined as a system that organizes groups into a single collective cognition with the potential for vastly greater general problem solving ability than that of any individual in the group. According to Williams, GCI represents a phase transition in human intelligence. When humans collectively put their cognitive capacities and activity together to solve a particular problem a collective intelligence emerges which is far more powerful than the cognitive abilities of any single individual. Communication and social cooperation between individual humans "putting their heads together" facilitated by cultural innovations for sharing information and ideas, within and across generations (such as writing, the internet, scientific organizations, research universities and other group cognitive efforts), create a kind of "superintelligence" not found in any other species. The powerful adaptive effects of collaborative problem solving combined with cultural transmission of learned information and ideas from generation to generation, built upon by each succeeding generation, is essential to the cognitive achievements which make us so different from other species. While other species such as dogs, apes, killer whales, dolphins, elephants and so on are quite intelligent, none has created an international space station or flown robots to Mars.

Nevertheless, cognition and intelligence have evolved in a wide variety of species. "Within the animal kingdom, complex brains and high intelligence have evolved several to many times independently, e.g. among ecdysozoans in some groups of insects (e.g. blattoid, dipteran, hymenopteran taxa, e.g. bees, wasps), among lophotrochozoans in octopodid molluscs (e.g. octopus), among vertebrates in teleosts (e.g. cichlid fish), corvid and psittacid birds (e.g. ravens, crows, parrots), and cetaceans e.g. whales, dolphins, porpoise), elephants and primates. High levels of intelligence are invariantly bound to multimodal centres such as the **mushroom bodies in insects**, the **vertical lobe in octopodids**, the **pallium in birds** and the **cerebral cortex in primates**, all of which contain highly ordered associative neuronal networks. The driving forces for high intelligence may vary among the mentioned taxa, e.g. needs for spatial learning and foraging strategies in insects and cephalopods, for social learning in cichlids, instrumental learning and spatial orientation in birds and social as well as instrumental learning in primates" (Roth, 2015, p. 0049). According to Roth, high intelligence, which evolved in a large variety of species, is dependent not only upon factors identified by others such as number of brain neurons, their packing density, myelination and speed of processing, but also upon the presence of "multimodal centers" where processing events from multiple sensory modalities can be integrated into whole object and whole event representations. Keep in mind, that as was discussed in Module 14.2, cognition and intelligence in any species are part of the guidance systems that direct behavior toward successful adaptation in response to the challenges and opportunities presented by the environment. In the human case, the control of fire for cooking food, especially meat, permitting larger numbers of brain neurons in Homo erectus and in the members of the Homo genus which followed appears, to have been critical for setting hominids on the path to brain expansion and increasingly sophisticated cognition. But the fossil record shows us that a large brain was a prominent feature not only of ancient Homo sapiens in Africa but also of the Neanderthals in Europe, east Asia, and the Middle East. Although, Neanderthals had a larger visual cortex than modern humans, accounting for some of their enlarged cranial capacity, their frontal lobes, associated with human intelligence, were approximately the same size as the frontal lobes of modern humans, suggesting the possibility of high intelligence in the Neanderthals.

Differentiation of the Frontal Cortex

The role of the frontal cortex in human intelligence cannot assume a uniform set of regions comprising this cortex. Instead research shows that the frontal cortex is differentiated into regions specialized for different functional roles. For example, Schenker et al. (2005, p. 547-548) note that "this large cortical territory comprises anatomical subdivisions with rather distinct functional attributes. The dorsal sector of the frontal lobe is involved in perception, response selection, working memory, and problem solving (Owen, 1997; Bechara et al., 1998; Petrides, 2000; Pochon et al., 2001). It also includes territories activated during language production in humans (Foundas, 2001) and most of the primary motor and premotor cortices (Zilles et al., 1995). The mesial frontal cortex, including the anterior cingulate, is important for processing emotional stimuli and for production of affective responses (Cummings, 1993; Rezai et al., 1993), planning and initiation of voluntary motor sequences (Tanji and Mushiake, 1996), theory of mind (Fletcher et al., 1995; Gallagher et al., 2000; Stuss et al.,2001), and attention management (Carter et al., 1999; Dagher et al., 1999). The orbital frontal cortex is known to be involved in the evaluation of actions based on emotional reinforcers (Damasio, 1994; Stone et al., 1998; Rolls, 2000)." It is not unreasonable to speculate that these functions of the orbital frontal cortex may play a role in human ability to plan behavior for future needs, which according to the Bischof's hypothesis,

discussed above, is a key feature of human cognition setting it apart from cognition in other primates.

Evolution of Increased Brain Size in Neanderthals and Early Humans

As discussed above, theorists have hypothesized many different factors to account for the expansion of the human brain and increases in intelligence. Fonseca-Azevedo and Herculano-Houzel (2012) hypothesized that a cooked diet was key to greater encephalization (larger brain and more neurons)--humans have the largest brain and the largest number of neurons among the living primates, perhaps as many as three times the number of neurons found in gorillas and orangutans. Lakatos and Janka (2008) proposed that upright posture and bipedalism in human ancestors freed the hands for improved tool-making and production of weapons which improved hunting, providing a richer diet of meat capable of sustaining evolution of larger brains. Also recall the "social brain" hypothesis that the evolution of intelligence and cognition in humans was stimulated by increased information processing required by complex social interactions.

Evolution of Brain Size and Intelligence in Neanderthals

Now consider the Neanderthals whose Mousterian manufacturing indicates higher levels of conceptualization. Neanderthal fossil skulls show brain size equal to or slightly larger than that of modern humans (see figure below). The size of frontal cortex in humans and Neanderthals is essentially the same. Considering their large brain size and frontal lobes comparable to those of modern humans, some anthropologists suggest that Neanderthal cognitive and social capacities were not significantly different from that in humans 30,000 years ago (Hayden, 2012). Given these facts, we may wonder to what extent the above hypotheses about the evolution of human intelligence might also apply to Neanderthals. Spear points at Neanderthal sites certainly suggest hunting and meat-eating by Neanderthals. Neanderthals also cooked their food (Hayden, 2012; Henry, 2017). There is evidence that Neanderthals lived in groups (although perhaps smaller than humans of 40,000 years ago) and may have had complex social interactions (Duveau et al., 2019; Hayden, 2012). Could any or all of these factors, hypothesized as catalysts for the evolution of complex cognition in humans, have also been catalysts for the evolution of greater brain size and higher intelligence in Neanderthals?

Cognitive Competition between Early Humans and Neanderthals in Eurasia

Another intriguing question involves possible competition between early humans and Neanderthals. Some researchers suggest that competition from humans migrating to Europe and Asia from Africa eventually caused the extinction of the Neanderthals. However, another possible effect of such competition may have been beneficial for both species. Could competition between early humans and Neanderthals have been a factor stimulating evolution of higher intelligence in both species, with humans eventually winning out? This hypothesis is weakened by the fact that no fossils of Neanderthals have ever been found in Africa, but only in Europe, the Middle East, and parts of east Asia. Without such fossil finds of Neanderthals in Africa we must assume that no interactions in Africa between early Homo species and Neanderthals were possible, eliminating competition between the two species as a potential cause of increased brain size and intelligence in early humans in Africa. But what about potential competition between the two species in Eurasia? Was contact between the two species frequent and sustained enough to create significant cognitive competition between them which might have influenced their brain evolution?

It is now generally accepted by scientists that Neanderthals and modern humans coexisted for tens of thousands of years, Neanderthals having become extinct only some 40,000 years ago, while the origin of modern humans is thought to have taken place some 200,000 to 300,000 years ago and human migration out of Africa to Europe and Asia is thought to have occurred about 70,000 to 100,000 years ago. Furthermore, about 1-4% of human DNA is Neanderthal in origin indicating interbreeding, suggesting significant contact between Neanderthals and humans in several places outside of Africa and during several periods between 40,000 and 100,000 years ago (Alex, 2018). Anthropological evidence suggests that Neanderthals were cognitively advanced. For example, they made stone tools for specialized tasks. These tools, found in a cave in France, were made using a manufacturing technique (dubbed Mousterian by experts) characterized by preparing the core of raw stone material from which flakes were struck and then worked. Sharper tools with a finer edge can be produced using this technique. Neanderthals shaped these flakes into tools like scrapers, blades, and projectile points--specifically spear points. In fact, at Neanderthal caves sites in the Middle East, there are a higher percentage of spear points found than at neighboring Homo sapiens sites. Mousterian tools are a technological advance, taking a high degree of conceptualization and knowledge of the properties of the stone (see section on Material Culture in this textbook).

Were Neanderthals smart enough to provide cognitive competition for early humans? Human and Neanderthal DNA is 99.8% the same including genes important for brain expansion and language (Alex, 2018). As already mentioned, measurements of

endocranial volume of Neanderthal skulls indicate that Neanderthals possessed a brain similar in size or even slightly larger than the brains of recent humans, with a larger visual cortex in Neanderthals, but a larger cerebellum in humans (Alex, 2018; Kochiyama, et al., 2018). But was any potential competition between Neanderthals and ancient humans sustained long enough to impact brain evolution? As discussed, we do know that the interactions between the two species were sufficient for some interbreeding between them, at least in Eurasia. Whether interactions between the two species led to cognitive competition between the two species that was sufficient to affect brain evolution of one or both species is unknown, but remains an intriguing question. However, one thing we do know is that most of the encephalization of the two species was already complete before early humans left Africa and therefore before any interactions could have taken place between them.

Sometime between 520,000 and 630,000 years ago the human and Neanderthal lines diverged from a common ancestor (Homo heidelbergensis; see figure below) and took separate evolutionary paths. Those who migrated to Europe eventually evolved into Neanderthals, while those in Africa gave rise to modern humans. These early humans later migrated out of Africa to Europe and other regions of the Earth. By 150,000 years ago both species had similar average brain size of about 1400 cubic centimeters, three times larger than the brains of modern day chimpanzees, and they also had very similar within-species variation in cranial capacity. The average brain volume of Neanderthals of 1410 cubic centimeters actually exceeds the 1349 cubic centimeter average of modern humans (Alex, 2018). These events appear to have occurred before any interactions between the two species, suggesting that the bulk of brain evolution in both took place before any encounters between them, further weakening the mutual competition hypothesis discussed above as a significant cause of the encephalization that occurred in the evolution of early humans and Neanderthals after they diverged from Homo heidelbergensis.

What accounts for the similar large brain size in both Neanderthals and humans? Were the genetics for large brain size present in the common ancestor of both before the two lines diverged? Or, alternatively, did the similar encephalization in the two species result from convergent evolution? Common genetics appears to be at least one important factor. *Homo heidelbergensis* is thought to be the common ancestor of *Homo neanderthalensis* in Europe and *Homo sapiens* in Africa (see section on Human Evolution in Chapter 3). The trend toward larger brain size was already evident in Homo habilis and Homo erectus, predecessors of Homo heidelbergensis, suggesting that the increase in encephalization in Neanderthals and Homo sapiens was a continuation of the trend toward encephalization already present in the genus Homo. The figure below from section 3.7 shows these evolutionary relationships.

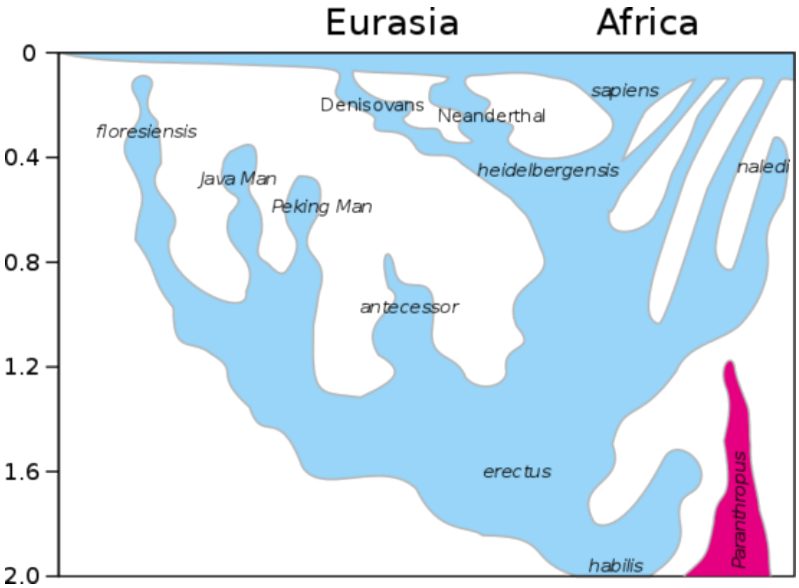

Figure 6.20.13.2: Evolutionary relationships among hominins. Note the divergence of Neanderthal and sapiens (the human line) from heidelbergensis, which evolved from habilis and erectus. (Image from Wikimedia Commons; File:Homo lineage 2017update.svg; https://commons.wikimedia.org/wiki/F...2017update.svg; by User:Conquistador, User:Dbachmann; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

One hypothesis about the disappearance of the Neanderthals was that competition from early humans led to their extinction some 30,000 to 40,000 years ago (Gilpin, et al., 2016). However, as suggested above, is it possible that competition between Neanderthals and humans in Europe, south Asia, and the Middle East (where fossils of early humans and Neanderthals have been found) might have played some role in stimulating the evolution of larger, smarter brains in both species? In the figure below, note the larger skull of the Neanderthal compared to the skull of a modern human. Many of the species of the Homo genus

coexisted with one another and could have interacted with one another. Perhaps competition between various Homo species played some role in the trend toward greater encephalization seen in the genus Homo beginning with species which diverged from Homo erectus. However, this hypothesis requires evidence of significant and sustained competition between these species, and that evidence has remained elusive. Perhaps future fossil finds will shed light on this intriguing possibility. On the other hand, small populations of these species may have precluded significant overlap of their ranges and reduced the chances of significant interaction and sustained competition among them.

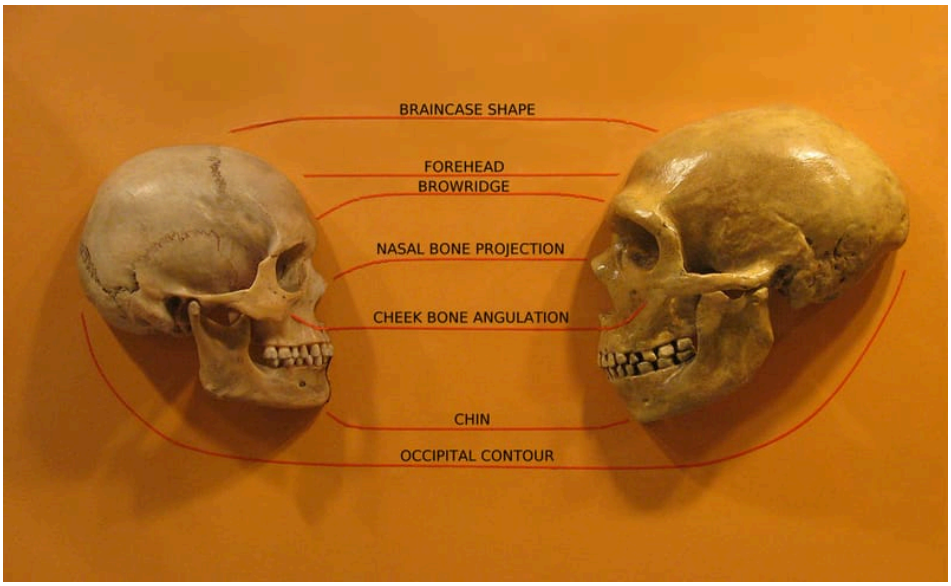

Figure 6.20.13.3: Comparison of Modern Human and Neanderthal skulls from the Cleveland Museum of Natural History. The cranial space in Neanderthal reveals a brain size slightly larger than the brain size of modern humans. This and other anthropological evidence suggests the possibility of significant competition between the two species, perhaps catalyzing the evolution of cognition in both. (Image and first sentence in caption from Wikimedia Commons, remainder of caption by Kenneth Koenigshofer, PhD, Chaffey College; File:Sapiens neanderthal comparison en.png; https://commons.wikimedia.org/wiki/F...parison_en.png; by hairymuseummatt (original photo), KaterBegemot (derivative work); licensed under the Creative Commons Attribution-Share Alike 2.0 Generic license).

An Integrative Model of the Evolution and Structure of Intelligence

A significant controversy among theorists is whether the human mind is **modular or general purpose**. The older model of the mind, originating with the British Empiricist philosophers of the 17th and 18th centuries and adopted by early behaviorists, sees the brain as a **general purpose processor** handling all kinds of adaptive problems without need for any specialized processing brain modules. An alternative model favored by many evolutionary psychologists such as Cosmides and Tooby at the University of California, Santa Barbara, is that the human mind is **highly modular** in nature, consisting of large numbers of specialized, domain-specific (specific to specific problem type) information processing modules which operate more or less independently of one another. Such modules or mini-computers are hypothesized to be specialized by evolution to operate on different types of information to achieve solutions to different types of adaptive problems. Although many evolutionary psychologists favor this modular view of the mind and brain, composed of special purpose brain modules, many psychologists disagree with this view, in part because it leaves out general intelligence and the flexibility in problem solving that seems to require general problem solving capabilities.

One solution that integrates both views is a model of the human brain that incorporates both types of processing mechanisms--some brain circuits specialized to solve specific adaptive problems such as mate selection, predator avoidance, and so on, and, in addition, brain mechanisms of general intelligence. Many evolutionary psychologists do not dispute the idea that some form of general intelligence exists; the problem is that they have been unable to understand how general intelligence, capable of solving noncurrent "novel problems," could have even evolved (Cosmides & Tooby, 2002; Kanasawa, 2004, 2010). This is because problems that are truly novel have not happened before and therefore have not been recurrent over many generations. This creates a theoretical problem because natural selection can only work on selection criteria consistently present generation after generation.

However, this problem has been solved. An analysis of the structure of events, including adaptive problems, reveals that every event contains two components: 1) abstract relational properties, such as cause-effect, similarity, and predictive relations, which have been consistently present in the environment generation after generation, and 2) specific event details which are idiosyncratic, nonrecurrent, perhaps even truly novel, and therefore transient and confined to a single generation (Koenigshofer, 2017). Any adaptive problem is a mixture of these two elements. Although event details which are idiosyncratic to specific situations encountered by different individuals may be unique and novel, and thus highly variable across generations, nevertheless the relational properties such as cause-effect exist across situations and adaptive problems generation after generation.

Because of the repetition of such relational properties (causal, similarity, and predictive relations) over countless generations in countless events, adaptive problems, and adaptive opportunities, natural selection has utilized these relational regularities of the world as selection criteria for evolution of important components of brain organization and function. As a consequence, information about these relational properties of the world has been genetically incorporated into the innate organization of the brains of many species, including our own (Koenigshofer, 2017). This innate knowledge about these relational properties of the world forms a set of cognitive instincts that collectively make up what psychologists call general intelligence (Koenigshofer, 2017), the g-factor first discovered by Spearman in the early 1900s.

On this view, novel problems are only novel in their details, but constant or invariant across generations in their abstract relational structures. It is the constancy of these relational structures over generations that provided the regularities across generations which acted as selection criteria for the evolution of innate knowledge about these abstract, relational invariants--the key components of general intelligence. Application of this innate knowledge of general intelligence permits the solution to a near infinite variety of problems and adaptive opportunities, regular in their relational structure, but novel in their details (Koenigshofer, 2017). According to this integrative model of intelligence, many specialized modules (the modular view of intelligence) act along with general intelligence--the innate knowledge of causal, similarity, and predictive relations--to flexibly solve problems and seize adaptive opportunities, accounting for the unprecedented achievements of the human intellect. These cultural innovations by humans and their preservation over generations by cultural transmission have permitted humans each generation to draw upon the innovations and inventions of prior generations, building upon them, generation after generation, ratcheting up human adaptive success, far beyond that found in any other species.

6.20.14: Chapter 14- Mirror Neurons, Theory of Mind, Social Cognition, and Neuroscience of Its Disorders

Learning Objectives

1. Describe mirror and canonical neurons, their locations in the brain, and their possible functions
2. Describe theory of mind (ToM) and its role in social cognition
3. Define the social brain

Overview

In the early 1990s, researchers working with monkeys identified a group of neurons in their frontal cortex that were activated when the monkeys made a particular motion with their hand or mouth. There was nothing surprising in that, since these neurons were located in what is considered a “motor” portion of the brain. What was surprising, though, was that this same group of neurons was also activated in monkeys who were not performing the motion themselves, but rather watching other monkeys perform it. Hence these neurons were given the name “mirror neurons”. Mirror neurons are one possible basis in the brain for what may be called social intelligence or social cognition, information processing necessary for successful interactions with conspecifics. The new field of social neuroscience studies the neurological structures and processes that carry out the information processing required for adaptive interactions with others, basis for all human social behavior. One of these capacities, labeled “theory of mind,” is ability to perceive and understand mental states of others, essential in human social life. Autism is in the category of *pervasive developmental disorders* and may result in part from impaired theory of mind and abnormalities in a number of brain structures collectively referred to by some neuroscientists as the "social brain."

Are Mirror Neurons the Basis for Communication?

Mirror neurons were discovered in area F5 of the ventral premotor cortex of macaque monkeys by researchers at the University of Parma, Italy, in 1992. The researchers found that these neurons had some very distinctive characteristics : they fired not only when a monkey performed a voluntary gesture (for example, turned a handle to open a door), but also when a monkey watched another monkey perform this same action. The part of the brain where these mirror neurons are found in monkeys corresponds to the part of the human brain known as Broca’s area, which since the 19th century has been known to play an important role in language. In addition to their being located in a brain area associated with language in humans, two other things about mirror neurons have led many researchers to suggest that they may play a role in the evolution and learning of language: these neurons tell us about the intentions of the people around us, and they help us to imitate the movements of other people’s lips and tongues.

Another category of neurons present in area F5, **canonical neurons**, may, like mirror neurons, be involved in human language faculties. The special characteristic of canonical neurons is that they fire when an individual simply sees a graspable object. For example, if a monkey looks at a ball, the canonical neurons that fire are the same ones that will fire if the monkey decides to actually grasp the ball. In contrast, the monkey’s mirror neurons will not be activated by the mere sight of a ball, but only if the monkey either grasps the ball or sees another monkey do so.

In essence, mirror neurons react to visual stimuli that represent an interaction between a biological means of action (such as the hand or mouth) and an object. These neurons thus act as agents for recognizing purposive actions as opposed to simple movements.

Even in the case of canonical neurons, which can be activated by the sight of a graspable object in the absence of movement, the internal representation is that of a purposive action, and not just a simple movement of the hand or arm.

This is what has led some researchers to think that mirror neurons might help to explain the cognitive foundations of language, by providing the neural substrate for the human ability to understand the meaning of other people’s actions, which is the basis for all social relations. This system of correspondences between perceptions and actions would help us to infer other people’s mental states and to interpret their actions as intentional behaviors arising from these states. We can then easily imagine how this mechanism for interpreting gestural communication might have been applied to verbal communication as well.

The hypothesis advanced is that the motor system, through its mirror neurons, is involved in perceiving speech, and that through evolution, the “motor resonance” generated by the mirror neurons has been diverted (or exapted) from its original function to serve the needs of language. One has to be impressed by the economy of such a cognitive system, in which one individual understands what other individuals are doing (or saying) on the basis of the internal neural representation of his or her own motor capabilities.

The point is that intentional communication between two individuals differs from the simple cries of alarm by which animals signal danger to all members of their group indiscriminately. Intentional communication, in contrast, requires one individual who is transmitting information and a second who is paying attention to receive it. Among all the possible origins of language , the first form of intentional communication among humans may have arisen from the imitation of gestures and facial expressions. Thus mirror neurons may have played a role in sharing these common representations and, eventually, a common language.

Mirror neurons have been shown to have some other interesting characteristics as well. First of all, as noted above, they will be activated when you see someone else’s hand grasp an object, but not when you see a tool grasp the same object. The explanation is that unlike tools and other human artifacts, human body parts are represented in the motor and premotor areas of the brain’s frontal lobes. Second—and here is where the implications for language become really interesting—mirror neurons do not react to just any movements of the hand or mouth, but only to movements that are involved in goal-directed actions.

In other words, it is only when an action has a meaning that it activates the mirror neurons. Their response is thus associated with the expression of intentionality—that is, with the purpose of the observed gesture. For example, certain mirror neurons that are activated when a monkey manipulates an object will remain quiet when the monkey uses the same muscles, connected to the same neurons, to perform a similar action for a different purpose, such as to scratch itself or to pick an insect out of its fur.

It is becoming more and more apparent that the brain’s motor system does not only control movements but can also in a certain sense read the actions performed by other individuals. Mirror neurons may thus play a fundamental role in all human social behavior, including language.

Summary

Mirror neurons discovered in area F5 of the frontal cortex in the macaque monkey, an area that corresponds to Broca's area of the left frontal lobe of humans, fire action potentials when a monkey performs a voluntary movement (for example, turning a handle to open a door), but also when a monkey watches another monkey perform this same action. if a monkey looks at a ball, the canonical neurons that fire are the same ones that will fire if the monkey decides to actually grasp the ball. However, by contrast, the monkey’s mirror neurons will not be activated by the mere sight of a ball, but only if the monkey either grasps the ball or sees another monkey do so. Mirror neurons do not react to just any movements of the hand or mouth, but only to movements that are involved in goal-directed actions. These neurons thus act as agents for recognizing purposive actions as opposed to simple movements. The hypothesis is that the motor system, through its mirror neurons, is involved in perceiving speech, and the intentions of others, and may thus play a fundamental role in all human social behavior.

The Social Brain and Social Neuroscience

The brain mechanisms of social cognition and social intelligence help us understand other people and accomplish adaptive interactions with them. Deficits in these abilities due to damage in the "social brain" can lead to disorders such as autism.

Social Neuroscience

By Tiffany A. Ito and Jennifer T. Kubota

University of Colorado Boulder, University of Delaware

This module provides an overview of the new field of social neuroscience, which combines the use of neuroscience methods and theories to understand how other people influence our thoughts, feelings, and behavior. The module reviews research measuring neural and hormonal responses to understand how we make judgments about other people and react to stress. Through these

examples, it illustrates how social neuroscience addresses three different questions: (1) how our understanding of social behavior can be expanded when we consider neural and physiological responses, (2) what the actual biological systems are that implement social behavior (e.g., what specific brain areas are associated with specific social tasks), and (3) how biological systems are impacted by social processes.

- Electroencephalography (EEG)
- fMRI
- mentalizing
- neuroendocrinology
- Prejudice
- Social neuroscience
- social psychology
- stereotyping
- stress

Learning Objectives

- Define social neuroscience and describe its three major goals.
- Describe how measures of brain activity such as EEG and fMRI are used to make inferences about social processes.
- Discuss how social categorization occurs.
- Describe how simulation may be used to make inferences about others.
- Discuss the ways in which other people can cause stress and also protect us against stress.

Psychology has a long tradition of trying to better understand how we think and act. For example, in 1939 Heinrich Kluver and Paul Bucy removed (i.e. lesioned) the temporal lobes in some rhesus monkeys and observed the effect on behavior. Included in these **lesions** was a subcortical area of the brain called the **amygdala**. After surgery, the monkeys experienced profound behavioral changes, including loss of fear. These results provided initial evidence that the amygdala plays a role in emotional responses, a finding that has since been confirmed by subsequent studies (Phelps & LeDoux, 2005; Whalen & Phelps, 2009).

What Is Social Neuroscience?

Social neuroscience seeks to understand how we think about and act toward other people. More specifically, we can think of social neuroscience as an interdisciplinary field that uses a range of neuroscience measures to understand social behavior. As such, social neuroscience studies the same topics as social psychology, but does so from a multilevel perspective that includes the study of the brain and body. Figure 1 shows the scope of social neuroscience with respect to the older fields of social psychology and neuroscience. Although the field is relatively new – the term first appeared in 1992 (Cacioppo & Berntson, 1992) – it has grown rapidly, thanks to technological advances in brain science, and to the recognition that neural and physiological information are critical to understanding how we interact with other people.

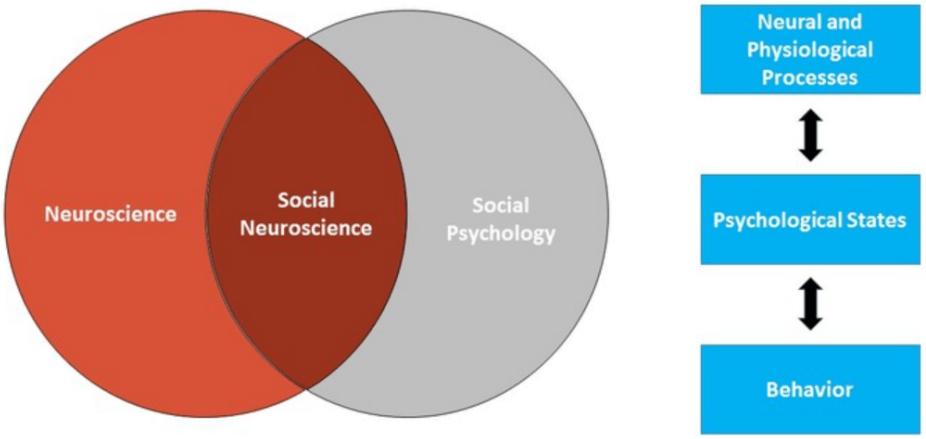

Figure 6.20.14.1: Social neuroscience is the intersection of social psychology and neuroscience. Under this multilevel approach, neural/physiological processes and behavior are two things we can measure or observe. Psychological states cannot be directly observed, but understanding them is the goal. Social neuroscientists use the observable neural/physiological processes and behavioral responses to make inferences about unobservable psychological states. The bidirectional arrows show that all levels of analysis are assumed to influence each other (e.g., psychological states can influence neural responses, and neural responses can influence psychological states).

Social neuroscience can be thought of as both a methodological approach (using measures of the brain and body to study social processes) and a theoretical orientation (seeing the benefits of integrating neuroscience into the study of social psychology). The overall approach in social neuroscience is to understand the psychological processes that underlie our social behavior. Because those psychological processes are intrapsychic phenomena that cannot be directly observed, social neuroscientists rely on a combination of measurable or observable neural and physiological responses as well as actual overt behavior to make inferences about psychological states (see Figure 1). Using this approach, social neuroscientists have been able to pursue three different types of questions: (1) What more can we learn about social behavior when we consider neural and physiological responses? (2) What are the actual biological systems that implement social behavior (e.g., what specific brain areas are associated with specific social tasks)? and (3) How are biological systems impacted by social processes?

How Automatically Do We Judge Other People?

Social categorization is the act of mentally classifying someone as belonging in a group. Why do we do this? It is an effective mental shortcut. Rather than effortfully thinking about every detail of every person we encounter, social categorization allows us to rely on information we already know about the person's group. For example, by classifying your restaurant server as a man, you can quickly activate all the information you have stored about men and use it to guide your behavior. But this shortcut comes with potentially high costs. The stored group beliefs might not be very accurate, and even when they do accurately describe some group members, they are unlikely to be true for every member you encounter. In addition, many beliefs we associate with groups – called **stereotypes** – are negative. This means that relying on social categorization can often lead people to make negative assumptions about others.

The potential costs of social categorization make it important to understand how social categorization occurs. Is it rare or does it occur often? Is it something we can easily stop, or is it hard to override? One difficulty answering these questions is that people are not always consciously aware of what they are doing. In this case, we might not always realize when we are categorizing someone. Another concern is that even when people are aware of their behavior, they can be reluctant to accurately report it to an experimenter. In the case of social categorization, subjects might worry they will look bad if they accurately report classifying someone into a group associated with negative stereotypes. For instance, many racial groups are associated with some negative stereotypes, and subjects may worry that admitting to classifying someone into one of those groups means they believe and use those negative stereotypes.

Figure 6.20.14.2: This man is wearing an elastic electrode cap into which individual electrodes (inside the white circles) are sewn into standardized locations. [Image: Hans, CC0 Public Domain, https://goo.gl/m25gce]

Social neuroscience has been useful for studying how social categorization occurs without having to rely on self-report measures, instead measuring brain activity differences that occur when people encounter members of different social groups. Much of this work has been recorded using the **electroencephalogram**, or **EEG**. EEG is a measure of electrical activity generated by the brain's neurons. Comparing this electrical activity at a given point in time against what a person is thinking and doing at that same time allows us to make inferences about brain activity associated with specific psychological states. One particularly nice feature of EEG is that it provides very precise timing information about when brain activity occurs. EEG is measured non-invasively with small electrodes that rest on the surface of the scalp. This is often done with a stretchy elastic cap, like the one shown in Figure 2, into which the small electrodes are sewn. Researchers simply pull the cap onto the subject's head to get the electrodes into place; wearing it is similar to wearing a swim cap. The subject can then be asked to think about different topics or engage in different tasks as brain activity is measured.

To study social categorization, subjects have been shown pictures of people who belong to different social groups. Brain activity recorded from many individual trials (e.g., looking at lots of different Black individuals) is then averaged together to get an overall idea of how the brain responds when viewing individuals who belong to a particular social group. These studies suggest that social categorization is an **automatic process** – something that happens with little conscious awareness or control – especially for dimensions like gender, race, and age (Ito & Urland, 2003; Mouchetant-Rostaing & Giard, 2003). The studies specifically show that brain activity differs when subjects view members of different social groups (e.g., men versus women, Blacks versus Whites), suggesting that the group differences are being encoded and processed by the perceiver. One interesting finding is that these brain changes occur both when subjects are purposely asked to categorize the people into social groups (e.g., to judge whether the person is Black or White), and also when they are asked to do something that draws attention away from group classifications (e.g., making a personality judgment about the person) (Ito & Urland, 2005). This tells us that we do not have to intend to make group classifications in order for them to happen. It is also very interesting to consider how quickly the changes in brain responses occur. Brain activity is altered by viewing members of different groups within 200 milliseconds of seeing a person's face. That is just two-tenths of a second. Such a fast response lends further support to the idea that social categorization occurs automatically and may not depend on conscious intention.

Overall, this research suggests that we engage in social categorization very frequently. In fact, it appears to happen automatically (i.e., without us consciously intending for it to happen) in most situations for dimensions like gender, age, and race. Since classifying someone into a group is the first step to activating a group stereotype, this research provides important information about how easily stereotypes can be activated. And because it is hard for people to accurately report on things that happen so quickly, this issue has been difficult to study using more traditional self-report measures. Using EEGs has, therefore, been helpful in providing interesting new insights into social behavior.

Do We Use Our Own Behavior to Help Us Understand Others?

Classifying someone into a social group then activating the associated stereotype is one way to make inferences about others. However, it is not the only method. Another strategy is to imagine what our own thoughts, feelings, and behaviors would be in a similar situation. Then we can use our simulated reaction as a best guess about how someone else will respond (Goldman, 2005). After all, we are experts in our own feelings, thoughts, and tendencies. It might be hard to know what other people are feeling and thinking, but we can always ask ourselves how we would feel and act if we were in their shoes.

There has been some debate about whether **simulation** is used to get into the minds of others (Carruthers & Smith, 1996; Gallese & Goldman, 1998). Social neuroscience research has addressed this question by looking at the brain areas used when people think about themselves and others. If the same brain areas are active for the two types of judgments, it lends support to the idea that the self may be used to make inferences about others via simulation.

We know that an area in the prefrontal cortex called the **medial prefrontal cortex** (mPFC) – located in the middle of the frontal lobe – is active when people think about themselves (Kelley, Macrae, Wyland, Caglar, Inati, & Heatherton, 2002). This conclusion comes from studies using **functional magnetic resonance imaging**, or fMRI. While EEG measures the brain's electrical activity, fMRI measures changes in the oxygenation of blood flowing in the brain. When neurons become more active, blood flow to the area increases to bring more oxygen and glucose to the active cells. fMRI allows us to image these changes in oxygenation by placing people in an fMRI machine or scanner (Figure 3), which consists of large magnets that create strong magnetic fields. The magnets affect the alignment of the oxygen molecules within the blood (i.e., how they are tilted). As the oxygen molecules move in and out of alignment with the magnetic fields, their nuclei produce energy that can be detected with special sensors placed close to the head. Recording fMRI involves having the subject lay on a small bed that is then rolled into the scanner. While fMRI does require subjects to lie still within the small scanner and the large magnets involved are noisy, the scanning itself is safe and painless. Like EEG, the subject can then be asked to think about different topics or engage in different tasks as brain activity is measured. If we know what a person is thinking or doing when fMRI detects a blood flow increase to a particular brain area, we can infer that part of the brain is involved with the thought or action. fMRI is particularly useful for identifying which particular brain areas are active at a given point in time.

Figure 6.20.14.3: Functional magnetic resonance imaging (fMRI) scanner used to image the brain while people perform tasks. The scanner allows researchers to view the changes in blood oxygenation in specific locations in the brain during a task. Images are collected using powerful magnets and radio waves that shift the position of atoms in oxygenated blood that rushes to areas involved in performing the task. MRIs are non-invasive and there are no known risks from exposure to the magnetic fields or radio waves. Subjects lay on the while bed with their head inside the head coil, then the bed is moved into the scanner. [Image: Janne Moren, https://goo.gl/MKb2jn, CC BY-NC-SA 2.0, https://goo.gl/Toc0ZF]

The conclusion that the mPFC is associated with the self comes from studies measuring fMRI while subjects think about themselves (e.g., saying whether traits are descriptive of themselves). Using this knowledge, other researchers have looked at whether the same brain area is active when people make inferences about others. Mitchell, Neil Macrae, and Banaji (2005) showed subjects pictures of strangers and had them judge either how pleased the person was to have his or her picture taken or how symmetrical the face appeared. Judging whether someone is pleased about being photographed requires making an

inference about someone's internal feelings – we call this **mentalizing**. By contrast, facial symmetry judgments are based solely on physical appearances and do not involve mentalizing. A comparison of brain activity during the two types of judgments shows more activity in the mPFC when making the mental versus physical judgments, suggesting this brain area is involved when inferring the internal beliefs of others.

There are two other notable aspects of this study. First, mentalizing about others also increased activity in a variety of regions important for many aspects of social processing, including a region important in representing biological motion (**superior temporal sulcus** or STS), an area critical for emotional processing (amygdala), and a region also involved in thinking about the beliefs of others (**temporal parietal junction**, TPJ) (Gobbini & Haxby, 2007; Schultz, Imamizu, Kawato, & Frith, 2004) (Figure 4). This finding shows that a distributed and interacting set of brain areas is likely to be involved in social processing. Second, activity in the most ventral part of the mPFC (the part closer to the belly rather than toward the top of the head), which has been most consistently associated with thinking about the self, was particularly active when subjects mentalized about people they rated as similar to themselves. Simulation is thought to be most likely for similar others, so this finding lends support to the conclusion that we use simulation to mentalize about others. After all, if you encounter someone who has the same musical taste as you, you will probably assume you have other things in common with him. By contrast, if you learn that someone loves music that you hate, you might expect him to differ from you in other ways (Srivastava, Guglielmo, & Beer, 2010). Using a simulation of our own feelings and thoughts will be most accurate if we have reason to think the person's internal experiences are like our own. Thus, we may be most likely to use simulation to make inferences about others if we think they are similar to us.

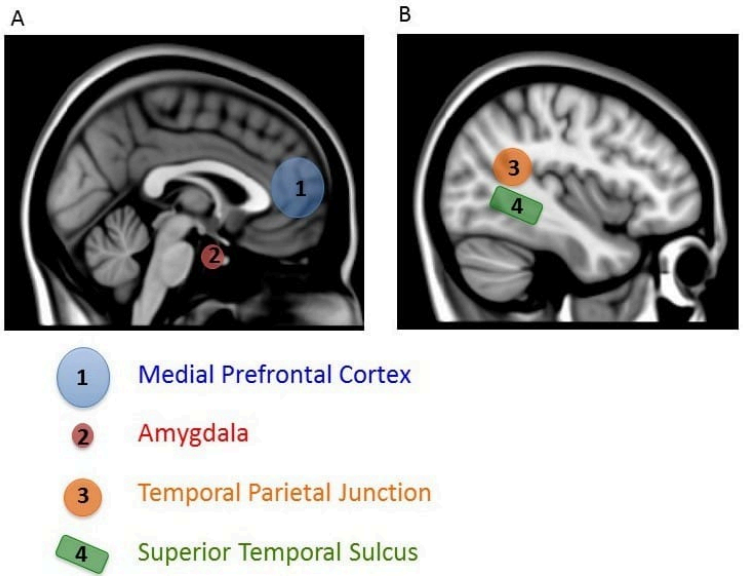

Figure 6.20.14.4: The areas of the brain most commonly associated with processing of self and others. Panel A is a sagittal view, looking at the inside of the brain as if it were sliced in half. Panel B is a lateral view, showing the brain from the outside. The medial prefrontal cortex (mPFC) (Structure 1) is commonly activated when thinking about one's self and when thinking about similar others. Additionally, the amygdala (Structure 2) is important for learning about and detecting important things in our environments and plays an important role in fear learning and expression. The temporal parietal junction (TPJ) (Structure 3), located at the intersection of the parietal and temporal lobes, is activated when people think about the beliefs of others. Activity in the superior temporal sulcus (STS) (Structure 4) is commonly observed when people view biological motion. The common activation of this network of regions when people think about the feelings, thoughts, and intentions of others indicates that the processing of others involves a number of complex psychological processes.

This research is a good example of how social neuroscience is revealing the **functional neuroanatomy** of social behavior. That is, it tells us which brain areas are involved with social behavior. The mPFC (as well as other areas such as the STS, amygdala, and TPJ) is involved in making judgments about the self and others. This research also provides new information about how inferences are made about others. Whereas some have doubted the widespread use of simulation as a means for making inferences about others, the activation of the mPFC when mentalizing about others, and the sensitivity of this activation to similarity between self and other, provides evidence that simulation occurs.

What Is the Cost of Social Stress?

Stress is an unfortunately frequent experience for many of us. **Stress** – which can be broadly defined as a threat or challenge to our well-being – can result from everyday events like a course exam or more extreme events such as experiencing a natural

disaster. When faced with a stressor, **sympathetic nervous system** activity increases in order to prepare our body to respond to the challenge. This produces what Selye (1950) called a **fight or flight response**. The release of **hormones**, which act as messengers from one part of an organism (e.g., a cell or gland) to another part of the organism, is part of the stress response.

A small amount of stress can actually help us stay alert and active. In comparison, sustained stressors, or chronic stress, detrimentally affect our health and impair performance (Al'Absi, Hugdahl, & Lovallo, 2002; Black, 2002; Lazarus, 1974). This happens in part through the chronic secretion of stress-related hormones (e.g., Davidson, Pizzagalli, Nitschke, & Putnam, 2002; Dickerson, Gable, Irwin, Aziz, & Kemeny, 2009). In particular, stress activates the **hypothalamic-pituitary-adrenal (HPA) axis** to release **cortisol** (see Figure 5 for a discussion). Chronic stress, by way of increases in cortisol, impairs attention, memory, and self-control (Arnsten, 2009). Cortisol levels can be measured non-invasively in bodily fluids, including blood and saliva. Researchers often collect a cortisol sample before and after a potentially stressful task. In one common collection method, subjects place polymer swabs under their tongue for 1 to 2 minutes to soak up saliva. The saliva samples are then stored and analyzed later to determine the level of cortisol present at each time point.

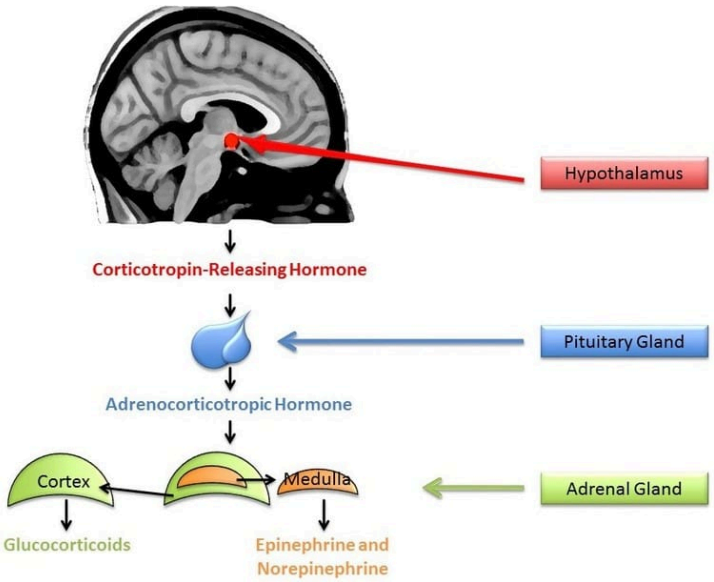

Figure 6.20.14.5: The Hypothalamic-pituitary-adrenal (HPA) axis. Black arrows represent the stress response pathway starting in the brain at the hypothalamus (an area within the brain). Stress triggers neurons in the hypothalamus to release corticotrophin-releasing hormone (CRH). The CRH is transported to the pituitary gland, another area in the brain, that activates the secretion of andrenocorticotropic hormone (ACTH). In turn, ACTH stimulates the adrenal glands that sit on top of the kidneys. The adrenal glands are composed of the outer adrenal cortex and inner adrenal medulla. The adrenal cortex secretes glucorcorticoids (including cortisol) and the medulla secretes epinephrine and norepinephrine. Stress, both psychological and physical, activates the HPA axis and results in the systemic release of cortisol, epinephrine, and norepinephrine.

Whereas early stress researchers studied the effects of physical stressors like loud noises, social neuroscientists have been instrumental in studying how our interactions with other people can cause stress. This question has been addressed through **neuroendocrinology**, or the study of how the brain and hormones act in concert to coordinate the physiology of the body. One contribution of this work has been in understanding the conditions under which other people can cause stress. In one study, Dickerson, Mycek, and Zaldivar (2008) asked undergraduates to deliver a speech either alone or to two other people. When the students gave the speech in front of others, there was a marked increase in cortisol compared with when they were asked to give a speech alone. This suggests that like chronic physical stress, everyday social stressors, like having your performance judged by others, induces a stress response. Interestingly, simply giving a speech in the same room with someone who is doing something else did not induce a stress response. This suggests that the mere presence of others is not stressful, but rather it is the potential for them to judge us that induces stress.

Worrying about what other people think of us is not the only source of social stress in our lives. Other research has shown that interacting with people who belong to different social groups than us – what social psychologists call **outgroup** members – can increase physiological stress responses. For example, cardiovascular responses associated with stress like contractility of the heart ventricles and the amount of blood pumped by the heart (what is called cardiac output) are increased when interacting with outgroup as compared with **ingroup** members (i.e., people who belong to the same social group we do) (Mendes, Blascovich, Likel, & Hunter, 2002). This stress may derive from the expectation that interactions with dissimilar others will be uncomfortable (Stephan & Stephan, 1985) or concern about being judged as unfriendly and prejudiced if the interaction goes poorly (Plant &

Devine, 2003).

The research just reviewed shows that events in our social lives can be stressful, but are social interactions always bad for us? No. In fact, while others can be the source of much stress, they are also a major buffer against stress. Research on **social support** shows that relying on a network of individuals in tough times gives us tools for dealing with stress and can ward off loneliness (Cacioppo & Patrick, 2008). For instance, people who report greater social support show a smaller increase in cortisol when performing a speech in front of two evaluators (Eisenberger, Taylor, Gable, Hilmert, & Lieberman, 2007).

What determines whether others will increase or decrease stress? What matters is the context of the social interaction. When it has potential to reflect badly on the self, social interaction can be stressful, but when it provides support and comfort, social interaction can protect us from the negative effects of stress. Using neuroendocrinology by measuring hormonal changes in the body has helped researchers better understand how social factors impact our body and ultimately our health.

Conclusions

Human beings are intensely social creatures – our lives are intertwined with other people and our health and well-being depend on others. Social neuroscience helps us to understand the critical function of how we make sense of and interact with other people. This module provides an introduction to what social neuroscience is and what we have already learned from it, but there is much still to understand. As we move forward, one exciting future direction will be to better understand how different parts of the brain and body interact to produce the numerous and complex patterns of social behavior that humans display. We hinted at some of this complexity when we reviewed research showing that while the mPFC is involved in mentalizing, other areas such as the STS, amygdala, and TPJ are as well. There are likely additional brain areas involved as well, interacting in ways we do not yet fully understand. These brain areas in turn control other aspects of the body to coordinate our responses during social interactions. Social neuroscience will continue to investigate these questions, revealing new information about how social processes occur, while also increasing our understanding of basic neural and physiological processes.

Video: See a demonstration of fMRI data being collected.

Video: See an example of EEG data being collected.

Video: View two tasks frequently used in the lab to create stress – giving a speech in front of strangers, and doing math computations out loud in front of others. Notice how some subjects show obvious signs of stress, but in some situations, cortisol changes suggest that even people who appear calm are experiencing a physiological response associated with stress.

Video: Watch a video used by Fritz Heider and Marianne Simmel in a landmark study on social perception published in 1944. Their goal was to investigate how we perceive other people, and they studied it by seeing how readily we apply people-like interpretations to non-social stimuli.

Discussion Questions

1. Categorizing someone as a member of a social group can activate group stereotypes. EEG research suggests that social categorization occurs quickly and often automatically. What does this tell us about the likelihood of stereotyping occurring? How can we use this information to develop ways to stop stereotyping from happening?
2. Watch this video, similar to what was used by Fritz Heider and Marianne Simmel in a landmark study on social perception published in 1944, and imagine telling a friend what happened in the video. http://intentionperception.org/wp-co...ider_Flash.swf. After watching the video, think about the following: Did you describe the motion of the objects solely in geometric terms (e.g., a large triangle moved from the left to the right), or did you describe the movements as actions of animate beings, maybe even of people (e.g., the circle goes into the house and shuts the door)? In the original research, 33 of 34 subjects described the action of the shapes using human terms. What does this tell us about our tendency to mentalize?
3. Consider the types of things you find stressful. How many of them are social in nature (e.g., are related to your interactions with other people)? Why do you think our social relations have such potential for stress? In what ways can social relations be beneficial and serve as a buffer for stress?

Vocabulary

Amygdala
A region located deep within the brain in the medial area (toward the center) of the temporal lobes (parallel to the ears). If you could draw a line through your eye sloping toward the back of your head and another line between your two ears, the amygdala would be located at the intersection of these lines. The amygdala is involved in detecting relevant stimuli in our environment and has been implicated in emotional responses.

Automatic process
When a thought, feeling, or behavior occurs with little or no mental effort. Typically, automatic processes are described as involuntary or spontaneous, often resulting from a great deal of practice or repetition.

Cortisol
A hormone made by the adrenal glands, within the cortex. Cortisol helps the body maintain blood pressure and immune function. Cortisol increases when the body is under stress.

Electroencephalogram
A measure of electrical activity generated by the brain's neurons.

Fight or flight response
The physiological response that occurs in response to a perceived threat, preparing the body for actions needed to deal with the threat.

Functional magnetic resonance imaging
A measure of changes in the oxygenation of blood flow as areas in the brain become active.

Functional neuroanatomy
Classifying how regions within the nervous system relate to psychology and behavior.

Hormones
Chemicals released by cells in the brain or body that affect cells in other parts of the brain or body.

Hypothalamic-pituitary-adrenal (HPA) axis
A system that involves the hypothalamus (within the brain), the pituitary gland (within the brain), and the adrenal glands (at the top of the kidneys). This system helps maintain homeostasis (keeping the body's systems within normal ranges) by regulating digestion, immune function, mood, temperature, and energy use. Through this, the HPA regulates the body's response to stress and injury.

Ingroup
A social group to which an individual identifies or belongs.

Lesions
Damage or tissue abnormality due, for example, to an injury, surgery, or a vascular problem.

Medial prefrontal cortex
An area of the brain located in the middle of the frontal lobes (at the front of the head), active when people mentalize about the self and others.

Mentalizing
The act of representing the mental states of oneself and others. Mentalizing allows humans to interpret the intentions, beliefs, and emotional states of others.

Neuroendocrinology
The study of how the brain and hormones act in concert to coordinate the physiology of the body.

Outgroup
A social group to which an individual does not identify or belong.

Simulation
Imaginary or real imitation of other people's behavior or feelings.

Social categorization
The act of mentally classifying someone into a social group (e.g., as female, elderly, a librarian).

Social support
A subjective feeling of psychological or physical comfort provided by family, friends, and others.

Stereotypes
The beliefs or attributes we associate with a specific social group. Stereotyping refers to the act of assuming that because someone is a member of a particular group, he or she possesses the group's attributes. For example, stereotyping occurs when we assume someone is unemotional just because he is man, or particularly athletic just because she is African American.

Stress
A threat or challenge to our well-being. Stress can have both a psychological component, which consists of our subjective thoughts and feelings about being threatened or challenged, as well as a physiological component, which consists of our body's response to the threat or challenge (see "fight or flight response").

Superior temporal sulcus
The sulcus (a fissure in the surface of the brain) that separates the superior temporal gyrus from the middle temporal gyrus. Located in the temporal lobes (parallel to the ears), it is involved in perception of biological motion or the movement of animate objects.

Sympathetic nervous system
A branch of the autonomic nervous system that controls many of the body's internal organs. Activity of the SNS generally mobilizes the body's fight or flight response.

Temporal parietal junction
The area where the temporal lobes (parallel to the ears) and parieta lobes (at the top of the head toward the back) meet. This area is important in mentalizing and distinguishing between the self and others.

Theory of Mind and Social Cognition

Overview

We now continue exploration of social cognition by examining an important cognitive ability in humans essential for successful social interaction--theory of mind, a capacity that some scholars prefer to label “mentalizing” or “mindreading,” the ability to perceive and interpret other people’s behavior in terms of their mental states. The capacity may have evolved sometime in the last few million years. Theory of mind is thought to be a prerequisite for natural language acquisition, strategic social interaction, reflexive thought, and moral judgment. Humans need to understand minds in order to engage in the kinds of complex interactions that social communities (small and large) require--interactions that have given rise to the complex products of human cultural evolution. The capacity is severely limited in autism.

Theory of Mind

By Bertram Malle

Brown University

One of the most remarkable human capacities is to perceive and understand mental states. This capacity, often labeled “theory of mind,” consists of an array of psychological processes that play essential roles in human social life. We review some of these roles, examine what happens when the capacity is deficient, and explore the many processes that make up the capacity to understand minds.

Learning Objectives

- Explain what theory of mind is.
- Enumerate the many domains of social life in which theory of mind is critical.
- Describe some characteristics of how autistic individuals differ in their processing of others’ minds.
- Describe and explain some of the many concepts and processes that comprise the human understanding of minds.
- Have a basic understanding of how ordinary people explain unintentional and intentional behavior.

Introduction

One of the most fascinating human capacities is the ability to perceive and interpret other people’s behavior in terms of their mental states. Having an appreciation for the workings of another person’s mind is considered a prerequisite for natural language acquisition (Baldwin & Tomasello, 1998), strategic social interaction (Zhang, Hedden, & Chia, 2012), reflexive thought (Bogdan, 2000), and moral judgment (Guglielmo, Monroe, & Malle, 2009). This capacity develops from early beginnings in the first year of life to the adult’s fast and often effortless understanding of others’ thoughts, feelings, and intentions. And though we must speculate about its evolutionary origin, we do have indications that the capacity evolved sometime in the last few million years.

In this module we will focus on two questions: What is the role of understanding others’ minds in human social life? And what is known about the mental processes that underlie such understanding? For simplicity, we will label this understanding “**theory of mind**,” even though it is not literally a “theory” that people have about the mind; rather, it is a capacity that some scholars prefer to label “mentalizing” or “mindreading.” But we will go behind all these labels by breaking down the capacity into distinct components: the specific concepts and mental processes that underlie the human understanding of minds.

First, let’s get clear about the roles that this understanding plays in social life.

The Role of Theory of Mind in Social Life

Figure 6.20.14.6: We rely on the theory of mind in social situations to infer what others are thinking and feeling. Among other things, this capability helps us work successfully in teams. [Image: Office of Public Affairs, https://goo.gl/O8zvFj, CC BY-SA 2.0, https://goo.gl/rxiUsF]

Put yourself in this scene: You observe two people's movements, one behind a large wooden object, the other reaching behind him and then holding a thin object in front of the other. Without a theory of mind you would neither understand what this movement stream meant nor be able to predict either person's likely responses. With the capacity to interpret certain physical movements in terms of mental states, perceivers can parse this complex scene into intentional actions of reaching and giving (Baird & Baldwin, 2001); they can interpret the actions as instances of offering and trading; and with an appropriate cultural script, they know that all that was going on was a customer pulling out her credit card with the intention to pay the cashier behind the register. People's theory of mind thus frames and interprets perceptions of human behavior in a particular way—as perceptions of agents who can act intentionally and who have desires, beliefs, and other mental states that guide their actions (Perner, 1991; Wellman, 1990).

Not only would social perceivers without a theory of mind be utterly lost in a simple payment interaction; without a theory of mind, there would probably be no such things as cashiers, credit cards, and payment (Tomasello, 2003). Plain and simple, humans need to understand minds in order to engage in the kinds of complex interactions that social communities (small and large) require. And it is these complex social interactions that have given rise, in human cultural evolution, to houses, cities, and nations; to books, money, and computers; to education, law, and science.

The list of social interactions that rely deeply on theory of mind is long; here are a few highlights.

- Teaching another person new actions or rules by taking into account what the learner knows or doesn't know and how one might best make him understand.
- Learning the words of a language by monitoring what other people attend to and are trying to do when they use certain words.
- Figuring out our social standing by trying to guess what others think and feel about us.
- Sharing experiences by telling a friend how much we liked a movie or by showing her something beautiful.
- Collaborating on a task by signaling to one another that we share a goal and understand and trust the other's intention to pursue this joint goal.

Autism and Theory of Mind

Figure 6.20.14.7: Individuals with autism can have a harder time using the theory of mind because it involves processing facial expressions and inferring people's intentions. A look that might convey a lot of meaning to most people conveys little or nothing to someone with autism. [Image: WarzauWynn, https://goo.gl/gUO8HE, CC BY-NC 2.0, https://goo.gl/tgFydH]

Another way of appreciating the enormous impact that theory of mind has on social interactions is to study what happens when the capacity is severely limited, as in the case of autism (Tager-Flusberg, 2007). In a fascinating discussion in which (high-functioning) autistic individuals talk about their difficulties with other people's minds (Blackburn, Gottschewski, George, & L—, 2000), one person reports: "I know people's faces down to the acne scars on the left corners of their chins . . . and how the hairs of their eyebrows curl. . . . The best I can do is start picking up bits of data during my encounter with them because there's not much else I can do. . . . I'm not sure what kind of information about them I'm attempting to process." What seems to be missing, as another person with autism remarks, is an "automatic processing of 'people information.'" Some autistic people report that they perceive others "in a more analytical way." This analytical mode of processing, however, is very tiresome and slow: "Given time I may be able to analyze someone in various ways, and seem to get good results, but may not pick up on certain aspects of an interaction until I am obsessing over it hours or days later" (Blackburn et al., 2000).

So what is this magical potion that allows most people to gain quick and automatic access to other people's minds and to recognize the meaning underlying human behavior? Scientific research has accumulated a good deal of knowledge in the past few decades, and here is a synopsis of what we know.

The Mental Processes Underlying Theory of Mind

The first thing to note is that "theory of mind" is not a single thing. What underlies people's capacity to recognize and understand mental states is a whole host of components—a toolbox, as it were, for many different but related tasks in the social world (Malle, 2008). Figure 1 shows some of the most important tools, organized in a way that reflects the complexity of involved processes: from simple and automatic on the bottom to complex and deliberate on the top. This organization also reflects development—from tools that infants master within the first 6–12 months to tools they need to acquire over the next 3–5 years. Strikingly, the organization also reflects evolution: monkeys have available the tools on the bottom; chimpanzees have available the tools at the second level; but only humans master the remaining tools above. Let's look at a few of them in more detail.

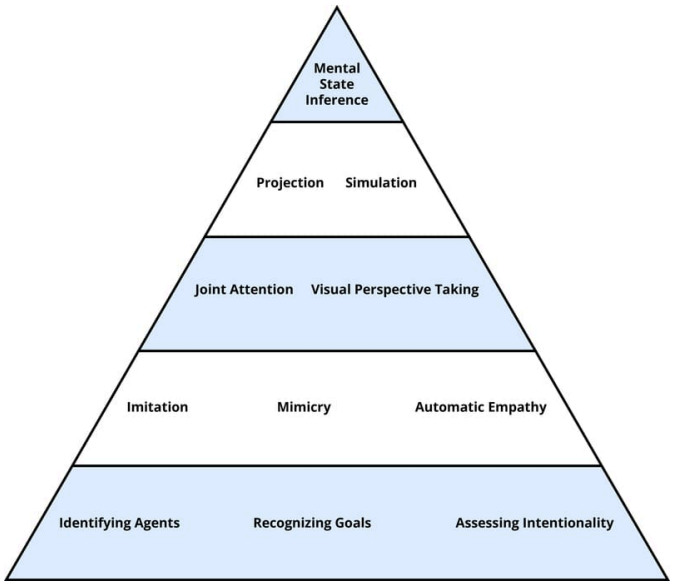

Figure 6.20.14.8: Some of the major tools of theory of mind, with the bottom showing simple, automatic, early developing, and evolutionarily old processes, and the top showing complex, more deliberate, late developing, and evolutionarily recent processes.

Agents, Goals, and Intentionality

The *agent* category allows humans to identify those moving objects in the world that can act on their own. Features that even very young children take to be indicators of being an agent include being self-propelled, having eyes, and reacting systematically to the interaction partner's behavior, such as following gaze or imitating (Johnson, 2000; Premack, 1990).

The process of *recognizing goals* builds on this agent category, because agents are characteristically directed toward goal objects, which means they seek out, track, and often physically contact said objects. Even before the end of their first year, infants recognize that humans reach toward an object they strive for even if that object changes location or if the path to the object contains obstacles (Gergely, Nádasdy, Csibra, & Bíró, 1995; Woodward, 1998). What it means to recognize goals, therefore, is to see the systematic and predictable relationship between a particular agent pursuing a particular object across various circumstances.

Through learning to recognize the many ways by which agents pursue goals, humans learn to pick out behaviors that are **intentional**. The concept of **intentionality** is more sophisticated than the *goal* concept. For one thing, human perceivers recognize that some behaviors can be unintentional even if they were goal-directed—such as when you unintentionally make a fool of yourself even though you had the earnest goal of impressing your date. To act intentionally you need, aside from a goal, the right kinds of beliefs about how to achieve the goal. Moreover, the adult concept of intentionality requires that an agent have the *skill* to perform the intentional action in question: If I am flipping a coin, trying to make it land on heads, and if I get it to land on heads on my first try, you would not judge my action of making it land on heads as intentional—you would say it was luck (Malle & Knobe, 1997).

Imitation, Synchrony, and Empathy

Figure 6.20.14.9: It's natural when having a conversation to unconsciously synchronize with our partners. [Image: Jacopo Aneghini Photos , https://goo.gl/QDpPln, CC BY-NC 2.0, https://goo.gl/VnKlK8]

Imitation and empathy are two other basic capacities that aid the understanding of mind from childhood on (Meltzoff & Decety, 2003). *Imitation* is the human tendency to carefully observe others' behaviors and do as they do—even if it is the first time the perceiver has seen this behavior. A subtle, automatic form of imitation is called **mimicry**, and when people mutually mimic one another they can reach a state of **synchrony**. Have you ever noticed when two people in conversation take on similar gestures, body positions, even tone of voice? They "synchronize" their behaviors by way of (largely) unconscious imitation. Such synchrony can happen even at very low levels, such as negative physiological arousal (Levenson & Ruef, 1992), though the famous claim of synchrony in women's menstrual cycles is a myth (Yang & Schank, 2006). Interestingly, people who enjoy an interaction synchronize their behaviors more, and increased synchrony (even manipulated in an experiment) makes people enjoy their interaction more (Chartrand & Bargh, 1999). Some research findings suggest that synchronizing is made possible by brain mechanisms that tightly link perceptual information with motor information (when I see you move your arm, my arm-moving program is activated). In monkeys, highly specialized so-called **mirror neurons** fire both when the monkey sees a certain action and when it performs that same action (Rizzolatti, Fogassi, & Gallese, 2001). In humans, however, things are a bit more complex. In many everyday settings, people perceive uncountable behaviors and fortunately don't copy all of them (just consider walking in a crowd—hundreds of your mirror neurons would fire in a blaze of confusion). Human imitation and mirroring is selective, triggering primarily actions that are relevant to the perceiver's current state or aim.

Automatic empathy builds on imitation and synchrony in a clever way. If Bill is sad and expresses this emotion in his face and body, and if Elena watches or interacts with Bill, then she will subtly imitate his dejected behavior and, through well-practiced associations of certain behaviors and emotions, she will feel a little sad as well (Sonnby-Borgström, Jönsson, & Svensson, 2003). Thus, she empathizes with him—whether she wants to or not. Try it yourself. Type "sad human faces" into your Internet search engine and select images from your results. Look at 20 photos and pay careful attention to what happens to your face and to your mood. Do you feel almost a "pull" of some of your facial muscles? Do you feel a tinge of melancholy?

Joint Attention, Visual Perspective Taking

Going beyond the automatic, humans are capable of actively engaging with other people's mental states, such as when they enter into situations of **joint attention**—like Marissa and Noah, who are each looking at an object and are both aware that each of them is looking at the object. This sounds more complicated than it really is. Just point to an object when a 3-year old is around and notice how both the child and you check in with each other, ensuring that you are really *jointly* engaging with the object. Such shared engagement is critical for children to learn the meaning of objects—both their value (is it safe and rewarding to approach?) and the words that refer to them (what do you call this?). When I hold up my keyboard and show it to you, we are jointly attending to it, and if I then say it's called "Tastatur" in German, you know that I am referring to the keyboard and not to the table on which it had been resting.

Another important capacity of engagement is **visual perspective taking**: You are sitting at a dinner table and advise another person on where the salt is—do you consider that it is to *her* left even though it is to *your* right? When we overcome our egocentric perspective this way, we imaginatively adopt the other person's spatial viewpoint and determine how the world looks from their perspective. In fact, there is evidence that we mentally "rotate" toward the other's spatial location, because the farther away the person sits (e.g., 60, 90, or 120 degrees away from you) the longer it takes to adopt the person's perspective (Michelon & Zacks, 2006).

Projection, Simulation (and the Specter of Egocentrism)

When imagining what it might be like to be in another person's *psychological* position, humans have to go beyond mental rotation. One tool to understand the other's thoughts or feelings is **simulation**—using one's own mental states as a model for others' mental states: "What would it feel like sitting across from the stern interrogator? *I* would feel scared . . ." An even simpler form of such modeling is the assumption that the other thinks, feels, wants what we do—which has been called the "like-me" assumption (Meltzoff, 2007) or the inclination toward *social* **projection** (Krueger, 2007). In a sense, this is an absence of perspective taking, because we assume that the other's perspective equals our own. This can be an effective strategy if we share with the other person the same environment, background, knowledge, and goals, but it gets us into trouble when this presumed common ground is in reality lacking. Let's say you know that Brianna doesn't like Fred's new curtains, but you hear her exclaim to Fred, "These are beautiful!" Now you have to predict whether Fred can figure out that Brianna was being sarcastic. It turns out that you will have a hard time suppressing your own knowledge in this case and you may overestimate how easy it is for Fred to spot the sarcasm (Keysar, 1994). Similarly, you will overestimate how visible that pimple is on your chin—even though it feels big and ugly to you, in reality very few people will ever notice it (Gilovich & Savitsky, 1999). So the next time when you spot a magnificent bird high up in the tree and you get impatient with your friend who just can't see what is clearly obvious, remember: it's obvious to *you*.

What all these examples show is that people use their own current state—of knowledge, concern, or perception—to grasp other people's mental states. And though they often do so correctly, they also get things wrong at times. This is why couples counselors, political advisors, and Buddhists agree on at least one thing: we all need to try harder to recognize our egocentrism and actively take other people's perspective—that is, grasp their actual mental states, even if (or especially when) they are different from our own.

Explicit Mental State Inference

The ability to truly take another person's perspective requires that we separate what we want, feel, and know from what the other person is likely to want, feel, and know. To do so humans make use of a variety of information. For one thing, they rely on stored knowledge—both general knowledge ("Everybody would be nervous when threatened by a man with a gun") and agent-specific knowledge ("Joe was fearless because he was trained in martial arts"). For another, they critically rely on perceived facts of the concrete situation—such as what is happening to the agent, the agent's facial expressions and behaviors, and what the person saw or didn't see.

This capacity of integrating multiple lines of information into a mental-state inference develops steadily within the first few years of life, and this process has led to a substantial body of research (Wellman, Cross, & Watson, 2001). The research began with a clever experiment by Wimmer and Perner (1983), who tested whether children can pass a **false-belief test** (see Figure 2). The child is shown a picture story of Sally, who puts her ball in a basket and leaves the room. While Sally is out of the room, Anne comes along and takes the ball from the basket and puts it inside a box. The child is then asked *where* Sally thinks the ball is located when she comes back to the room. Is she going to look first *in the box* or *in the basket*?

The right answer is that she will look in the basket, because that's where she put it and thinks it is; but we have to infer this *false belief* against our own better knowledge that the ball is in the box. This is very difficult for children before the age of 4, and it usually takes some cognitive effort in adults (Epley, Morewedge, & Keysar, 2004).

The challenge is clear: People are good at automatically relating to other people, using their own minds as a fitting model for others' minds. But people need to recognize when to step out of their own perspective and truly represent the other person's perspective—which may harbor very different thoughts, feelings, and intentions.

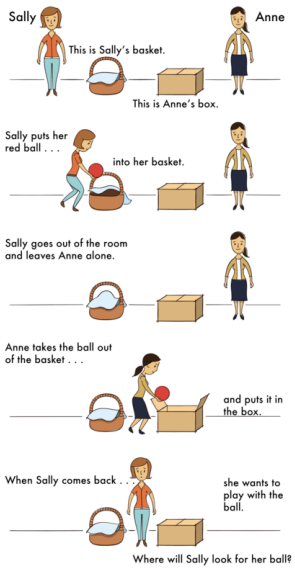

Figure 6.20.14.10: Sally–Anne task to test children's ability to infer false beliefs.

Tools in Summary

We have seen that the human understanding of other minds relies on many tools. People process such information as motion, faces, and gestures and categorize it into such concepts as agent, intentional action, or fear. They rely on relatively automatic psychological processes, such as imitation, joint attention, and projection. And they rely on more effortful processes, such as simulation and mental-state inference. These processes all link behavior that humans observe to mental states that humans infer. If we call this stunning capacity a "theory," it is a theory of mind *and* behavior.

Folk Explanations of Behavior

Nowhere is this mind–behavior link clearer than in **people's explanations of behavior**—when they try to understand why somebody acted or felt a certain way. People have a strong need to answer such "why" questions, from the trivial to the significant: why the neighbor's teenage daughter is wearing a short skirt in the middle of winter; why the policeman is suddenly so friendly; why the murderer killed three people. The need to explain this last behavior seems puzzling, because typical benefits of explanation are absent: We do not need to predict or control the criminal's behavior since we will never have anything to do with him. Nonetheless, we have an insatiable desire to *understand*, to find *meaning* in this person's behavior—and in people's behavior generally.

This makes evolutionary sense for at least two reasons: 1) because we are highly social creatures by virtue of our genetic evolution as a species, and success in the social group, including being valued by others in your group, was especially important to our survival in our evolutionary past (if you "don't get" others and consequently aren't valued and liked by the group, they are less likely to risk themselves to save you from a predator or to share food and other resources with you), strong motivation to understand other people would be favored by natural selection; 2) strong motivation to understand behavior of others increases chances of being able to predict behavior of others, and to predict their intentions, thereby allowing prediction of their future behavior allowing strategic preparation for it increasing your success in your social interactions, essential to human adaptation.

Figure 6.20.14.11: When people behave in ways that don't make sense to us we often feel compelled to come up with reasonable explanations. What are their motives? What circumstances would lead to this? How could this happen? [Image: lwpkommunikacio, https://goo.gl/5x1SAN, CC BY 2.0, https://goo.gl/axKpvj]

Older theories of how people explain and understand behavior suggested that people merely identify causes of the behavior (e.g., Kelley, 1967). That is true for most unintentional behaviors—tripping, having a headache, calling someone by the wrong name. But to explain *intentional* behaviors, people use a more sophisticated framework of interpretation, which follows directly from their concept of intentionality and the associated mental states they infer (Malle, 2004). We have already mentioned the complexity of people's concept of intentionality; here it is in full (Malle & Knobe, 1997): For an agent to perform a behavior intentionally, she must have a desire for an outcome (what we had called a goal), beliefs about how a particular action leads to the outcome, and an intention to perform that action; if the agent then actually performs the action with awareness and skill, people take it to be an intentional action. To explain *why* the agent performed the action, humans try to make the inverse inference of *what desire* and *what beliefs* the agent had that led her to so act, and these inferred desires and beliefs are the *reasons* for which she acted. What was her reason for wearing a short skirt in the winter? "She wanted to annoy her mother." What was the policeman's reason for suddenly being so nice? "He thought he was speaking with an influential politician." What was his reason for killing three people? In fact, with such extreme actions, people are often at a loss for an answer. If they do offer an answer, they frequently retreat to "causal history explanations" (Malle, 1999), which step outside the agent's own reasoning and refer instead to more general background facts—for example, that he was mentally ill or a member of an extremist group. But people clearly prefer to explain others' actions by referring to their beliefs and desires, the specific reasons for which they acted.

By relying on a theory of mind, explanations of behavior make meaningful what would otherwise be inexplicable motions—just like in our initial example of two persons passing some object between them. We recognize that the customer wanted to pay and that's why she passed her credit card to the cashier, who in turn knew that he was given a credit card and swiped it. It all seems perfectly clear, almost trivial to us. But that is only because humans have a theory of mind and use it to retrieve the relevant knowledge, simulate the other people's perspective, infer beliefs and desires, and explain what a given action means. Humans do this effortlessly and often accurately. Moreover, they do it within seconds or less. What's so special about that? Well, it takes years for a child to develop this capacity, and it took our species a few million years to evolve it. That's pretty special.

Discussion Questions

1. Recall a situation in which you tried to infer what a person was thinking or feeling but you just couldn't figure it out, and recall another situation in which you tried the same but succeeded. Which tools were you able to use in the successful case that you didn't or couldn't use in the failed case?
2. Mindfulness training improves keen awareness of one's own mental states. Look up a few such training programs (easily found online) and develop a similar training program to improve awareness of other people's minds.
3. In the near future we will have robots that closely interact with people. Which theory of mind tools should a robot definitely have? Which ones are less important? Why?
4. Humans assume that everybody has the capacity to make choices and perform intentional actions. But in a sense, a choice is just a series of brain states, caused by previous brain states and states of the world, all governed by the physical laws of the universe. Is the concept of choice an illusion?
5. The capacity to understand others' minds is intimately related to another unique human capacity: language. How might these two capacities have evolved? Together? One before the other? Which one?

Vocabulary

Automatic empathy
A social perceiver unwittingly taking on the internal state of another person, usually because of mimicking the person's expressive behavior and thereby feeling the expressed emotion.

False-belief test
An experimental procedure that assesses whether a perceiver recognizes that another person has a false belief—a belief that contradicts reality.

Folk explanations of behavior
People's natural explanations for why somebody did something, felt something, etc. (differing substantially for unintentional and intentional behaviors).

Intention
An agent's mental state of committing to perform an action that the agent believes will bring about a desired outcome.

Intentionality
The quality of an agent's performing a behavior intentionally—that is, with skill and awareness and executing an intention (which is in turn based on a desire and relevant beliefs).

Joint attention
Two people attending to the same object and being aware that they both are attending to it.

Mimicry
: Copying others' behavior, usually without awareness.

Mirror neurons
: Neurons identified in monkey brains that fire both when the monkey performs a certain action and when it perceives another agent performing that action.

Projection
: A social perceiver's assumption that the other person wants, knows, or feels the same as the perceiver wants, know, or feels.

Simulation
: The process of representing the other person's mental state.

Synchrony
: Two people displaying the same behaviors or having the same internal states (typically because of mutual mimicry).

Theory of mind
: The human capacity to understand minds, a capacity that is made up of a collection of concepts (e.g., agent, intentionality) and processes (e.g., goal detection, imitation, empathy, perspective taking).

Visual perspective taking
: Can refer to visual perspective taking (perceiving something from another person's spatial vantage point) or more generally to effortful mental state inference (trying to infer the other person's thoughts, desires, emotions).

Disorders of the Social Brain

Overview

We now continue exploration of social cognition by examining a spectrum of disorders of social processing and the brain mechanisms involved. Here we encounter social neuroscience once again. Autism is in the category of *pervasive developmental disorders*, which includes Asperger's disorder, childhood disintegrative disorder, autistic disorder, and pervasive developmental disorder - not otherwise specified. These disorders, together, are labeled *autism spectrum disorder* (ASD). ASD is defined by the presence of profound difficulties in social interactions and communication combined with the presence of repetitive or restricted interests, cognition and behaviors. The social brain is a set of interconnected neuroanatomical structures that process social information, enabling the recognition of other individuals and the evaluation their mental states. The social brain is hypothesized to consist of the amygdala, the orbital frontal cortex (OFC), fusiform gyrus (FG), and the posterior superior temporal sulcus (STS) region, among other structures. Because autism is a developmental disorder, it is particularly important to diagnose and treat ASD early in life.

Autism: Insights from the Study of the Social Brain

By Kevin A. Pelphrey

Yale University

People with autism spectrum disorder (ASD) suffer from a profound social disability. Social neuroscience is the study of the parts of the brain that support social interactions or the “social brain.” This module provides an overview of ASD and focuses on understanding how social brain dysfunction leads to ASD. Our increasing understanding of the social brain and its dysfunction in ASD will allow us to better identify the genes that cause ASD and will help us to create and pick out treatments to better match individuals. Because social brain systems emerge in infancy, social neuroscience can help us to figure out how to diagnose ASD even before the symptoms of ASD are clearly present. This is a hopeful time because social brain systems remain malleable well into adulthood and thus open to creative new interventions that are informed by state-of-the-art science.

- Autism Spectrum Disorder
- Social brain
- Social neuroscience

Learning Objectives

- Know the basic symptoms of ASD.
- Distinguish components of the social brain and understand their dysfunction in ASD.
- Appreciate how social neuroscience may facilitate the diagnosis and treatment of ASD.

Defining Autism Spectrum Disorder

Autism Spectrum Disorder (ASD) is a developmental disorder that usually emerges in the first three years and persists throughout the individual's life. Though the key symptoms of ASD fall into three general categories (see below), each person with ASD exhibits symptoms in these domains in different ways and to varying degrees. This *phenotypic heterogeneity* reflects the high degree of variability in the genes underlying ASD (Geschwind & Levitt, 2007). Though we have identified genetic differences associated with individual cases of ASD, each accounts for only a small number of the actual cases, suggesting that no single genetic cause will apply in the majority of people with ASD. There is currently no biological test for ASD.

Autism is in the category of *pervasive developmental disorders*, which includes Asperger's disorder, childhood disintegrative disorder, autistic disorder, and pervasive developmental disorder - not otherwise specified. These disorders, together, are labeled *autism spectrum disorder* (ASD). ASD is defined by the presence of profound difficulties in social interactions and communication combined with the presence of repetitive or restricted interests, cognitions and behaviors. The diagnostic process involves a combination of parental report and clinical observation. Children with significant impairments across the social/communication domain who also exhibit repetitive behaviors can qualify for the ASD diagnosis. There is wide variability in the precise symptom profile an individual may exhibit.

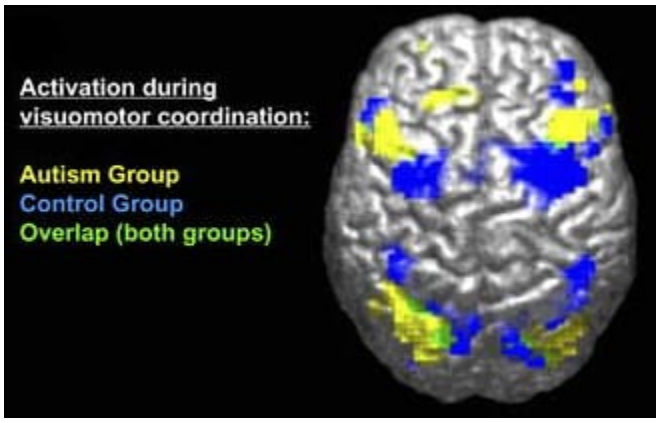

Figure 6.20.14.12: The red lines indicate the scan paths (collection of eye movements) used by people with (right column) and without (left column) autism to explore faces. Modified from Pelphrey et al., (2002).

Since Kanner first described ASD in 1943, important commonalities in symptom presentation have been used to compile criteria for the diagnosis of ASD. These diagnostic criteria have evolved during the past 70 years and continue to evolve (e.g., see the recent changes to the diagnostic criteria on the American Psychiatric Association's website, http://www.dsm5.org/), yet impaired social functioning remains a required symptom for an ASD diagnosis. Deficits in social functioning are present in varying degrees for simple behaviors such as eye contact, and complex behaviors like navigating the give and take of a group conversation for individuals of all functioning levels (i.e. high or low IQ). Moreover, difficulties with social information processing occur in both visual (e.g., Pelphrey et al., 2002) and auditory (e.g., Dawson, Meltzoff, Osterling, Rinaldi, & Brown, 1998) sensory modalities.

Consider the results of an eye tracking study in which Pelphrey and colleagues (2002) observed that individuals with autism did not make use of the eyes when judging facial expressions of emotion (see right panels of Figure 1). While repetitive behaviors or language deficits are seen in other disorders (e.g., obsessive-compulsive disorder and specific language impairment, respectively), basic social deficits of this nature are unique to ASD. Onset of the social deficits appears to precede difficulties in

other domains (Osterling, Dawson, & Munson, 2002) and may emerge as early as 6 months of age (Maestro et al., 2002).

Defining the Social Brain

Within the past few decades, research has elucidated specific brain circuits that support perception of humans and other species. This *social perception* refers to “the initial stages in the processing of information that culminates in the accurate analysis of the dispositions and intentions of other individuals” (Allison, Puce, & McCarthy, 2000). Basic social perception is a critical building block for more sophisticated social behaviors, such as thinking about the motives and emotions of others. Brothers (1990) first suggested the notion of a **social brain**, a set of interconnected neuroanatomical structures that process social information, enabling the recognition of other individuals and the evaluation their mental states (e.g., intentions, dispositions, desires, and beliefs).

The social brain is hypothesized to consist of the amygdala, the orbital frontal cortex (OFC), fusiform gyrus (FG), and the posterior superior temporal sulcus (STS) region, among other structures. Though all areas work in coordination to support social processing, each appears to serve a distinct role. The amygdala helps us recognize the emotional states of others (e.g., Morris et al., 1996) and also to experience and regulate our own emotions (e.g., LeDoux, 1992). The OFC supports the "reward" feelings we have when we are around other people (e.g., Rolls, 2000). The FG, located at the bottom of the surface of the temporal lobes detects faces and supports face recognition (e.g., Puce, Allison, Asgari, Gore, & McCarthy, 1996). The posterior STS region recognizes the biological motion, including eye, hand and other body movements, and helps to interpret and predict the actions and intentions of others (e.g., Pelphrey, Morris, Michelich, Allison, & McCarthy, 2005).

Current Understanding of Social Perception in ASD

Figure 6.20.14.13: The human brain has specialized functions to help guide our social interactions. [Image: Allan Ajifo, https://goo.gl/jv4iXf, CC BY 2.0, https://goo.gl/BRvSA7]

The social brain is of great research interest because the social difficulties characteristic of ASD are thought to relate closely to the functioning of this brain network. **Functional magnetic resonance imaging (fMRI)** and **event-related potentials (ERP)** are complementary brain imaging methods used to study activity in the brain across the lifespan. Each method measures a distinct facet of brain activity and contributes unique information to our understanding of brain function.

FMRI uses powerful magnets to measure the levels of oxygen within the brain, which vary according to changes in neural activity. As the neurons in specific brain regions “work harder”, they require more oxygen. FMRI detects the brain regions that exhibit a relative increase in blood flow (and oxygen levels) while people listen to or view social stimuli in the MRI scanner. The areas of the brain most crucial for different social processes are thus identified, with spatial information being accurate to the millimeter.

In contrast, ERP provides direct measurements of the firing of groups of neurons in the cortex. Non-invasive sensors on the scalp record the small electrical currents created by this neuronal activity while the subject views stimuli or listens to specific kinds of information. While fMRI provides information about *where* brain activity occurs, ERP specifies *when* by detailing the timing of

processing at the millisecond pace at which it unfolds.

ERP and fMRI are complementary, with fMRI providing excellent *spatial resolution* and ERP offering outstanding *temporal resolution*. Together, this information is critical to understanding the nature of social perception in ASD. To date, the most thoroughly investigated areas of the social brain in ASD are the superior temporal sulcus (STS), which underlies the perception and interpretation of biological motion, and the fusiform gyrus (FG), which supports face perception. Heightened sensitivity to biological motion (for humans, motion such as walking) serves an essential role in the development of humans and other highly social species. Emerging in the first days of life, the ability to detect biological motion helps to orient vulnerable young to critical sources of sustenance, support, and learning, and develops independent of visual experience with biological motion (e.g., Simion, Regolin, & Bulf, 2008). This inborn "life detector" serves as a foundation for the subsequent development of more complex social behaviors (Johnson, 2006).

Figure 6.20.14.14: From an evolutionary standpoint, it was incredibly important for our survival to maintain social relationships. Therefore, it makes sense that we would be able to recognize faces within the first few days of our infancy. [Image: donnierayjones, https://goo.gl/obrI2x, CC BY 2.0, https://goo.gl/v4Y0Zv]

From very early in life, children with ASD display reduced sensitivity to biological motion (Klin, Lin, Gorrindo, Ramsay, & Jones, 2009). Individuals with ASD have reduced activity in the STS during biological motion perception. Similarly, people at increased genetic risk for ASD but who do not develop symptoms of the disorder (i.e. unaffected siblings of individuals with ASD) show increased activity in this region, which is hypothesized to be a compensatory mechanism to offset genetic vulnerability (Kaiser et al., 2010).

In typical development, preferential attention to faces and the ability to recognize individual faces emerge in the first days of life (e.g., Goren, Sarty, & Wu, 1975). The special way in which the brain responds to faces usually emerges by three months of age (e.g., de Haan, Johnson, & Halit, 2003) and continues throughout the lifespan (e.g., Bentin et al., 1996). Children with ASD, however, tend to show decreased attention to human faces by six to 12 months (Osterling & Dawson, 1994). Children with ASD also show reduced activity in the FG when viewing faces (e.g., Schultz et al., 2000). Slowed processing of faces (McPartland, Dawson, Webb, Panagiotides, & Carver, 2004) is a characteristic of people with ASD that is shared by parents of children with ASD (Dawson, Webb, & McPartland, 2005) and infants at increased risk for developing ASD because of having a sibling with ASD (McCleery, Akshoomoff, Dobkins, & Carver, 2009). Behavioral and attentional differences in face perception and recognition are evident in children and adults with ASD as well (e.g., Hobson, 1986).

Exploring Diversity in ASD

Because of the limited quality of the behavioral methods used to diagnose ASD and current clinical diagnostic practice, which permits similar diagnoses despite distinct symptom profiles (McPartland, Webb, Keehn, & Dawson, 2011), it is possible that the group of children currently referred to as having ASD may actually represent different syndromes with distinct causes. Examination of the social brain may well reveal diagnostically meaningful subgroups of children with ASD. Measurements of the "where" and "when" of brain activity during social processing tasks provide reliable sources of the detailed information needed to profile

children with ASD with greater accuracy. These profiles, in turn, may help to inform treatment of ASD by helping us to match specific treatments to specific profiles.

The integration of imaging methods is critical for this endeavor. Using face perception as an example, the combination of fMRI and ERP could identify who, of those individuals with ASD, shows anomalies in the FG and then determine the stage of information processing at which these impairments occur. Because different processing stages often reflect discrete cognitive processes, this level of understanding could encourage treatments that address specific processing deficits at the neural level.

For example, differences observed in the early processing stages might reflect problems with low-level visual perception, while later differences would indicate problems with higher-order processes, such as emotion recognition. These same principles can be applied to the broader network of social brain regions and, combined with measures of behavioral functioning, could offer a comprehensive profile of brain-behavior performance for a given individual. A fundamental goal for this kind of subgroup approach is to improve the ability to tailor treatments to the individual.

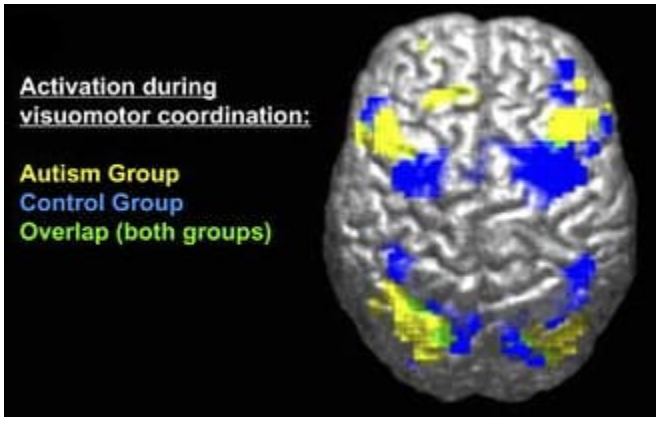

Figure 6.20.14.15: Trying to diagnose the precise autism disorder can be difficult; many cases share similar symptoms. However, burgeoning technology, like the fMRI, allows clinicians a glimpse into the patient's brain and thus a better understanding of his or her disorder. [Image: Ralph-Axel Müller, https://goo.gl/WwxCV1, CC BY 2.5, https://goo.gl/0QtWcf]

Another objective is to improve the power of other scientific tools. Most studies of individuals with ASD compare groups of individuals, for example, individuals on with ASD compared to typically developing peers. However, studies have also attempted to compare children across the autism spectrum by group according to differential diagnosis (e.g., Asperger's disorder versus autistic disorder), or by other behavioral or cognitive characteristics (e.g., cognitively able versus intellectually disabled or anxious versus non-anxious). Yet, the power of a scientific study to detect these kinds of significant, meaningful, individual differences is only as strong as the accuracy of the factor used to define the compared groups.

The identification of distinct subgroups within the autism spectrum according to information about the brain would allow for a more accurate and detailed exposition of the individual differences seen in those with ASD. This is especially critical for the success of investigations into the genetic basis of ASD. As mentioned before, the genes discovered thus far account for only a small portion of ASD cases. If meaningful, quantitative distinctions in individuals with ASD are identified; a more focused examination into the genetic causes specific to each subgroup could then be pursued. Moreover, distinct findings from neuroimaging, or *biomarkers*, can help guide genetic research. **Endophenotypes**, or characteristics that are not immediately available to observation but that reflect an underlying genetic liability for disease, expose the most basic components of a complex psychiatric disorder and are more stable across the lifespan than observable behavior (Gottesman & Shields, 1973). By describing the key characteristics of ASD in these objective ways, neuroimaging research will facilitate identification of genetic contributions to ASD.

Atypical Brain Development Before the Emergence of Atypical Behavior

Because autism is a developmental disorder, it is particularly important to diagnose and treat ASD early in life. Early deficits in attention to biological motion, for instance, derail subsequent experiences in attending to higher level social information, thereby driving development toward more severe dysfunction and stimulating deficits in additional domains of functioning, such as language development. The lack of reliable predictors of the condition during the first year of life has been a major impediment to the effective treatment of ASD. Without early predictors, and in the absence of a firm diagnosis until behavioral symptoms emerge, treatment is often delayed for two or more years, eclipsing a crucial period in which intervention may be particularly

successful in ameliorating some of the social and communicative impairments seen in ASD.

In response to the great need for sensitive (able to identify subtle cases) and specific (able to distinguish autism from other disorders) early indicators of ASD, such as biomarkers, many research groups from around the world have been studying patterns of infant development using prospective longitudinal studies of infant siblings of children with ASD and a comparison group of infant siblings without familial risks. Such designs gather longitudinal information about developmental trajectories across the first three years of life for both groups followed by clinical diagnosis at approximately 36 months.

Figure 6.20.14.16: If autism is diagnosed early enough, treatments have developed to the point that children with ASD can learn and grow to have more intensive social interactions. [Image: hepingting, https://goo.gl/TIoAcY, CC BY-SA 2.0, https://goo.gl/rxiUsF]

These studies are problematic in that many of the social features of autism do not emerge in typical development until after 12 months of age, and it is not certain that these symptoms will manifest during the limited periods of observation involved in clinical evaluations or in pediatricians' offices. Moreover, across development, but especially during infancy, behavior is widely variable and often unreliable, and at present, behavioral observation is the only means to detect symptoms of ASD and to confirm a diagnosis. This is quite problematic because, even highly sophisticated behavioral methods, such as eye tracking (see Figure 1), do not necessarily reveal reliable differences in infants with ASD (Ozonoff et al., 2010). However, measuring the brain activity associated with social perception can detect differences that do not appear in behavior until much later. The identification of biomarkers utilizing the imaging methods we have described offers promise for earlier detection of atypical social development.

ERP measures of brain response predict subsequent development of autism in infants as young as six months old who showed normal patterns of visual fixation (as measured by eye tracking) (Elsabbagh et al., 2012). This suggests the great promise of brain imaging for earlier recognition of ASD. With earlier detection, treatments could move from addressing existing symptoms to preventing their emergence by altering the course of abnormal brain development and steering it toward normality.

Hope for Improved Outcomes

The brain imaging research described above offers hope for the future of ASD treatment. Many of the functions of the social brain demonstrate significant *plasticity*, meaning that their functioning can be affected by experience over time. In contrast to theories that suggest difficulty processing complex information or communicating across large expanses of cortex (Minshew & Williams, 2007), this malleability of the social brain is a positive prognosticator for the development of treatment. The brains of people with ASD are not wired to process optimally social information. But this does not mean that these systems are irretrievably *broken*. Given the observed plasticity of the social brain, remediation of these difficulties may be possible with appropriate and timely intervention.

Discussion Questions

1. How can neuroimaging inform our understanding of the causes of autism?
2. What are the ways in which neuroimaging, including fMRI and ERP, may benefit efforts to diagnosis and treat autism?
3. How can an understanding of the social brain help us to understand ASD?
4. What are the core symptoms of ASD, and why is the social brain of particular interest?
5. What are some of the components of the social brain, and what functions do they serve?

Vocabulary

Endophenotypes
A characteristic that reflects a genetic liability for disease and a more basic component of a complex clinical presentation. Endophenotypes are less developmentally malleable than overt behavior.

Event-related potentials (ERP)
Measures the firing of groups of neurons in the cortex. As a person views or listens to specific types of information, neuronal activity creates small electrical currents that can be recorded from non-invasive sensors placed on the scalp. ERP provides excellent information about the timing of processing, clarifying brain activity at the millisecond pace at which it unfolds.

Functional magnetic resonance imaging (fMRI)
Entails the use of powerful magnets to measure the levels of oxygen within the brain that vary with changes in neural activity. That is, as the neurons in specific brain regions "work harder" when performing a specific task, they require more oxygen. By having people listen to or view social percepts in an MRI scanner, fMRI specifies the brain regions that evidence a relative increase in blood flow. In this way, fMRI provides excellent spatial information, pinpointing with millimeter accuracy, the brain regions most critical for different social processes.

Social brain
The set of neuroanatomical structures that allows us to understand the actions and intentions of other people.

6.20.15: Chapter 15- A Gene Essential for Speech

Learning Objectives

1. Explain the first evidence that the FOXP2 gene was involved in human speech
2. Describe evidence that FOXP2 is involved in vocalization in other species
3. Describe the single nucleotide mutation on the FOXP2 gene, and the resulting alteration of the FOXP2 protein, which causes language difficulties
4. Describe the general location of the FOXP2 gene in humans by identifying the chromosome where it is found
5. Identify the differences between the human FOXP2 gene and the same gene in representative mammals and non-human primates

Overview

FOXP2 was the first gene discovered to be essential for human speech. It is expressed in many areas of the brain, including the basal ganglia and inferior frontal cortex, where it is essential for brain maturation and speech and language development (Enard et al., 2002). FOXP2 is found in many vertebrates ranging mouse to alligator and is involved in the vocalizations of many animals. For example, it is found in song birds and is important in their production of birdsong. In bats, FOXP2 is involved in echolocation. The gene has been highly conserved in mammals and few differences in the gene exist among mammal species. The protein that the gene produces is nearly identical in mice and primates.

The FOXP2 Gene

The FOXP2 (short for “forkhead box P2”) gene is the first gene that scientists ever associated with the human ability to speak (Nudel & Newbury, 2013). FOXP2 was first discovered in the KE family (medical name for this British family), about half of whose members had specific language impairments. Towards the end of 1980's, seven children of the family attended a special educational needs unit at a primary school in London. The head of the special needs unit discovered that the family had a speech disorder for three generations. Of the 30 family members, about half suffer from severe language deficiency, some are affected mildly, and few are unaffected (Watkins, et al., 1999). Their faces show rigidity at the lower half, and most cannot complete pronouncing a word. Many of them have severe stuttering and limited vocabulary. In particular, they have difficulty with consonants, and omit them, such as "boon" for "spoon", "able" for "table", and "bu" for "blue." Linguistic deficiency is also noted in written language both in reading and writing. They are characterized by lower nonverbal IQ in addition to their language difficulties. The first scientific report on the family's disorder, by Hurst, et al. (1990), showed that 16 family members were affected by severe abnormality, though their hearing was normal and some had normal intelligence, and that the condition was genetically inherited and was autosomal dominant.

Figure 6.20.15.1: FOXP2 protein and DNA. **Forkhead box protein P2** (**FOXP2**) is a protein that, in humans, is encoded by the **FOXP2 gene**. FOXP2 is a member of the forkhead box family of transcription factors, proteins that regulate gene expression by binding to DNA. It has multiple effects and is expressed in the brain, heart, lungs and digestive system. Ribbon diagram of forkhead box P2 (FOXP2) protein. (Image from Wikimedia Commons; File:FOXP2 (2as5).png; https://commons.wikimedia.org/wiki/F...XP2_(2as5).png; by SWISS-MODEL, based on 2as5 from PDB; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

Using positron emission tomography (PET) and magnetic resonance imaging (MRI), Vargha-Khadem, et al. (1998) found that some brain regions were underactive (compared to baseline levels) in the KE family members and that some were overactive, when compared to normal people. The underactive regions included motor neurons that control face and mouth regions. The areas that were overactive included Broca's area, the speech center (which might indicate that the speech center is having to work much harder than in normal people in order to produce even faulty speech).

Fisher, et al. (1998) identified the exact location of the gene on the long arm of chromosome 7 (7q31). The chromosomal region (locus) was named *SPCH1* (for speech-and-language-disorder-1), and it contains 70 genes. Using the known gene location of speech disorder from a boy, designated CS, of an unrelated family, they discovered in 2001 that the **main gene responsible for speech impairment** in both KE family and CS was **FOXP2**, and that this gene plays **a major role in** the **origin and development of language** (Lai, et al., 2001). Mutations in the gene result in speech and language problems (Vargha-Khadem & Liegeois, 2007) as seen in the KE family.

The exact problems caused by mutations in this gene remain hard to identify. This is not surprising when you consider the family of genes to which this one belongs. **The FOX family of genes are transcription factors, which means that they produce proteins that can regulate the expression of a number of other genes** by binding directly to their DNA. (The binding ability of these particular proteins comes from their forked shape, from which the gene family gets its name.) The **FOXP2 gene** would appear to play an **important role in orchestrating the establishment of the neural pathways during embryonic development, some of which are required for normal vocalizations in several species** studied, **including humans.** Surprisingly, this gene is extremely **well preserved phylogenetically** (across species): the **protein** that it produces is **almost identical in mice and in primates**, which are separated by some 130 million years of evolution.

The protein that the FOXP2 gene produces in humans differs by only two or three amino acids from the protein that it produces in other species. It is very **likely these two or three amino acids make the difference between animals that cannot speak and humans who can**. Moreover, the mutations that caused this difference are estimated to have occurred between 100,000 and 200,000 years ago, roughly the time that articulate language may have first emerged in human beings.

By performing a detailed analysis of **the defective FOXP2 gene** sequence in several members of the KE family, scientists were also able to identify the precise site of the mutation that caused this gene to malfunction in these individuals. This **mutation** occurs on exon 14 **of the FOXP2 gene**, when the **guanine in a nucleotide is replaced by an adenine.** As it happens, the part of the gene where this mutation occurs is precisely the one that codes for the “forkhead” portion of the protein—the part that binds to the DNA on other genes. **This change in a single nucleotide on the FOXP2 gene** has a **direct impact on this protein,**

causing the amino acid arginine to be replaced with a histidine.

In the hundreds of **normal subjects** tested, **the protein produced by FOXP2 always has an arginine** at this particular site, **while in the members of the KE family who suffered from specific language impairments,** it **always had a histidine.** Hence there is not a shadow of a doubt about the mutation that causes this disorder. That said, it is still amazing to think that the **mutation of a single one of the 2,500 nucleic bases in the FOXP2 gene** is **sufficient to impair language**!

FOXP2 is also required for proper lung development, not only in humans but in other species as well. Additional research showed that Knockout mice with only one functional copy of the FOXP2 gene have significantly reduced vocalizations as pups (Shu et al., 2005). Knockout mice with no functional copies of FOXP2 are runted, display abnormalities in brain regions such as the Purkinje layer, and die an average of 21 days after birth from inadequate lung development.

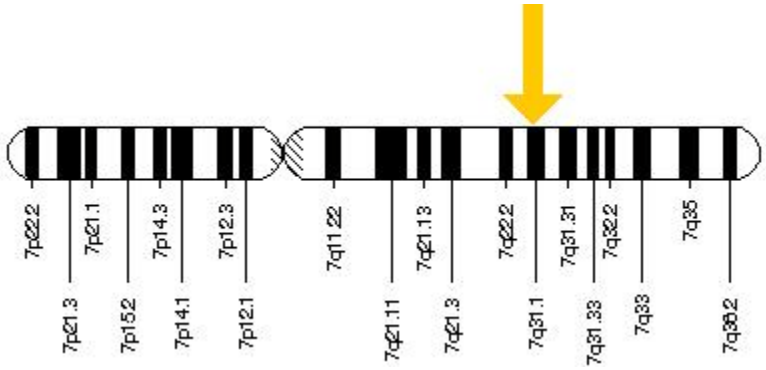

Figure 6.20.15.2: The FOXP2 gene is located on the long (q) arm of chromosome 7 at position 31. More precisely, the FOXP2 gene is located from base pair 114,086,309 to base pair 114,693,771 on chromosome 7 (Image and caption from Wikimedia Commons; File:FOXP2 location.png; https://commons.wikimedia.org/wiki/F...2_location.png; by U.S. National Library of Medicine; in the public domain).

Evolution

The FOXP2 Gene is Found in Many Diverse Species

The **FOXP2** gene is **highly conserved in mammals** (Enard et al., 2002). Conserved, in the evolutionary context, means that a trait or gene and its variants are found in a range of diverse species over long periods of evolutionary time suggesting that once it appeared it was retained as new species diverged from original ancestral species. The human gene differs from that in non-human primates by the substitution of just two amino acids, a threonine to asparagine substitution at position 303 (T303N) and an asparagine to serine substitution at position 325 (N325S) (Preuss, 2012). In mice it differs from that of humans by three substitutions, and in zebra finch by seven amino acids (Enard et al., 2002; Haesler et al., 2004; Teramitsu et al., 2004). One of the two amino acid differences between human and chimps also arose independently in carnivores and bats (Li et al., 2007; Shu et al., 2007). Similar FOXP2 proteins can be found in songbirds, fish, and reptiles such as alligators (Webb et al., 2005; Scharff & Haesler, 2005).

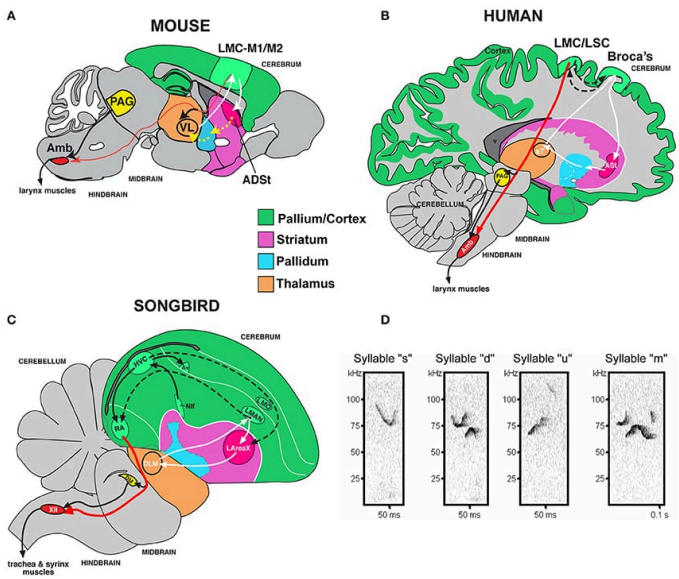

Figure 6.20.15.3: Mouse song system anatomy and syllable types. **(A)** Proposed anatomy of the rudimentary mouse forebrain vocal communication circuit based on Arriaga et al. (2012). Not shown are other connected brainstem regions, the amygdala, and insula. **(B)** Comparison with human, based on Arriaga et al. (2012) and Pfenning et al. (2014). **(C)** Comparison with songbird. **(D)** Sonograms of examples syllables of the four syllable categories quantified from a C57 male mouse USV song, labeled according to pitch jumps. Anatomical abbreviations: ADSt, anterior dorsal striatum; Amb, nucleus ambiguous; ASt, anterior striatum; aT, anterior thalamus; Av, nucleus avalanche; HVC, a letter-based name; LArea X, lateral Area X; LMO, lateral mesopallium oval nucleus; LMAN, lateral magnocellular nucleus of the nidopallium; LMC, laryngeal motor cortex; LSC, laryngeal somatosensory cortex; M1, primary motor cortex; M2, secondary motor cortex; NIf, interfacial nucleus of the nidopallium; PAG, periaqueductal gray; RA, robust nucleus of the arcopallium; T, thalamus; VL, ventral lateral nucleus of the thalamus; XIIts, 12th vocal motor nucleus, tracheosyringeal part (Figure and caption from Chabout et al., 2016).

The FOXP2 Gene Found in Neanderthal Fossils

DNA sampling from *Homo neanderthalensis* bones indicates that their FOXP2 gene is a little different though largely similar to those of *Homo sapiens* (i.e. humans) (Krause et al., 2005; Zimmer, 2016). Previous genetic analysis had suggested that the *H. sapiens* FOXP2 gene became fixed in the population around 125,000 years ago (Benítez-Burraco et al., 2008). Some researchers consider the Neanderthal findings to indicate that the gene instead swept through the population over 260,000 years ago, before our most recent common ancestor with the Neanderthals (Benítez-Burraco et al., 2008). Other researchers offer alternative explanations for how the *H. sapiens* version would have appeared in Neanderthals living 43,000 years ago (Benítez-Burraco et al., 2008).

Positive Selection for FOXP2

According to a 2002 study (Enard, et al., 2002), the FOXP2 gene showed indications of recent positive selection (Enard, et al., 2002; Toda et al., 1992). Some researchers have speculated that positive selection is crucial for the evolution of language in humans (Enard, et al., 2002).

The figure below (Figure 14.15.4) shows three types of selection. The top shows positive selection. Positive selection is also known as Darwinian selection and is the type of selection that Darwin envisioned as the primary mechanism of evolution (for more on the types of selection, see Module 3.5). The original population distribution, before selection, is shown in red. The population distribution after selection is shown in blue. In directional evolution, the population values for the trait move toward one extreme of the trait. By positive selection, a new adaptive trait can sweep through a population. However, "though advantageous mutations are of great interest, they are difficult to detect and analyze because of the fact that neutral and deleterious mutations predominate them in frequency" (Thomas Lab, University of Washington).

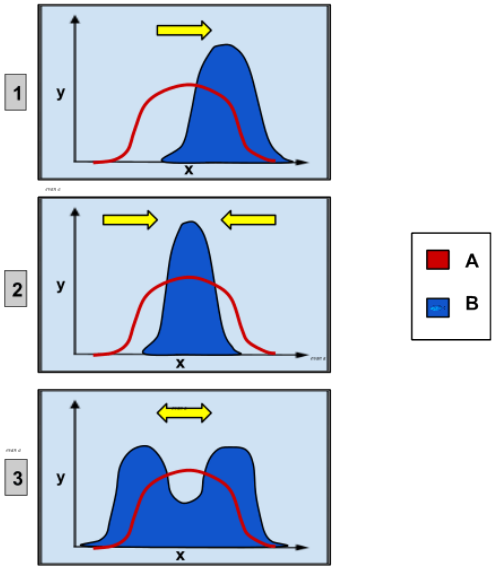

Figure 6.20.15.4: These charts depict the different types of genetic selection. On each graph, the x-axis variable is the type of phenotypic trait and the y-axis variable is the number of organisms. Group A is the original population and Group B is the population after selection. Graph 1 shows directional selection, in which a single extreme phenotype is favored. Graph 2 depicts stabilizing selection, where the intermediate phenotype is favored over the extreme traits. Graph 3 shows disruptive selection, in which the extreme phenotypes are favored over the intermediate (Image and caption from Wikimedia Commons; File:Genetic Distribution.svg; https://commons.wikimedia.org/wiki/F...stribution.svg; by Ealbert17; licensed under the Creative Commons Attribution-Share Alike 4.0 International license).

Recent Positive Selection for FOXP2 Disputed

Others, however, were unable to find a clear association between species with learned vocalizations and similar mutations in FOXP2 (Webb et al., 2005; Scharff & Haesler, 2005). A 2018 analysis of a large sample of globally distributed genomes confirmed there was no evidence of positive selection, suggesting that the original signal of positive selection may be driven by sample composition (Atkinson et al., 2018; Williams, 2020). Insertion of both human mutations into mice, whose version of FOXP2 otherwise differs from the human and chimpanzee versions in only one additional base pair, causes changes in vocalizations as well as other behavioral changes, such as a reduction in exploratory tendencies, and a decrease in maze learning time. A reduction in dopamine levels and changes in the morphology of certain nerve cells are also observed (Enard et al., 2009).

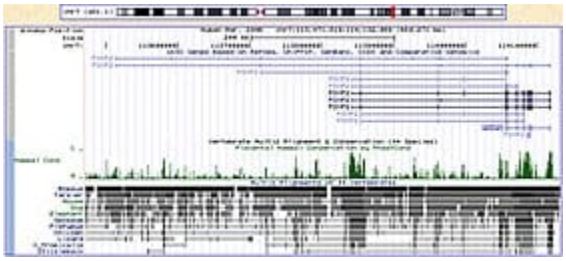

Figure 6.20.15.5: Human *FOXP2* gene and evolutionary conservation is shown in a multiple alignment (at bottom of figure) in this image from the UCSC Genome Browser. Note that conservation tends to cluster around coding regions (exons).

Migration of Human Groups and Genetic and Linguistic Relationships

Around the end of World War II, the Italian population geneticist Luca Cavalli-Sforza began constructing genealogical trees that established relationships among populations throughout the world. By cross-tabulating data on several dozen genes, Cavalli-Sforza established a relationship between American Indians and Asians. This finding is consistent with the most common theory about how the New World was populated: by peoples who crossed from Siberia to Alaska when the Bering Strait was frozen over during the last great Ice Age, some 30,000 years ago.

Cavalli-Sforza's findings assumed even greater importance when he correlated them with analogous studies on languages. When Cavalli-Sforza compared the genealogical trees established by geneticists with those established by linguists, with just a few exceptions, he found that the people who speak each of the 15 major families of languages are genetically related as well. The explanation for this remarkable concordance is that when a population migrates to a new territory, it takes its genes along as well as its language.

But there have been many criticisms of Cavalli-Sforza's approach, and in particular his way of defining a population. In the works of Cavalli-Sforza and his followers, the first step is to define a population, by linguistic criteria among others. Correlations are then established between these populations and their languages, which seems like a dangerously circular approach. It has also been noted that these studies are more convincing on a small scale or a large scale, but far less so on an intermediate one. The reason is that it is easier to distinguish Inuit from Bantu, for example, than to differentiate the various populations that speak Bantu languages.

In addition, the DNA samples used in many studies come from blood banks, and the accompanying records may be biased or false, because for various reasons, when people give blood, they may report their ethnicity as different from what it actually is. This points to the fact that errors in interpretation may be found when controls are applied to both linguistic and genetic data.

Summary

The FOXP2 gene is found widely in the animal kingdom and the human version of the gene differs little from that in other species, yet the human variant appears to have made language possible. Mutation of a single one of the 2,500 nucleic bases in the FOXP2 gene is sufficient to impair language. Though many researchers believe that the FOXP2 gene played an important role in the evolution of human language, evidence for positive selection for it is still controversial.

6.20.16: Chapter 15- The Origins of Language

Learning Objectives

1. Distinguish between continuity and discontinuity theories of the origins of language; provide examples
2. Distinguish between innate and cultural theories of the origins of language; provide examples
3. Define polygenism and monogenism
4. Define "spandrel" and "exaptation"
5. Contrast Chomsky's views with Deacon's views on the origins of language
6. Briefly describe the evidence related to whether Neanderthals had spoken language

Overview

In this section, we review a number of ideas about the origins of human language. Two prominent approaches are continuity and discontinuity theories. Continuity theorists assume that language evolved gradually from earlier forms of communication in non-human animals and hominids from as recently as 40,000 years ago, according to some theorists, to over 2 million years ago in Homo habilis, according to others. Discontinuity theorists believe that human language is so unique that it must have appeared relatively quickly in human evolution without being derived from any form of animal communication. Some theories propose that language is mostly innate, determined primarily by genes, while others hypothesize that human language has cultural origins, resulting from learning in social interaction, with limited and only general contributions from genetics.

Evolution of Language

From Primate Origins to a Language Ready Human Brain

The **origin of language** (spoken, signed, and written) and its relationship to human evolution are complex subjects requiring inferences from the fossil record, archeological evidence, contemporary language similarities and differences, studies of language acquisition, and comparisons between human language and communication in other animals (particularly other primates).

Language clearly depends upon the human brain having acquired features that made it capable of the production and understanding of vocal symbols. However, how human language and a language-ready brain evolved is not known. Nevertheless, most theorists assume that language must have evolved from earlier, more primitive forms of communication.

One integrative approach to the complex issue of the evolutionary origins of human language and a brain capable of human language comes from "comparative neuroprimatology." This is the study of the brains, behaviors and communication systems of monkeys, apes and humans in order to investigate "the biological and cultural evolution of the human language-ready brain" (Arbib et al., 2018, p. 371). The brains of many animals, including non-human primates, show left lateralization of vocalization in the brain, just as the dominant hemisphere for language in most humans is the left. This suggests a long evolutionary history of human language from earlier forms of vocalization.

Theoretical Approaches to the Origins of Language

Approaches to the origin of language can be sub-divided according to some underlying assumptions (Ulbaek, 1998):

- **"Continuity theories"** work from the assumption that language exhibits so much complexity that it could not have developed from nothing in its final form; therefore it must have evolved from earlier pre-linguistic systems among humans' primate ancestors.
- **"Discontinuity theories"** take the opposite approach—that language is such a unique trait that it cannot be compared to anything found among non-humans, and that it must have appeared fairly suddenly during the course of human evolution.
- **Innate theories**: some theories consider language mostly as an innate faculty—largely genetically encoded.
- **Cultural theories**: other theories regard language as a mainly cultural system—learned through social interaction.

Continuity Approaches

A majority of linguistic scholars believe continuity-based theories, but they vary in how they hypothesize language development. Among those who consider language as mostly innate, some—notably, Steven Pinker (Pinker & Bloom, 1990)—avoid speculating about specific precursors in nonhuman primates, stressing simply that the language faculty must have evolved in the usual gradual way (Pinker, 1994) as Darwin proposed for most traits. Others in this intellectual camp—notably Ib Ulbæk (1998)—hold that language evolved not from primate communication but from primate cognition, which is significantly more complex.

Those who consider language as learned socially, such as Michael Tomasello, propose that it developed from the cognitively controlled aspects of primate communication, these being mostly gestural as opposed to vocal (Pika & Mitani, 2006; Tomasello, 1996). Regarding the vocal precursors of human language, many continuity theorists hypothesize that language evolved from early human capacities for song (Dunn, et al., 2011; Vaneechoutte, 2014).

Discontinuity Approaches

Noam Chomsky, at the Massachusetts Institute of Technology, a proponent of discontinuity theory, argues that a single chance mutation occurred in one individual in the order of 100,000 years ago, installing the language faculty (a hypothetical component of the mind-brain) in "perfect" or "near-perfect" form (Chomsky, 1996). However, it seems unlikely that this would produce adaptive advantage unless a sufficiently large number of others also had similar capacities for communication at the same time.

When Did Language Develop?

Clearly, there are many theories about the origins of language, and the dates cited for its first appearance vary greatly from one author to another. They range from the time of **Cro-Magnon man**, about **40,000 years ago**, to the time of **Homo habilis**, about **2 million years back**.

The hypothesis that language dates as far back as the time of Homo habilis is supported by the **resilience of tool cultures** in Homo habilis and later hominid species. Tool making techniques (see module on Material Culture) must be passed from generation to generation to be sustained over long spans of time. This can be accomplished by imitation (younger members of the group learning by watching more skillful and experienced tool makers) or by verbal instruction or by a combination of both. Homo habilis "retained their tool cultures despite many climate change cycles at the timescales of centuries to millennia each, [suggesting that Homo habilis and later] species had sufficiently developed language abilities [including grammar] to verbally describe complete procedures" (Model, 2010, p. 7) for toolmaking. Research with non-human primates shows that toolmaking skills based on imitation alone, without verbal instruction, are lost under environmental changes like the changes in climate referred to above. "Chimpanzees, macaques and capuchin monkeys are all known to lose tool techniques under such circumstances" (Model, 2010, p. 7). Many experts content that the **resilience of tool culture in Homo habilis supports** the view that **language existed in these early human ancestors**.

Monogenism or Polygenism?

Regardless of how and when language emerged, another question arises immediately: did it do so once, or many times? In other words, do all languages have a common origin, a proto-language that gave rise to all the rest, or did several different dialects emerge, at various places in the world?

Those who argue for the multiple origins, or **polygenism**, of language, say that the first modern humans did not share the potential for the faculty of speech, and that only after they dispersed through migration did actual languages develop independently among various groups of *Homo sapiens*.

The proponents of polygenism base their arguments on events and behaviors that would have had little chance of occurring without spoken language, such as great migrations that would have required major planning and organizing efforts. From this premise, the polygenists have deduced, for example, that the peoples who left Africa and arrived in Australia about 60,000 years ago must have spoken a complex language before those who migrated to the Middle East.

The alternative view, the theory of **monogenism,** proposes that all languages have a common origin, a proto-language at one location that gave rise to language once, and from that original language all the world's languages developed.

Monogenists were greatly influenced by Meritt Ruhlen's *On the Origin of Language*s, which posited the existence of a single proto-

language over 50,000 years ago. Ruhlen's work was based, among other things, on analyses of population genetics that showed a high correlation between the genetic diversification of human populations and the diversification of the languages that they spoke. But other studies have shown the the correspondences between genetic classifications of populations and genealogical classifications of languages are more uncertain than was once believed. The fact remains that even though Ruhlen's work has been questioned on linguistic grounds, many people still endorse the key idea in his book: that all languages had a common origin. Among these proponents of monogenism, there are two major schools of thought. there are two major schools of thought.

Two Major Views within Monogenism

A Chance Mutation and Spandrels

Following Chomsky (see above), the first major view starts from the premise that the **human species** as we know it **arose from** an unlikely **genetic mutation** that occurred **about 100,000 years ago**, in which certain of the brain's circuits were reorganized. This reorganization gave rise to the human **"language instinct,"** thus paving the way for the explosive growth in all the cognitive abilities that the powerful communication tool of language provides. On this view, **language** is an **innate** component of human brain organization, which includes a **"universal grammar,"** which all humans inherit within their innate brain organization. This universal grammar is therefore a species-specific human trait and is expressed in similarities in the grammars of all languages of the world. This universal grammar organizes and guides language learning regardless of the human language being acquired. This view makes it hard to imagine any intermediate form of language that could function without all the grammatical structures found in languages today.

This discontinuity view of the origins of language has been criticized by some experts as anti-evolutionist, but several renowned scholars of evolution have ideas consistent with the uniqueness of human language and with discontinuity views of its origins. For example, paleoanthropologist Ian Tattersall, writes that Homo sapiens sapiens "is not simply an improved version of its ancestors—it's a new [development], qualitatively distinct from them." For Tattersall and many other scientists, the mechanism that gave rise to language involved the **relatively sudden combination of pre-existing elements** that had **not** been **selected specifically** to produce this attribute but that, together, made it possible. On this view, characteristics evolved for other purposes make a new capability, like language, possible, so that a trait like language itself was at least initially not selected for by natural selection but rather emerged from other evolved capabilities.

This type of evolutionary mechanism is thought to have come into play many times in the course of evolution; the Harvard paleontologist Stephen Jay **Gould calls it exaptation.** Exaptation means that a trait, feature, or structure that **evolved for one function takes on a different function**; for example, feathers originally evolved to keep ancestral birds warm, but then in later descendants became essential for flight.

Steven Jay Gould calls the features that result from exaptation, such as language, **"spandrels. "** In evolutionary biology, a spandrel is **a phenotypic trait that is a byproduct of the evolution of some other characteristic**, **rather than a direct product of adaptive selection**. These ideas were brought into biology by Steven Jay Gould and Richard Lewontin in a 1979 scientific paper in which they sought to temper the influence of **adaptationism**, the **view that** sees **most organismal traits** as **adaptive products of natural selection**. Gould and Lewontin argued that chance and other non-selection factors played a larger role in evolution than adaptationists claimed. They believed that many traits were evolved for other purposes become "recruited" to perform other unrelated functions during the course of evolution. These recruited "spandrels" are examples of exaptation.

Like Noam Chomsky, Steven Gould also believed that human language is so different from anything else in the animal kingdom that he did not see how it could have developed from ancestral cries or gestures, but he did imagine its having emerged as a side effect of the explosive growth of human cognitive abilities.

A More Adaptationist View

The **second major school of monogenism** posits a concept of the evolution of Homo sapiens in which **language developed from cognitive faculties** that were **already well established, and that once it was present in some earlier form, it was then naturally selected for**. In this view, the birth of language was **triggered not by a random mutation** (as the first view states), but simply by the availability of an increasingly powerful cognitive tool. Bit by bit, by natural selection, those groups of hominids who developed an articulate **language that let them discuss past and imaginary events** would thereby have gradually supplanted those groups that as yet had only a proto-language. The emphasis here on natural selection for language ability makes this approach more of an adaptationist view.

This second school of monogenism is identified with the linguist and psychologist, **Steven Pinker**, who believes that language may very well have been the target that evolution was "aiming for" (this phrase is not to be taken literally since evolution has no purpose or goal but happens automatically; see Chapter 3; natural selection selected for language ability only in the sense that those who were better at language survived and reproduced more offspring). Pinker argues that the **brain has a general capacity for language**—a concept often associated with connectionist theory in cognitive science (see module on connectionist networks in the chapter on learning and memory). Pinker invokes the **Baldwin effect**, for example, as a major evolutionary force that could have led to modern language (see discussion of Baldwin Effect below). The **ability to learn language would therefore have become a target of natural selection**, thus **permitting the selection of language-acquisition devices that were genetically pre-wired** into the brain's circuits.

Figure 6.20.16.1: The Tower of Babel by Pieter Bruegel the Elder (1563). According to the Biblical story of the Tower of Babel, everyone originally spoke the same language, but then God changed things so that everyone spoke different languages. As a result, the tower, which was supposed to reach to the heavens, was never completed, because the people building it could no longer understand one another (Image and caption: public domain via Wikimedia Commons; https://commons.wikimedia.org/wiki/F...t_-_edited.jpg).

This theory of monogenism favored by Steven **Pinker also implies intermediate forms of language** that eventually led to our own. For example, Derek **Bickerton**, a linguist renowned for his work on the evolution of language, suggests that human **language abilities evolved in two stages**. In the **first**, humans would have used a **proto-language** of symbolic representations that took the concrete form of vocal and/or gestural signs. This stage might have lasted nearly 2 million years. Then, **about 50 000 years ago**, humans would have developed a **more formal syntax** that let them exchange ideas with significantly more precision and clarity. With syntax, people could not only label things ("leopard paw print", "danger", etc.), but also join several labels together to express even more meaning ("When you see a leopard paw print, watch out!").

Thus, if **symbolic representations**, already present **in the proto-languages**, made the construction of the **first mental models of reality** possible, it was the emergence of **syntax** that gave human language the great richness that it has today. To give some idea of how the transition from symbolic representations to syntax may have occurred, Bickerton cites the example of the pidgin languages of the colonial period. These rudimentary languages were developed by people of different cultural origins who needed to communicate. Though the pidgin languages themselves had no grammar at all, when they were learned by a second generation, they became what are known as creoles: new, grammatical languages derived from multiple mother tongues.

Another important scholar of the origins of language, **anthropologist Terrence Deacon**, takes exception to the primacy of grammar, believing instead that the **essential feature of language is its use of symbols**. According to Deacon, the so-called symbols that some authors say animals use are actually only indexes. He says that people who try to teach language to chimpanzees always ensure that the things designated by the words or icons being taught are present in the animal's environment, which makes these words or icons mere indexes. Deacon associates this inferior level of language, based on signs and icons, with that used by children in their earliest years. By contrast, says Deacon, articulate adult language depends on the specificity of the symbols, which in turn depends on the logical connections that **each symbol** in a language **has with the others**. For Deacon, it is this **network of relationships**, far more than the mere occurrence of arbitrary signs, that **characterizes** the **symbols used by human** beings.

Deacon therefore thinks that we must try to **understand the evolution of language not in terms of innate grammatical functions**, **but rather** in terms of the manipulation of symbols and of **relationships among symbols**. There is certainly a human predisposition for language, but this predisposition would be the result of the **co-evolution of the brain and of language**. What is **innate, according to Deacon, is a set of mental abilities** that give us certain natural tendencies, which are expressed in the same universal language structures. Thus Deacon offers a different concept from Chomsky, who associates the origins of universal grammar with a language-specific innovation in the brain.

Deacon sees this co-evolution of the brain and language as being **rooted in the complexity of humans' social lives**, which involved not only a high degree of co-operation between the men and women of a community to acquire resources, but also exclusive monogamous relationships to ensure proper care for very young children who were greatly dependent on adults. This highly explosive mixture is **not found in any other species** (the great apes, for example, gather their food individually). To ensure the stability of the group, rituals and restrictions were required: in other words, abstractions that could be comprehended only if the individuals **involved** could understand and **use symbols**.

Universal Human Language Circuitry

The first changes in the neurons of the left hemisphere that accompanied the development of language faculties during hominization may have occurred about 100,000 years ago, or even earlier. But the truly explosive growth in these faculties most likely began with the evolution of the **angular gyrus**, about 50,000 years ago (see modules 14.10 and 14.11).

Together, the angular and supramarginal gyri constitute a multimodal associative area that receives auditory, visual, and somatosensory inputs. The neurons in this area are thus very well positioned to process the phonological and semantic aspect of language that enables us to identify and categorize objects.

The language areas of the brain are distinct from the circuits responsible for auditory perception of the words we hear or visual perception of the words we read. The auditory cortex lets us recognize sounds, an essential prerequisite for understanding language. The visual cortex, which lets us consciously see the outside world, is also crucial for language, because it enables us to read words and to recognize objects as the first step in identifying them by a name.

Scientists believe that articulate language as we now know it must have already appeared 50,000 or 60,000 years ago, because it was then that the various human ethnic groups became differentiated. But all these groups still retain the ability to learn any language spoken anywhere in the world. Thus a Polish or Chinese immigrant to New York City ends up speaking with a New York accent, and vice versa, which just goes to show that all of us have inherited the same linguistic potential.

Pidgin

A **pidgin** is a language created spontaneously from a mixture of several languages, so that the people who speak them can communicate. The people who develop a pidgin language agree on a limited vocabulary and employ only a rudimentary grammar. For example, in Franco-Vietnamese pidgin, this results in sentences such as "Moi faim. Moi tasse. Lui aver permission repos. Demain moi retour campagne." [Me hunger. Me lie down. He have permission rest. Tomorrow me return country.]

The first documented pidgin, the Lingua Franca, was used by Mediterranean merchants in the Middle Ages. Another well known pidgin was developed from a mixture of Chinese, English, and Portuguese to facilitate trade in Canton, China during the 18th and 19th centuries. Another classic example is the pidgin developed by slaves in the Caribbean, whose cultural origins were too diverse for their own languages to survive after their forced transplantation.

Children who grow up together and learn a pidgin tend to spontaneously impose a lexical structure on it to create a creole: a true language whose vocabulary comes from other languages. But this does not happen with all pidgins, and some are lost or become obsolete.

According to researchers such as Derek Bickerton, people who find themselves in the particular circumstances described above revert to an older form of communication, what Bickerton calls a proto-language, of which pidgin would be the modern manifestation.

Baldwin Effect

In 1896, American psychologist James Mark Baldwin proposed an evolutionary mechanism that soon came to be known as the "**Baldwin effect**". It is a process whereby a **behavior that originally had to be learned can eventually become innate**, that is, fixed in the genetic programming of the species concerned (Sznajder, et al., 2012). The effectiveness of the learning plays a key role in the Baldwin effect, which **distinguishes it from Lamarckian inheritance of acquired characteristics.**

The idea behind the Baldwin effect is that individuals who are able to learn a given kind of behavior more effectively may over the course of their lives acquire advantages that individuals whose brains are less plastic will not. Natural selection will therefore tend to favor those who always learn faster until, at some point in evolution, the behavior will no longer need to be learned at all: it will have become instinctive.

It should be noted that the Baldwin effect assumes that the environment remains relatively stable, because if it changed too much, there would be no selection against plasticity, which would become an important adaptive factor. But if the environment remains stable for a long time, natural selection may favor a mutation that makes the behavior innate and hence more robust and efficient.

The Baldwin effect, as an evolutionary mechanism that targets learning abilities, has been successfully simulated with many computer programs. Many scientists believe that it may have played a decisive role in the evolution of language, nevertheless the existence of the effect is controversial and many evolutionary biologists dismiss the idea (French & Messinger, 1994).

Neanderthal man

It was long believed that Neanderthal man could not communicate verbally—that Neanderthals must have had some primitive form of language, but could not produce the complete range of sounds of human language. According to a hypothesis advanced by American linguist Philip Lieberman, Neanderthals' larynxes had not yet descended so low as those of Homo sapiens, so they would have had a great deal of difficulty in pronouncing the three main vowels present in the majority of the world's languages (ee as in "beet", oo as "boot" and a as in "aha!").

However, some authors argue that to speak a rudimentary language, one need not master all of the vowels, so long as the language has a sufficient number of consonants.

Moreover, recent research has raised questions about Lieberman's hypothesis. Many researchers find it hard to believe that Neanderthals, who produced sophisticated tools, adorned their bodies with bracelets and necklaces, buried their dead, and produced works of art, had little or no ability to communicate verbally.

Some authors even believe that the skull on which Lieberman based his work was not truly representative of Neanderthal man. Contrary to his findings, reconstructions of other Neanderthal skulls have shown that their base would have allowed the existence of a vocal tract very similar to that of modern humans. For example, the discovery in 1989 of the 60,000-year-old skull of a male Neanderthal with a hyoid bone (the bone that supports the larynx) even led some researchers to say that he had probably been able to speak.

One thing is certain: Neanderthals disappeared about 28,000 years ago, leaving the Earth to their rivals, Homo sapiens sapiens, who had everything they needed to use an articulate symbolic language with elaborate syntax. We should not discount the possibility that Neanderthals also had developed the ability to speak and that language may have played a significant role in their lives as well.

Summary

It is assumed by most theorists that language must have evolved from earlier, more primitive forms of communication such as pre-linguistic systems used by our primate ancestors. Some theorists such as Steve Pinker consider language to be mostly innate. Explosive growth of language capacities in humans, according to some theorists, began about 50,000 years ago with the evolution of the angular gyrus, a multimodal area of cortex. It is speculated that human language must have evolved at least 50,000 to 60,000 years ago when human ethnic groups differentiated yet all retained the ability to learn any human language with ease that they are exposed to in their early experience.

8: About This Book

This book is being curated by IVC Faculty Ivette Merced PhD for IVC. It is currently undergoing updates while being used to teach with to get real time feedback from students. If you want to read ahead, please contact your professor as changes are being made in real time for modules not yet open. Reading ahead too far could mean missing some of these updates. Additionally please note if you download a PDF it might not have the newest updates, so for most accurate information read it live or ask your professor!

1. What are the Divisions of Biopsychology?
1.1: What is Physiological Psychology?
1.11.1: Introduction to Research in Biological Psychology
1.11.2: Non-Invasive Techniques- Structural Imaging
1.11.3: Non-Invasive Techniques- Direct Functional Imaging Techniques
1.11.4: Non-Invasive Techniques- Indirect Functional Imaging Techniques
1.11.5: Other Non-Invasive Techniques
1.11.6: Invasive Techniques
1.11.7: Ethical Considerations
1.2.1: History of Biopsychology
1.3: Connecting Biology to Behavior
1.5.1: Nervous System Tissue
1.5.2: Nervous System Structure and Terminology
1.5.3: Nervous System Development
1.5.4: The Central Nervous System
1.5.5: The Peripheral Nervous System
1.5.6: Communication and the Endocrine System
1.7.1: Neurons and their Basic Functions
1.7.2: Neurons Generate Voltage Changes to Code Information
1.7.3: Synaptic Transmission
2.1: Senses Overview
2.2.13: Vision
2.3.22: Hearing
2.4: Taste and Smell
2.5.20: Touch
2.6.1: Classification of Muscle Types and Functions
2.6.2: Synaptic Control of Movement- Neuromuscular Junction and Motor Units
2.6.3: Spinal Reflexes
2.6.4: Motor Circuitry- Neural Structures and Pathways
2.6.5: Impact of Disease States and Neural Damage on Motor Control
2.7: Psychophysical Methods
2.8: Sensation vs Perception
2.9: Gestalt Principles of Perception
3.1.23: Consciousness
3.1.24: What is Sleep?
3.1.25: Stages of Sleep
3.1.26: The Brain and Sleep
3.1.27: Theories of Sleep
3.1.28: Sleep Disorders
3.1.29: Maintaining Water Balance
3.1.30: Triggering Drinking Behavior - Osmometric and Volumetric Thirst
3.1.31: Ingestive Behavior Basics
3.1.32: Digestion and the Hormonal Control of Metabolism
3.1.33: Hunger - Theories, Detectors, and the Hypothalamus
3.1.34: Ingestive Behavior in Context
3.3.11: Sex Hormones, Sexual Motivation, and Reproductive Behaviors
3.3.12: Sexual Development, Anatomy and Physiology
3.3.13: Differences of Sexual Development
3.3.14: Gender
3.3.15: Sexual Orientation
3.3.16: Sex Differences and Evolutionary Interpretations
3.4.1: Evolution of Minds and Behavior
3.4.2: Evolution - Mechanisms and Evidence
3.4.3: Human Evolution
3.4.4: Evolutionary Theories in Psychology
3.4.5: DNA, Chromosomes, and Gene-Environment Correlations
3.4.6: The Nature-Nurture Question
3.4.7: Epigenetics in Psychology
3.4.8: Human Genetics
3.4.9: Genes and Behavior
4.1.1: Overview of Brain Mechanisms in Intelligence, Language, and Cognition
4.1.2: Cognition, Intelligence, and Language as Psychological Adaptations
4.1.3: High Intelligence-Nature or Nurture; Learning Disabilities
4.1.4: Cognition- Categories, Concepts, Schemas and the Brain
4.1.5: Brain Mechanisms and Intelligence
4.2.23: Learning, Genes, and Adaptation
4.2.24: Types of Learning and Biological Adaptation
4.2.25: Introduction to Memory and the Brain
4.2.26: Synaptic Mechanisms of Learning and Memory
4.2.27: Brain Mechanisms of Memory Disorders
4.2.28: Localization of Types and Stages of Memory
4.2.29: Hormones, Learning, and Memory
4.3: Language and the Brain
4.3.1: Introduction to Language
4.3.2: Broca's Area, Wernicke's Area, and Additional Language-Processing Areas in the Brain
4.3.3: Other Brain Models of Spoken and Written Language
4.3.4: Handedness, Language, and Brain Lateralization
4.3.5: The Right Hemisphere's Contribution to Language
4.5.21: The Neurological Bases of Emotions
4.5.22: Valence of Emotions
4.5.23: Fight or Flight
4.5.24: Social Neuroscience
4.5.25: Stress and health
5.2: Psychopharmacology and Psychoactive Drug Classification
5.3: Mechanisms of Psychoactive Drug Action
5.4: Substance Use and Addiction - Theories, Brain Mechanisms, and Treatment
5.5: Specific Drug Effects, Misuse, and Risks
5.6: Psychotherapeutics
5.8.1: Biological Factors in Psychological Disorders- An Introduction
5.8.2: Biological Basis of Mood Disorders- Major Depressive and Bipolar Disorders
5.8.3: Biological Basis of Anxiety Disorders
5.8.4: Biological Basis of Schizophrenia Spectrum Disorder
6.20: Supplemental Content
6.20.1: Chapter 3- Population Evolution (and the Modern Synthesis)
6.20.10: Chapter 10- Psychological Factors Affecting Learning, Memory, and Forgetting
6.20.11: Chapter 14- Traditional Models of Human Intelligence
6.20.12: Chapter 14- Problem Solving, Categories and Concepts
6.20.13: Chapter 14- The Brain and Evolution of Cognition

1.1: Perception and Action

GLOSSARY

Learning Objectives

- Explain how perception guides action with an example
- Describe how action changes perception with an example
- Understand that acting on unconscious sensory information is possible

Brief Overview

What is the point of perceiving things if we cannot interact with them in some way? Perception is rarely a passive experience; it is almost always shaped by some kind of goal. Our perception is also shaped by the fact that it simply isn't feasible to process our entire sensory experience. We selectively attend to subsets of our experience and process that; much of our sensory world is not encoded. What we attend to depends on our goals at the moment, so our actions shape our perception and our perception shapes our action.

The relationship between perception and action is best described by a diagram with an arrow pointing both ways. Perception selects targets for action and helps us correct errors as we execute actions. Broadly speaking, there are two kinds of actions: navigation (moving around our environment) and intentional movements (such as reaching/grabbing) Fig 8.3.1.

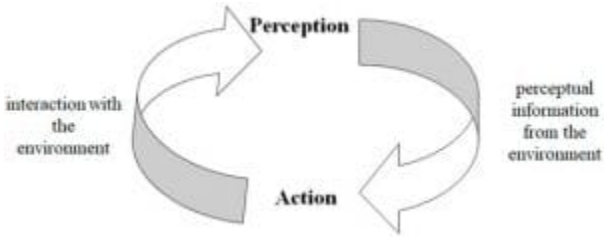

Fig 8.3.1 This figure shows the relationship between perception and action, which is described as a cycle of arrows pointing back and forth. An example of this cycle is when you reach out for a bottle sitting on a slanted surface: Banks et al (2000) showed that your sense of touch updates your visual estimates of the surface slant. (Provided by: MDPI. License: CC-BY 4.0)

Acting on unconscious sensory information is possible. There are a few dramatic examples of action without perception. For example a patient, DF, could mail letters through a slot but couldn't tell you if the slot had a horizontal or vertical orientation, or patient TN, who was completely blind but could navigate cluttered hallways. TN's case makes it obvious that visual information reaches the non-visual regions of the brain (such as areas of the **parietal cortex**) even when the **primary visual cortex** (V1) is not functioning typically.

The **Ebbinghaus size illusion** Fig 8.3.2is an optical illusion of relative size perception. In the best-known version of the illusion, two circles of identical size are placed near to each other, and one is surrounded by large circles while the other is surrounded by small circles. As a result of the juxtaposition of circles, the central circle surrounded by large circles appears smaller than the central circle surrounded by small circles.

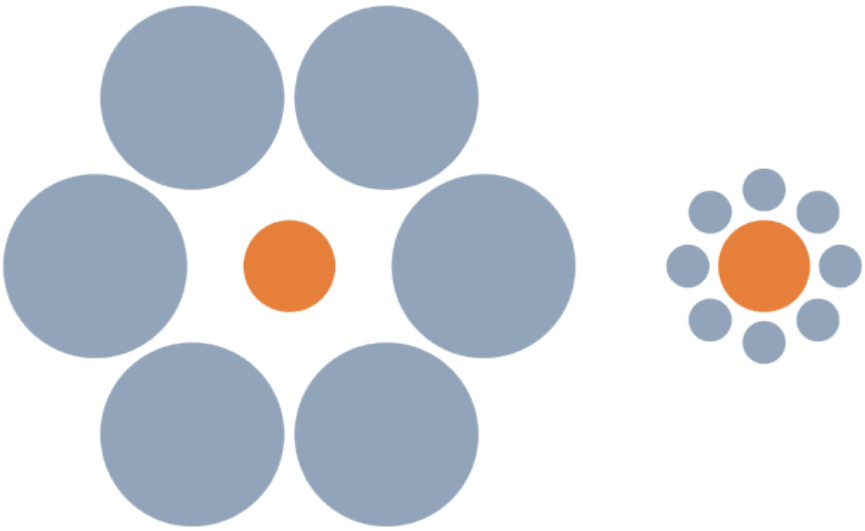

Fig 8.3.2 The two orange central circles are exactly the same size; however, the one on the right appears larger.

Similarly, healthy controls accurately grasp a center object affected by the rod-and-frame illusion, which is the phenomenon that the orientation of a line is altered by surrounding lines or grating (Dyde, 2000). These studies suggest that all of us maintain a “raw copy” of sensory information, separate from the version that we’re consciously aware of (which has been shaped by inference), to guide action. However, there is contradictory research indicating that motor planning (Craje, 2008) and reaching behaviors (Dyde, 2000) can be impacted by illusions. So it remains an open and interesting question: When is our behavior influenced by illusions, and when does control of our motor system ignore illusions?

- 2.6: Motor Control - *CC BY-NC 4.0*
  - 2.6.1: Classification of Muscle Types and Functions - *CC BY-NC 4.0*
  - 2.6.2: Synaptic Control of Movement- Neuromuscular Junction and Motor Units - *CC BY-NC 4.0*
  - 2.6.3: Spinal Reflexes - *CC BY-NC 4.0*
  - 2.6.4: Motor Circuitry- Neural Structures and Pathways - *CC BY-NC 4.0*
  - 2.6.5: Impact of Disease States and Neural Damage on Motor Control - *CC BY-NC 4.0*
- 2.7: Psychophysical Methods - *CC BY-NC 4.0*
- 2.8: Sensation vs Perception - *CC BY-NC 4.0*
- 2.9: Gestalt Principles of Perception - *CC BY-NC 4.0*

◦ 3: Part III- Rhythms, Drives, and Motivation - *CC BY-NC 4.0*
- 3.1: Biological Rhythms, Sleep, and Homeostasis - *CC BY-NC 4.0*
  - 3.1.1: Introduction - *CC BY-NC 4.0*
  - 3.1.2: What Are Circadian Rhythms? - *CC BY-NC 4.0*
  - 3.1.3: Where Are Rhythms in the Brain? - *CC BY-NC 4.0*
  - 3.1.4: Regulation of Sleep - *CC BY-NC 4.0*
  - 3.1.5: Disorders of Sleep and Circadian Rhythms - *CC BY-NC 4.0*
  - 3.1.6: Circadian Rhythms and Society - *CC BY-NC 4.0*
  - 3.1.7: Section Summary - *CC BY-NC 4.0*
  - 3.1.8: Key Terms - *CC BY-NC 4.0*
  - 3.1.9: References - *CC BY-NC 4.0*
  - 3.1.10: Multiple Choice - *CC BY-NC 4.0*
  - 3.1.11: Fill in the Blank - *CC BY-NC 4.0*
  - 3.1.12: Introduction - *CC BY-NC 4.0*
  - 3.1.13: Principles of Homeostasis - *CC BY-NC 4.0*
  - 3.1.14: Neural Control of Blood Oxygenation Levels - *CC BY-NC 4.0*
  - 3.1.15: Neural Control of Core Body Temperature - *CC BY-NC 4.0*
  - 3.1.16: Neural Control of Feeding Behavior - *CC BY-NC 4.0*
  - 3.1.17: Neural Control of Drinking Behavior - *CC BY-NC 4.0*
  - 3.1.18: Section Summary - *CC BY-NC 4.0*
  - 3.1.19: Key Terms - *CC BY-NC 4.0*
  - 3.1.20: References - *CC BY-NC 4.0*
  - 3.1.21: Multiple Choice - *CC BY-NC 4.0*
  - 3.1.22: Fill in the Blank - *CC BY-NC 4.0*
  - 3.1.23: Consciousness - *CC BY-NC 4.0*
  - 3.1.24: What is Sleep? - *CC BY-NC 4.0*
  - 3.1.25: Stages of Sleep - *CC BY-NC 4.0*
  - 3.1.26: The Brain and Sleep - *CC BY-NC 4.0*
  - 3.1.27: Theories of Sleep - *CC BY-NC 4.0*
  - 3.1.28: Sleep Disorders - *CC BY-NC 4.0*

- 3.1.29: Maintaining Water Balance - *CC BY-NC 4.0*
- 3.1.30: Triggering Drinking Behavior - Osmometric and Volumetric Thirst - *CC BY-NC 4.0*
- 3.1.31: Ingestive Behavior Basics - *CC BY-NC 4.0*
- 3.1.32: Digestion and the Hormonal Control of Metabolism - *CC BY-NC 4.0*
- 3.1.33: Hunger - Theories, Detectors, and the Hypothalamus - *CC BY-NC 4.0*
- 3.1.34: Ingestive Behavior in Context - *CC BY-NC 4.0*
- 3.2: Homeostasis - *CC BY-NC 4.0*
- 3.3: Sexual Behavior and Development - *CC BY-NC 4.0*
  - 3.3.1: Introduction - *CC BY-NC 4.0*
  - 3.3.2: Understanding Sexual Reproduction and Sexual Dimorphism - *CC BY-NC 4.0*
  - 3.3.3: Mechanisms of Sexual Determination and Differentiation - *CC BY-NC 4.0*
  - 3.3.4: Sex Differences in Brain and Behavior- Genetic, Hormonal, and Environmental Mechanisms - *CC BY-NC 4.0*
  - 3.3.5: Sex Differences in Brain Circuits and Susceptibility to Psychiatric Disease - *CC BY-NC 4.0*
  - 3.3.6: Section Summary - *CC BY-NC 4.0*
  - 3.3.7: Key Terms - *CC BY-NC 4.0*
  - 3.3.8: References - *CC BY-NC 4.0*
  - 3.3.9: Multiple Choice - *CC BY-NC 4.0*
  - 3.3.10: Fill in the Blank - *CC BY-NC 4.0*
  - 3.3.11: Sex Hormones, Sexual Motivation, and Reproductive Behaviors - *CC BY-NC 4.0*
  - 3.3.12: Sexual Development, Anatomy and Physiology - *CC BY-NC 4.0*
  - 3.3.13: Differences of Sexual Development - *CC BY-NC 4.0*
  - 3.3.14: Gender - *CC BY-NC 4.0*
  - 3.3.15: Sexual Orientation - *CC BY-NC 4.0*
  - 3.3.16: Sex Differences and Evolutionary Interpretations - *CC BY-NC 4.0*
- 3.4: Evolution, Genes and Behaviors - *CC BY-NC 4.0*
  - 3.4.1: Evolution of Minds and Behavior - *CC BY-NC 4.0*
  - 3.4.2: Evolution - Mechanisms and Evidence - *CC BY-NC 4.0*
  - 3.4.3: Human Evolution - *CC BY-NC 4.0*
  - 3.4.4: Evolutionary Theories in Psychology - *CC BY-NC 4.0*
  - 3.4.5: DNA, Chromosomes, and Gene-Environment Correlations - *CC BY-NC 4.0*
  - 3.4.6: The Nature-Nurture Question - *CC BY-NC 4.0*
  - 3.4.7: Epigenetics in Psychology - *CC BY-NC 4.0*
  - 3.4.8: Human Genetics - *CC BY-NC 4.0*
  - 3.4.9: Genes and Behavior - *CC BY-NC 4.0*
- 4: Part IV- Cognition and Emotion - *CC BY-NC 4.0*
  - 4.1: Intelligence - *CC BY-NC 4.0*
    - 4.1.1: Overview of Brain Mechanisms in Intelligence, Language, and Cognition - *CC BY-NC 4.0*
    - 4.1.2: Cognition, Intelligence, and Language as Psychological Adaptations - *CC BY-NC 4.0*
    - 4.1.3: High Intelligence-Nature or Nurture; Learning Disabilities - *CC BY-NC 4.0*
    - 4.1.4: Cognition- Categories, Concepts, Schemas and the Brain - *CC BY-NC 4.0*
    - 4.1.5: Brain Mechanisms and Intelligence - *CC BY-NC 4.0*
  - 4.2: Learning, Memory, and Attention - *CC BY-NC 4.0*
    - 4.2.1: Introduction - *CC BY-NC 4.0*
    - 4.2.2: Memory is Classified Based on Time Course and Type of Information Stored - *CC BY-NC 4.0*
    - 4.2.3: Implicit Memories- Associative vs. Nonassociative Learning - *CC BY-NC 4.0*
    - 4.2.4: Explicit Memories- Episodic and Semantic Memories - *CC BY-NC 4.0*
    - 4.2.5: Synaptic Mechanisms of Long-Term Memory - *CC BY-NC 4.0*
    - 4.2.6: Section Summary - *CC BY-NC 4.0*
    - 4.2.7: Key Terms - *CC BY-NC 4.0*
    - 4.2.8: References - *CC BY-NC 4.0*
    - 4.2.9: Multiple Choice - *CC BY-NC 4.0*
    - 4.2.10: Fill in the Blank - *CC BY-NC 4.0*
    - 4.2.11: Introduction - *CC BY-NC 4.0*
    - 4.2.12: What are the Different Psychological Processes Associated with Attention? - *CC BY-NC 4.0*
    - 4.2.13: How is Attention Implemented in the Brain? - *CC BY-NC 4.0*
    - 4.2.14: What Happens to Unattended Information? - *CC BY-NC 4.0*
    - 4.2.15: What is the Relationship between Attention and Eye Movements? - *CC BY-NC 4.0*
    - 4.2.16: How Do Clinical Disorders Affect Attentional Function? - *CC BY-NC 4.0*
    - 4.2.17: How Do We Use Executive Functions to Make Decisions and Achieve Goals? - *CC BY-NC 4.0*
    - 4.2.18: Section Summary - *CC BY-NC 4.0*
    - 4.2.19: Key Terms - *CC BY-NC 4.0*
    - 4.2.20: References - *CC BY-NC 4.0*
    - 4.2.21: Multiple Choice - *CC BY-NC 4.0*
    - 4.2.22: Fill in the Blank - *CC BY-NC 4.0*
    - 4.2.23: Learning, Genes, and Adaptation - *CC BY-NC 4.0*
    - 4.2.24: Types of Learning and Biological

Adaptation - *CC BY-NC 4.0*
- 4.2.25: Introduction to Memory and the Brain - *CC BY-NC 4.0*
- 4.2.26: Synaptic Mechanisms of Learning and Memory - *CC BY-NC 4.0*
- 4.2.27: Brain Mechanisms of Memory Disorders - *CC BY-NC 4.0*
- 4.2.28: Localization of Types and Stages of Memory - *CC BY-NC 4.0*
- 4.2.29: Hormones, Learning, and Memory - *CC BY-NC 4.0*

- 4.3: Language and the Brain - *CC BY-NC 4.0*
  - 4.3.1: Introduction to Language - *CC BY-NC 4.0*
  - 4.3.2: Broca's Area, Wernicke's Area, and Additional Language-Processing Areas in the Brain - *CC BY-NC 4.0*
  - 4.3.3: Other Brain Models of Spoken and Written Language - *CC BY-NC 4.0*
  - 4.3.4: Handedness, Language, and Brain Lateralization - *CC BY-NC 4.0*
  - 4.3.5: The Right Hemisphere's Contribution to Language - *CC BY-NC 4.0*
- 4.4: Attention and Executive Function - *CC BY-NC 4.0*
- 4.5: Stress and Emotion - *CC BY-NC 4.0*
  - 4.5.1: Introduction - *CC BY-NC 4.0*
  - 4.5.2: What Is Stress? - *CC BY-NC 4.0*
  - 4.5.3: Neural Mechanisms and Circuitry of the Stress Response - *CC BY-NC 4.0*
  - 4.5.4: Interindividual Variability and Resilience in Response to Stress - *CC BY-NC 4.0*
  - 4.5.5: Clinical Implications of Stress - *CC BY-NC 4.0*
  - 4.5.6: Section Summary - *CC BY-NC 4.0*
  - 4.5.7: Key Terms - *CC BY-NC 4.0*
  - 4.5.8: References - *CC BY-NC 4.0*
  - 4.5.9: Multiple Choice - *CC BY-NC 4.0*
  - 4.5.10: Fill in the Blank - *CC BY-NC 4.0*
  - 4.5.11: Introduction - *CC BY-NC 4.0*
  - 4.5.12: Foundational and Contemporary Theories of Emotion - *CC BY-NC 4.0*
  - 4.5.13: What Category of Feelings Are Considered as the “Basic Emotions”? - *CC BY-NC 4.0*
  - 4.5.14: What Is the Contribution of Brain Structures in Emotional States? - *CC BY-NC 4.0*
  - 4.5.15: Mood and Emotional Disorders Associated with Depression - *CC BY-NC 4.0*
  - 4.5.16: Section Summary - *CC BY-NC 4.0*
  - 4.5.17: Key Terms - *CC BY-NC 4.0*
  - 4.5.18: References - *CC BY-NC 4.0*
  - 4.5.19: Multiple Choice - *CC BY-NC 4.0*
  - 4.5.20: Fill in the Blank - *CC BY-NC 4.0*
  - 4.5.21: The Neurological Bases of Emotions - *CC BY-NC 4.0*
  - 4.5.22: Valence of Emotions - *CC BY-NC 4.0*
  - 4.5.23: Fight or Flight - *CC BY-NC 4.0*
  - 4.5.24: Social Neuroscience - *CC BY-NC 4.0*
  - 4.5.25: Stress and health - *CC BY-NC 4.0*
- 4.6: Emotion and Mood - *CC BY-NC 4.0*

- 5: Part V- Drugs, Disorders, and Brain Health - *CC BY-NC 4.0*
  - 5.1: Psychopharmacology - *CC BY-NC 4.0*
    - 5.1.1: Introduction - *CC BY-NC 4.0*
    - 5.1.2: Basic Principles of Pharmacology - *CC BY-NC 4.0*
    - 5.1.3: Psychotherapeutics - *CC BY-NC 4.0*
    - 5.1.4: Neural Circuitry of Drug Reward - *CC BY-NC 4.0*
    - 5.1.5: Neurobiology of Addiction - *CC BY-NC 4.0*
    - 5.1.6: Section Summary - *CC BY-NC 4.0*
    - 5.1.7: Key Terms - *CC BY-NC 4.0*
    - 5.1.8: References - *CC BY-NC 4.0*
    - 5.1.9: Multiple Choice - *CC BY-NC 4.0*
    - 5.1.10: Fill in the Blank - *CC BY-NC 4.0*
  - 5.2: Psychopharmacology and Psychoactive Drug Classification - *CC BY-NC 4.0*
  - 5.3: Mechanisms of Psychoactive Drug Action - *CC BY-NC 4.0*
  - 5.4: Substance Use and Addiction - Theories, Brain Mechanisms, and Treatment - *CC BY-NC 4.0*
  - 5.5: Specific Drug Effects, Misuse, and Risks - *CC BY-NC 4.0*
  - 5.6: Psychotherapeutics - *CC BY-NC 4.0*
  - 5.7: Clinical Applications- Addiction, Developmental Disorders, Anxiety, Affective Disorders - *CC BY-NC 4.0*
  - 5.8: Other Neuropsychiatric Disorders - *CC BY-NC 4.0*
    - 5.8.1: Biological Factors in Psychological Disorders- An Introduction - *CC BY-NC 4.0*
    - 5.8.2: Biological Basis of Mood Disorders- Major Depressive and Bipolar Disorders - *CC BY-NC 4.0*
    - 5.8.3: Biological Basis of Anxiety Disorders - *CC BY-NC 4.0*
    - 5.8.4: Biological Basis of Schizophrenia Spectrum Disorder - *CC BY-NC 4.0*
  - 5.9: Clinical ConsiderationsL- Brain Injury and Brain Pathology - *CC BY-NC 4.0*
- 6: Answer Key - *CC BY-NC 4.0*
  - 6.1: Chapter 1 - *CC BY-NC 4.0*
  - 6.2: Chapter 2 - *CC BY-NC 4.0*
  - 6.3: Chapter 3 - *CC BY-NC 4.0*
  - 6.4: Chapter 4 - *CC BY-NC 4.0*
  - 6.5: Chapter 5 - *CC BY-NC 4.0*
  - 6.6: Chapter 6 - *CC BY-NC 4.0*
  - 6.7: Chapter 7 - *CC BY-NC 4.0*

- 6.8: Chapter 8 - *CC BY-NC 4.0*
- 6.9: Chapter 9 - *CC BY-NC 4.0*
